(Dated: February 28, 2012)

We review the problem of electron-electron interactions in graphene. Starting from the screening of long range interactions in these systems, we discuss the existence of an emerging Dirac liquid of Lorentz invariant quasi-particles in the weak coupling regime, and strongly correlated electronic states in the strong coupling regime. We also analyze the analogy and connections between the many-body problem and the Coulomb impurity problem. The problem of the magnetic instability and Kondo effect of impurities and/or adatoms in graphene is also discussed in analogy with classical models of many-body effects in ordinary metals. We show that Lorentz invariance plays a fundamental role and leads to effects that span the whole spectrum, from the ultraviolet to the infrared. The effect of an emerging Lorentz invariance is also discussed in the context of finite size and edge effects as well as mesoscopic physics. We also briefly discuss the effects of strong magnetic fields in single layers and review some of the main aspects of the many-body problem in graphene bilayers. In addition to reviewing the fully understood aspects of the many-body problem in graphene, we show that a plethora of interesting issues remain open, both theoretically and experimentally, and that the field of graphene research is still exciting and vibrant.

I. INTRODUCTION

One of the most important problems in theoretical physics is the understanding of the properties of quantum systems with an infinitely large number of interacting degrees of freedom, the so-called many-body problem. Interactions are present in almost all areas of physics: soft and hard condensed matter, field theory, atomic physics, quantum chemistry, nuclear physics, astrophysics, and so on. Interactions between particles are responsible for a plethora of effects and many-body states, from the band structure of crystals to superconductivity in metals, from the quark-gluon plasma to asymptotic freedom in quantum chromodynamics (QCD). It is the competition between kinetic energy of the particles, that is, their inertia, and interactions among them that leads to the richness and complexity of these different phases. For these reasons, many-body interactions are very specific, and the hardest to describe theoretically.

One of the greatest theoretical achievements of the last century, the Landau theory of the Fermi liquid (Baym and Pethick, 1991), asserts something very simple but, at the same time, very deep: that the excitations of a large (indeed, infinite) collection of strongly interacting particles can be described as an equally large collection of weakly-interacting quasi-particles that carry the same quantum numbers as the original particles. This statement is far from trivial. Consider, for instance, the behavior of electrons in a metal. The electrons interact among themselves and with the ions in the crystal via strong long-range Coulomb interactions. It is not at all clear what is the outcome of this complex interacting problem. Without having any deep theoretical resources to treat this problem, except an extraordinary intuition, visionaries like Paul Drude (Drude, 1900a,b) and Arnold Sommerfeld (Hoddeson et al., 1987) settled the foundations for the understanding of this complex problem by postulating, shamelessly, that (1) electrons propagate freely in a non-relativistic (Galilean invariant) way (Drude’s contribution), and (2) electrons obey Fermi-Dirac statistics (Sommerfeld’s contribution). Galilean invariance dictates that the electrons have a kinetic energy given by

$$K_0 = \frac{p^2}{2m^*}, \quad (1.1)$$

where \( p \) is the electron momentum and \( m^* \) is a free parameter of the theory that, for lack of a better name, is called effective mass. Fermi-Dirac statistics implies that electrons carry spin 1/2 and that, in the ground state, all states with energy below the so-called Fermi energy, \( E_F \), are occupied, and all the states above it are empty. With these two basic assumptions and simple considerations about electron scattering by defects, the Drude-Sommerfeld model was capable of describing experimental data of several generations of scientists.

The understanding of why these two assumptions are valid for a strongly interacting problem, such as electrons in a metal, had to wait for the development of two major concepts: (i) the band structure theory that explains that the interaction of the electrons with a periodic lattice of ions produces states that, as the plane waves described by (1.1), are extended over the entire lattice (Bloch, 1928); and (ii) the theory of screening, that is, that metals are dynamically polarizable materials and that electrons act collectively to screen electric fields in their interior (Lindhard, 1954). Hence, long range Coulomb interactions become effectively short ranged and weak enough to give substance to Drude’s assumptions. In this case the effective mass \( m^* \) reflects the change in the inertia of the electron as it moves around in an effective medium. Nevertheless, there are situations when these assumptions fail even in crystalline systems, and that is when interesting things happen, namely, the free electron picture breaks down.

