Abstract

We present a general framework of analyzing existing story corpora to generate controllable and creative new stories. The proposed framework needs little manual annotation to achieve controllable story generation. It creates a new interface for humans to interact with computers to generate personalized stories. We apply the framework to build recurrent neural network (RNN)-based generation models to control story ending valence\(^1\) (Egidi and Gerrig, 2009) and storyline. Experiments show that our methods successfully achieve the control and enhance the coherence of stories through introducing storylines. With additional control factors, the generation model gets lower perplexity, and yields more coherent stories that are faithful to the control factors according to human evaluation.

1 Introduction

Storytelling is an important task in natural language generation, which plays a crucial role in the generation of various types of texts, such as novels, movies, and news articles. Automatic story generation efforts started as early as the 1970s with the TALE-SPIN system (Meehan, 1977). Early attempts in this field relied on symbolic planning (Meehan, 1977; Lebowitz, 1987; Turner, 1993; Bringsjord and Ferrucci, 1999; Perez and Sharple, 2001; Riedl and Young, 2010), case-based reasoning (Gervas et al., 2005), or generalizing knowledge from existing stories to assemble new ones (Swanson and Gordon, 2012; Li et al., 2013). In recent years, deep learning models are used to capture higher level structure in stories. Roemmele et al. (2017) use skip-thought vectors (Kiros et al., 2015) to encode sentences, and a Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997) to generate stories. Martin et al. (2017) train a recurrent encoder-decoder neural network (Sutskever et al., 2014) to predict the next event in the story.

Despite significant progress in automatic story generation, there has been less emphasis on controllability: having a system takes human inputs and composes stories accordingly. With the recent successes on controllable generation of images (Chen et al., 2016; Siddharth et al., 2017; Lample et al., 2017), dialog responses (Wang et al., 2017), poems (Ghazvininejad et al., 2017), and different styles of text (Hu et al., 2017; Ficler and Goldberg, 2017; Shen et al., 2017; Fu et al., 2017), people would want to control a story generation system to produce interesting and personalized stories.

This paper emphasizes the controllability aspect. We propose a completely data-driven approach towards controllable story generation by analyzing the existing story corpora. First, an analyzer extracts control factors from existing stories, and then a generator learns to generate stories according to the control factors. This creates an excellent interface for humans to interact: the generator can take human-supplied control factors to generate stories that reflect a user’s intent. Fig-

\(^1\)Happy or sad endings.
ure 1 gives the overview (upper) and an example (lower) of the framework. The instantiations of the analyzer and the generator are flexible and can be easily applied to different scenarios. We explore two control factors: (1) ending valence (happy or sad ending) and (2) storyline keywords. We use supervised classifiers and rule-based keyword extractors for analysis, and conditional RNNs for generation.

The contributions of the paper are two-fold:

1. We propose a general framework enabling interactive story generation by analyzing existing story corpora.
2. We apply the framework to control story ending valence and storyline, and show that with these additional control factors, our models generate stories that are both more coherent and more faithful to human inputs.

2 Controllable Story Generation

As a pilot study, we explore the control of 1) ending valence, which is an abstract, style-level element of stories, and 2) storyline, which is a more concrete, content-level concept for stories.

2.1 Ending Valence Control

Prior work has explored manipulating emotion in interactive storytelling (Cavazza et al., 2009). For simplicity, we refine our scope to manipulating the ending valence for controllable story generation. We categorize ending valence into happyEnding, sadEnding, or cannotTell.

**Analyzer.** The analyzer for the ending valence control is a classifier that labels each story as happyEnding, sadEnding, or cannotTell. Formally, given a story corpus $X = \{x_1, x_2, \cdots, x_N\}$ with $N$ stories, the ending valence analyzer is a function $f^e$ that maps each story $x_i$ to a label $l_i$:

$$l_i = f^e(x_i),$$

where $i$ indexes instances. Since there is no prior work on analyzing story ending valence, we build our own analyzer by collecting some annotations for story ending valence from Amazon Mechanical Turk (AMT) and building a supervised classifier. We employ an LSTM-based logistic regression classifier as it learns feature representations that capture long-term dependencies between the words, and has been shown efficient in text classification tasks (Tang et al., 2015).

Specifically, we use a bidirectional-LSTM to encode an input story into a sequence of vector representations $h_i = \{h_{i,1}, h_{i,2}, \cdots, h_{i,T}\}$, where $h_i = BiLSTM(x_i) = [\bar{h}_i; \bar{h}_i]$, $T$ denotes the story length, $[\cdot; \cdot]$ denotes element-wise concatenation. $\bar{h}_i$ and $\bar{h}_i$ are sequences of vectors computed by a forward and a backward LSTM. An LSTM-cell is applied at each step to complete the following computations:

$$
\begin{align*}
\begin{pmatrix} i_{i,t} \\ f_{i,t} \\ o_{i,t} \\ c_{i,t} \end{pmatrix} &= \begin{pmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{pmatrix} U \begin{pmatrix} E^w x_{i,t} \\ h_{i,t-1} \end{pmatrix} \tag{1a} \\
\tilde{c}_{i,t} &= f_{i,t} \odot \tilde{c}_{i,t-1} + i_{i,t} \odot c_{i,t} \tag{1b} \\
h_{i,t} &= LSTM-cell(x_{i,t}, h_{i,t-1}) \tag{1c} \\
\sigma(i_{i,t}) \odot \tanh(c_{i,t}) \tag{1d}
\end{align*}
$$

$i_{i,t}, f_{i,t}, o_{i,t}, c_{i,t}$ are the input, forget, output gates, and a contemporary central memory that control the information flow of the previous contexts and the current input. $\sigma$ and $\tanh$ denotes element-wise sigmoid and tanh function. $E^w$ is an embedding matrix that maps an input word $x_{i,t}$ to an $x$-dimensional vector. Each $h_{i,t}$ is a $d$-dimensional vector that can be viewed as the contextual representation of word $x_{i,t}$.

To obtain the sentence representation, we take a max pooling over the sentence, where for each dimension $j$ of the vector $h_i$, we have:

$$
\hat{h}_i^j = \max_{t \in [1, \cdots, T]} h_{i,t}^j, \quad j = 1, \ldots, d. \tag{2}
$$

The final classifier is defined as:

$$
f^v(x_i) = g(W \hat{h}_i + b), \tag{3}
$$

where $g(\cdot)$ is the softmax function, $W$ and $b$ are model parameters that are jointly learned with the BiLSTM parameters.

**Generator.** The generator for the ending valence-controlled story generation is a conditional language model, where the probability of generating each word is denoted as $p(w_k|w_{1:t-1}, l; \theta)$; $l$ represents the ending valence label and $\theta$ represents model parameters. We learn valence embeddings for the ending valence labels to facilitate the computation. Formally, we learn an embedding matrix $E^v$ to map each label $l^k$ into a vector:

$$
e_l^k = E^v[l^k],
$$

where
where $E^t$ is a $m \times p$ matrix that maps each label ($p$ of them) into a $m$-dimensional vector. The ending valence embeddings dimension are made the same as the word embedding dimension for simplicity.

We add the ending valence as follows:

$$ p(w_t|w_1^{t-1}, h; \theta) = \left\{ \begin{array}{l} g(V^t F(e_t, F(w_{t-1}, h_{t-1}))), t = s \\ g(V^t F(w_{t-1}, h_{t-1})), t = \text{others} \end{array} \right. \quad (4) $$

where $s$ denotes the position right before the ending sentence, $g()$ is the softmax function, $F$ means the computations of an LSTM-cell, and $V$ denotes parameters that perform a linear transformation. We treat the ending valence as an additional input to the story. The valence embeddings are jointly learned with other model parameters.

### 2.2 Storyline Control

Li et al. (2013) introduced plot graphs which contain events and their relations to represent storyline. Although the representation is rich, these plot graphs are hard to define and curate without highly specialized knowledge. In this pilot study, we follow what Yan (2016) did for poetry, to use a sequence of words as the storyline. We further confine the words to appear in the original story.