In fact, there are many instances where the Fermi liquid ground state becomes unstable. Electrons not only interact with static ions but also with their vibrations, the phonons. Electron-phonon interactions, in the presence of strong screening, can lead to an effective attractive interaction between electrons producing a catastrophic Fermi surface instability towards a superconducting ground state (Tinkham, 1996). Fermi surface instabilities also happen in special situations in the presence of Fermi surface nesting which can lead to charge and spin density wave ground states (Gruner, 1994). Crystals with inner shell electrons, such as transition metals, can also have many-body instabilities due to the strong local interactions between the electrons, leading to insulating states with magnetic properties as in the case of Mott insulators (Mott, 1949). Another important case of Fermi liquid breakdown is when the electron density is very low and the screening disappears.

Notice that in quantum mechanics the momentum of the particle relates to its wavelength, \( \lambda \), by \( p = h/\lambda \) and hence the kinetic energy (1.1) behaves as \( K = h^2/(2m^*\lambda^2) \). If the average distance between electrons is \( \ell \) we see that the average kinetic energy per electron has to be of the order \( E_K \approx h^2 n_d^{2/d} (2m^*) \) where \( n_d = 1/\ell^d \) is the average electron density in \( d \) spatial dimensions. On
the other hand, the Coulomb interaction is given by:

$$V(r) = \frac{e^2}{\epsilon_0 r},$$  

(1.2)

where $e$ is the electron charge, and $\epsilon_0$ the dielectric constant of the medium. Notice that the Coulomb energy per electron is of the order $E_C \approx e^2 n_d^{1/3}/\epsilon_0$. Thus, the ratio of Coulomb to kinetic energy is given by $r_s = E_C/E_F \propto (n_0/n_d)^{1/3}$, where $n_0 = [\pi^2 e^2/(\hbar^2 \epsilon_0)]^d$ depends only on material properties. Therefore, at high electron densities, $n_d \gg n_0$, the kinetic energy dominates over the Coulomb energy, which can be disregarded, and the Fermi liquid description is safe. At low densities, $n_d \ll n_0$ the Coulomb energy is dominant and new electronic phases, such as ferromagnetism and Wigner crystallization, can become stable (Ceperley, 1978). Therefore, the relative strength of the kinetic to Coulomb interactions in Galilean invariant systems is completely controlled by the electron density. Notice that in all the cases discussed above the Galilean invariance was kept intact and the driving force for the many-body instabilities was the enhancement of the Coulomb relative to the kinetic energy.

With the advent of graphene (Novoselov et al., 2004a), a two dimensional crystal of pure carbon, this picture has changed and a new example of Fermi liquid breakdown has emerged in a big way. In graphene, due to its peculiar lattice structure, the electrons at the Fermi energy are described in terms of an effective Lorentz invariant theory where the kinetic energy is given by the Dirac dispersion (Castro Neto et al., 2009a)

$$K_G = \pm v_F|p|,$$  

(1.3)

where $v_F$ is the Fermi-Dirac velocity, and the $\pm$ signs refer to two linearly dispersing bands. If we take (1.3) at face value and reconsider the argument given above on the relevance of the Coulomb interactions we reach very different conclusions. For one, the form of the Coulomb interaction remains the same as in (1.2), since $v_F$ is a material’s property and hence much smaller than the speed of light, $c$. This means that the photons which mediate the Coulomb interaction are still much faster than the electrons and, thus, the electron-electron interaction can be considered as instantaneous. Therefore, the Coulomb interaction (1.2) actually breaks the Lorentz invariance of (1.3). Secondly, because of the linear scaling of the kinetic energy with momentum, we see that the average kinetic energy per electron has to scale like $E_G \approx h v_F n^{1/2}$ and consequently the ratio of Coulomb to kinetic energy is given by

$$\alpha = \frac{E_C}{E_G} = \frac{e^2}{\epsilon_0 h v_F},$$  

(1.4)