**Analyzer.** The analyzer for storyline control is an extractor that extracts a sequence of words $k_t = \{k_{t,1}, k_{t,2}, \ldots, k_{t,\gamma}\}$ from each story $x_t$. The $k_{t,s}$ are ordered according to their order in the story. We adapt the RAKE algorithm (Rose et al., 2010) for keyword extraction, which builds document graphs and weights the importance of each word combining several word-level and graph-level criteria. We extract the most important word from each sentence as the storyline.

**Generator.** The generator for storyline-controlled generation is also a conditional language model. Specifically, we employ the seq2seq model with attention (Bahdanau et al., 2014) implemented in OpenNMT (Klein et al., 2017). Specifically, the storyline words are encoded into vectors by a BiLSTM: $h_k^t = BiLSTM(k) = [\overline{h}_k^t; \overline{h}_k^t]$, and the decoder generate each word according to the probability:

$$ p(w_t|w_1^{t-1}, h^k; \theta) = g(V^t s_t) \quad (5a) $$

$$ s_t = F^{at}(w_{t-1}, s_{t-1}, c_t) \quad (5b) $$

$$ c_t = \sum_{j=1}^{r} \alpha_{t,j} h_{t,j} \quad (5c) $$

$$ \alpha_{t,j} = \frac{\exp(a(s_{t-1}, h_{j}^k))}{\sum_{p=1}^{r} \exp(a(s_{t-1}, h_{p}^k))} \quad (5d) $$

$g()$ again denotes the softmax function, and $V^t$ denotes parameters that perform a linear transformation. $F^{at}()$ in Equation 5b denotes the computations of an LSTM-cell with attention mechanism, where the context vector $c_t$ is computed by an weighted summation of the storyline words vectors as in Equation 5c, and the weights are computed from some alignment function $a()$ as in Equation 5d.

### 3 Experimental Setup

We conduct experiments on the ROCstories dataset (Mostafazadeh et al., 2016), which consists of 98,162 five-line stories for training, and 1871 stories each for the development and test sets. We treat the first four sentences of each story as the body and the last sentence as the ending. We build analyzers to annotate the ending valence and the storyline for every story, and train the two controlled generators with 98,162 annotated stories.

#### 3.1 Ending Valence Annotation

We conduct a three-stage data collection procedure to gather ending valence annotations and train a classifier to analyze the whole corpora. We classify all the stories into happyEnding, sadEnding, or cannotTell. Table 1 summarizes the results.

In the first stage, two researchers annotate 150 stories to gauge the feasibility of the task. It is nontrivial, as the agreement between the two researchers is only 83%, mainly because of the cannotTell case. The second stage collects larger-

Table 3: Human evaluation for the ending valence (left) and storyline (right) controlled generation. Scores range in [1,5]. Three stories (one from each method) are grouped together so that people can give comparative scores. Faithfulness survey asks people to rate whether the generated stories reflect the given control factors. Coherence asks people to rate the coherence of the stories without considering the control factors. % win measures how often the generated result by one method is rated higher than others, excluding the instances that tie on the highest score.

scale annotations from AMT. We gather 3980 annotated stories with the turker-researcher agreement at 78%. A classifier as described in Section 2.1 is then trained to analyze the whole ROC-stories corpora. Using 5-fold cross-validation, we estimate the accuracy of the classifier to be 69%³, which, while not terribly impressive, is an 11% improvement over the majority baseline (happyEnding). Considering the low inter-annotator agreement on this problem, we consider this a decent analyzer.

4 Experimental Results

We compare the controlled generation under our proposed framework with the uncontrolled generation. We design the experiments to answer the following research questions:

1. How does the controlled generation framework affect the generation quantitatively?
2. Does the proposed framework enables controls to the stories while maintaining the coherence of the stories?

To answer the former question, we design automatic evaluations that measure the perplexity of the models given appropriate and inappropriate controls. For the latter question, we design human evaluations to compare the generated stories from controlled and uncontrolled versions in terms of the document-level coherence and the faithfulness to the control factors.