and is independent of the electronic density $n$, depending only on material properties and environmental conditions, such as $\epsilon_0$. Here, and from now on, we refer to graphene’s electron density as $n$. As the electronic properties of graphene are sensitive to environmental conditions, they will be modified by the presence of other layers. In fact, as we are going to show, bilayer graphene has properties which are rather different than its monolayer counterpart. Furthermore, due to the same peculiar dispersion relation, the electronic density of states, $\rho(E)$, vanishes at the Dirac point, $\rho(E) \propto |E|/v_F^2$, and hence graphene is a hybrid between an insulator and a metal: neutral graphene is not a metal because it has vanishing density of states at the Fermi energy, and it is not an insulator because it does not have a gap in the spectrum. This means that pristine (or lightly doped) graphene cannot screen the long range Coulomb interaction in the usual (metallic) way, although it is possible to produce electronic excitations at vanishingly small energy. This state of affairs makes of graphene a unique system from the point of view of electron-electron interactions. The long-range interactions lead to non-trivial renormalization of the Dirac quasiparticle characteristics near the charge neutrality point, and the resulting electronic state can be called Dirac liquid, to be distinguished from the Fermi liquid behavior at finite chemical potential (away from the Dirac point, where conventional screening takes place.)

The unusual relation between kinetic and Coulomb energies not only affects the electron-electron interactions, but also the interactions of the electrons with charged impurities, the so-called Coulomb impurity problem. In a metal described by a Galilean invariant theory of the form (1.1), screening also makes the interaction with the impurity short ranged, and hence the scattering problem effectively reduces to the one of a short range impurity. In graphene, because of the lack of screening the situation is rather different, and one has to face the problem of the effect of the long range part of the potential. Scattering by long range interactions has a long history in physics and it leads to the issue of logarithmic phase shifts (Baym, 1969). In graphene, because of its emergent Lorentz invariance, this issue is magnified. Since Coulomb interactions between electrons and electron scattering by Coulomb impurities are closely related issues, one expects that many of the anomalies of one problem are also reflected in the other.

Another interesting consequence of the scaling of the kinetic energy with momentum is related to the issue of electron confinement. If electrons are confined to a region of size $L$ the energy of the states is quantized, no matter whether the electrons obey Galilean or Lorentz invariance. However, the quantization of energy is rather different in these two cases. In a Galilean invariant system, like the one described by (1.1) the energy levels are spaced as $\Delta E_0 \propto 1/L^2$ while in graphene Lorentz invariance, (1.3), implies $\Delta E_G \propto 1/L$. Hence, the size dependence of the energy levels in sufficiently small samples of graphene is rather different than one would find in normal metals. Moreover, since the Coulomb energy scales like $1/L$ we expect Coulomb effects to be stronger
in nanoscopic and mesoscopic graphene samples.

Furthermore, the fact that graphene is a two dimensional (2D) system has strong consequences for electronic motion in the presence of perpendicular magnetic fields. Since a perpendicular magnetic field $B$ leads to a quantization of the energy in terms of Landau levels, and the electrons cannot propagate along the direction of the field, its effect is singular, in the sense that the problem has a massive degeneracy. So, strong magnetic fields can completely quench the kinetic energy of the electrons that become dispersionless. The electronic orbits are localized in a region of the size of the magnetic length: $\ell_B = \sqrt{\hbar c / (eB)}$. For a Galilean invariant system, such as the one described by (1.1), for $p \approx h/\ell_B$ the kinetic energy per electron is of order $K \approx h\omega_C \propto B$ where $\omega_C = h/(m^*\ell_B^2)$ is the cyclotron frequency. On the other hand, for graphene, using (1.3), one has $E_C \approx h\omega_C \propto \sqrt{B}$ where $\omega_C = \sqrt{2v_F / \ell_B}$, which is a consequence of the Lorentz invariance. Notice that in both cases the Coulomb energy per electron scales like $E_C \propto e^2 / (\epsilon\ell_B) \propto \sqrt{B}$. Hence, in a Galilean invariant system the Coulomb energy is smaller than the kinetic energy at high fields while for Lorentz invariant systems they are always comparable. Thus, one expects Coulomb interactions to be hugely enhanced in the presence of these magnetic fields. In the 2D electron gas (2DEG) this unusual state of affairs is what leads to the fractional quantum Hall effect (FQHE) (Laughlin, 1983).

Given all these unusual circumstances, many questions come to mind: How does screening of the long range Coulomb interaction work in graphene? Can graphene be described in terms a Lorentz invariant theory of quasiparticles? Is the Coulomb impurity problem in graphene the same as in a normal metal? In what circumstances is graphene unstable towards many-body ground states? Are there quantum phase transitions (Sachdev, 1999) in the phase diagram of graphene? Do magnetic moments form in graphene in the same way as they do in normal metals? What is the ground state of graphene in high magnetic fields?

The objective of this review is not to cover the basic aspects of graphene physics, since this was already covered in a recent review (Castro Neto et al., 2009a), but to try to address some of these questions while keeping others open. The field of many-body physics will always be an open field because a seemingly simple question always leads to another question even more profound and harder to answer in a definitive way. In many ways, what we have done here is to only scratch the surface of this rich and important field, and leave open a large number of interesting and unexplored problems.

II. CHARGE POLARIZATION AND LINEAR SCREENING

A. Tight-binding spectrum

In isolated form, carbon has six electrons in the orbital configuration $1s^22s^22p^2$. When arranged in the honeycomb crystal shown in Fig.1(a), two electrons remain in the core $1s$ orbital, while the other orbitals hybridize, forming three $sp^2$ bonds and one $p_z$ orbital. The $sp^2$ orbitals form the $\sigma$ band, which contains three localized electrons. The bonding configuration among the $p_z$ orbitals of different lattice sites generates a valence band, or $\pi$-band, containing one electron, whereas the antibonding configuration generates the conduction band ($\pi^*$), which is empty.

From a kinetic energy point of view, the electronic single particle dispersion in graphene is essentially defined by the hopping of the electrons between nearest neighbor carbon sites in the honeycomb lattice. Unlike square or triangular lattices, the honeycomb lattice is spanned by two different sets of Bravais lattice generators, forming a two component basis with one set for each triangular sublattice. Defining a label for electrons sitting in each of the two sublattices, say $A$ and $B$, the free hopping Hamiltonian of graphene is

$$H_0 = -t \sum_{\sigma,\langle ij \rangle} [a_\sigma^\dagger(R_i)b_\sigma(R_j)] + \text{h.c.} - \mu \sum_\sigma \hat{n}_\sigma(R_i),$$

(2.1)

where $a_\sigma(R_i)$, $b_\sigma(R_i)$ are fermionic operators for sublattices $A$ and $B$ respectively, $\hat{n}_\sigma(R_i)$ is the number operator, $\sigma = \uparrow, \downarrow$ labels the spin and $\langle ij \rangle$ means summa-
tion over nearest neighbors. The two energy scales in the Hamiltonian are $t \approx 2.8$ eV, which is the hopping energy between nearest carbons, and $\mu$, the chemical potential away from half-filling [see Fig.1(b)]. In a homogeneous system, deviations from half-filling ($\mu = 0$) are routinely induced either by charge transfer from a substrate (Giovannetti et al., 2008), by application of a back gate voltage (Novoselov et al., 2005, 2004a,b), or else by chemical doping (Calandra and Mauri, 2007; Grüneis et al., 2009; McChesney et al., 2010; Uchoa et al., 2008b).

In momentum space the free Hamiltonian of graphene is

$$H_0 = \sum_{p, \sigma} \Psi_p^\dagger (\begin{pmatrix} -\mu & -t \phi_p \\ -t \phi_p^* & -\mu \end{pmatrix}) \Psi_{p, \sigma},$$

(2.2)

where $\Psi_{p, \sigma} = (a_{p, \sigma}, b_{p, \sigma})$ is a two component spinor and

$$\phi_p = \sum_{i=1}^3 e^{i p \cdot a_i},$$

(2.3)

is a tight-binding function summed over the nearest neighbor vectors

$$a_1 = a \hat{x}, \quad a_2 = a \frac{\hat{x}}{2} + a \frac{\sqrt{3}}{2} \hat{y}, \quad a_3 = a \frac{\hat{x}}{2} - a \frac{\sqrt{3}}{2} \hat{y},$$

(2.4)

where $a \approx 1.42\text{Å}$ is the carbon-carbon spacing. The diagonalization of Hamiltonian (2.2) yields the spectrum of the two $\pi$-bands of graphene in tight-binding approximation (Wallace, 1947),

$$E_{\pm}(p) = \pm t |\phi_p| - \mu.$$  

(2.5)

The $+(-)$ sign in the spectrum corresponds to the conduction (valence) band.