4.1 Automatic Evaluation

The advantages of the automatic evaluation is that it can be conducted at scale and gives panoramic views of the systems. We compute the perplexities of different models on the ROCStories development dataset. Table 2 shows the results for the storyline experiments. With the additional storyline information, it is easier for the generation model to guess what will happen next in a story, thus yield lower perplexities. We conduct the same experiments for ending valence controlled generation and observe the same. However, since ending valence is only one bit of information, the perplexity difference is only 0.8.

4.2 Human Evaluation

We conduct a human evaluation with 1000 story groups for each setting. Each group consists of stories from: (1) the uncontrolled LSTM generation model, (2) controlled generation with our framework, and (3) a contrastive method which retrieves and re-ranks existing sentences in the training data. Users are asked to rate the three stories on a 1-5 scale with respect to faithfulness (whether stories reflect the control factor), and coherence. All the evaluations are conducted on Amazon Mechanical Turk. We compute the average score and percentage win of each method. Table 3 summarizes the results.

Ending Valence For the ending valence control, we supply each system with the first 4 sentences from ROCStories test set and an ending valence randomly assigned by a human. The systems generate endings⁴. We only let the systems generate happyEnding or sadEnding stories, with the ratio around 1:1. Faithfulness is defined as whether the generated stories reflect the given ending valence.

The contrastive method retrieves existing happy or sad endings from the training data instead of generating new sentences. Specifically, we gather all the stories that are annotated with happyEndings from the 3980 annotated stories in one set, and all the sadEndings in another set. When the given ending valence is happyEnding, the sys-

³We included the cannotTell cases and conducted a 3-class classification.

⁴The uncontrolled LSTM generation model has no way to take the ending valence input.
sarah had been dreaming of visiting europe for years. she had finally saved enough for the trip. she landed in spain and traveled east across the continent. she didn’t like how different everything was.

sarah decided she preferred home over europe. no-valence-control

Table 5: Samples of stories generated from user-given storyline words. The generated stories usually contains the words in the storyline. Changing one word in the storyline can result in another creative story.

tem scores all the sentences from the happenEnding set by combining it with the given 4 sentences, and using a trained uncontrolled generation model to compute the likelihood. This chooses the most coherent happyEnding for the given story. Similarly for the sadEnding stories. Table 3 shows that the proposed analyze-to-generate framework (“Controlled-Generated”) achieves the highest faithfulness score while retaining similar coherence as the uncontrolled one.

As shown in Table 3, the contrastive method achieves the highest faithfulness, probably because it guarantees the words in the storyline appear in the stories while the other systems cannot. However, the coherence of the contrastive method is lowest, because it is constrained by the existing sentences in the training data. Although an uncontrolled generation model is employed to encourage document-level coherence, the available choices are restricted. Our method achieves the

As shown in Table 3, the contrastive method achieves the highest faithfulness, probably because it guarantees the words in the storyline appear in the stories while the other systems cannot. However, the coherence of the contrastive method is lowest, because it is constrained by the existing sentences in the training data. Although an uncontrolled generation model is employed to encourage document-level coherence, the available choices are restricted. Our method achieves the
best coherence and higher faithfulness score than the uncontrolled version.

4.3 Generation Samples

Table 4 shows two examples of the ending valence controlled generation. The uncontrolled model “No-Valence-Control” can generate coherent endings; however, it cannot alter the ending valence. On the other hand, the two controlled models can generate different endings based on different ending valence. The contrastive retrieval method, restricted by the existing happyEnding and sadEnding in the training data, obtains endings that are not coherent with the whole story.

Table 5 demonstrates some examples from the storyline controlled generation. The storyline words are user supplied. We can see that this provides fun interactions: changing one word in the storyline can result in a creative new story.

5 Conclusion

We proposed an analyze-to-generate framework that enables controllable story generation. The framework is generally applicable for many control factors. In this paper, two instantiations of the framework are explored to control the ending valence and the storyline of stories. Experiments show that our framework enables human controls while achieving better coherence than an uncontrolled generation models. In the future, we will explore other control factors and better controllable generation models to adding the control factors into the generated stories. The current analyze-to-generate framework is done in a pipeline fashion. We also plan to explore the joint training of the analyzer and the generator to improve the quality of both.