The hexagonal Brillouin zone (BZ) of graphene shown in Fig.1(c) has three high symmetry points: the $\Gamma$ point, located at the center of the BZ, the $M$ point, which indicates the position of the Van Hove singularities of the $\pi-\pi^*$ bands, where the density of states (DOS) is logarithmically divergent, and the $K$ points, where the $\pi$-bands touch, and the DOS vanishes linearly. An extensive description of the band structure of graphene and its electronic properties is reviewed in detail by Castro Neto et al., 2009a.

**B. Dirac fermion Hamiltonian**

The topology of the Fermi surface in undoped graphene is defined by the six $K$ points where the conduction and valence bands touch, $E_{\pm}(K) = \pm |\phi_K| = 0$. These special points form two sets of nonequivalent points, $K$ and $K'$, with $K = -K'$ and $|K| = 4\pi/(3\sqrt{3}a)$, which cannot be connected by the generators of the reciprocal lattice. The linearization of the spectrum around the valleys centered at $\pm K$ gives rise to an effective low energy description of the electrons that mimics the spectrum of massless Dirac particles. In this effective theory, the elementary excitations around the Fermi surface are described by a Dirac Hamiltonian (Semenoff, 1984),

$$H_0 = \sum_{\sigma, k} \Psi_{k\sigma}^\dagger [v \mathbf{K} \cdot \gamma - \mu \tau_0 \otimes \sigma_0] \Psi_{k\sigma},$$

(2.6)

where

$$\Psi_{k\sigma} = (a_{K+k, \sigma}, b_{K+k, \sigma}, b_{-K+k, \sigma}, a_{-K+k, \sigma})$$

(2.7)

is a four component spinor for sublattice and valley degrees of freedom. In this representation, $\gamma_i = \tau_3 \otimes \sigma_i$ , where $\tau$ and $\sigma$ are the usual Pauli matrices, which operate in the valley and sublattice spaces respectively ($i = 1, 2, 3$ correspond to $x, y$ and $z$ directions, and $\tau_0 = 1$ and $\sigma_0 = 1$ are identity matrices). The form of the spectrum mimics the relativistic cone for massless fermions (Wallace, 1947),

$$E_{\pm}(k) = \pm v |k| - \mu$$

(2.8)

where the Fermi velocity $v = (3/2)\tau a \approx 6eVÅ$ is nearly 300 times smaller than the speed of light, i.e. $v \approx 1 \times 10^6$ m/s. From now on we set $\hbar = k_B = 1$ everywhere, except where it is needed. For simplicity of notation, we call the Fermi velocity $v$ (i.e. $v_F = v$) throughout this review.

The Hamiltonian (2.6) is invariant under a pseudo-time reversal symmetry operation, $S = i(\tau_0 \otimes \sigma_2)C$, $SHS^{-1} = H$, ($C$ is the complex conjugation operator), which is equivalent to a time reversal operation for each valley separately. It is also invariant under a true time reversal symmetry (TRS) operation, which involves an additional exchange between the valleys, $T = (\tau_1 \otimes \sigma_1)C$.

In the absence of back scattering connecting the two valleys, the Hamiltonian can be decomposed in two independent valley species of Dirac fermions with opposite chiralities:

$$H_{0,+} = \sum_{\sigma, k} \Psi_{+k,\sigma}^\dagger [v \mathbf{K} \cdot \sigma - \mu] \Psi_{+k,\sigma},$$

(2.9)

$$H_{0,-} = \sum_{\sigma, k} \Psi_{-k,\sigma}^\dagger [-v \mathbf{K} \cdot \sigma^* - \mu] \Psi_{-k,\sigma},$$

(2.10)

where $\Psi_{\pm k, \sigma} = (a_{K+k, \sigma}, b_{K+k, \sigma}, b_{K-k, \sigma}, a_{-K-k, \sigma})$ are two component spinors. In this review, unless otherwise specified, we will arbitrarily choose one of the two cones and assume an additional valley degeneracy in the Hamiltonian. So valley indexes will be generically omitted unless explicitly mentioned. A more detailed description of the symmetry properties of the graphene Hamiltonian can be found in (Gusynin et al., 2007).
C. Polarization function

The Green’s function of graphene is a $2 \times 2$ matrix represented in the sublattice basis by

$$\hat{G}(k, \tau) = \begin{pmatrix} G_{aa} & G_{ab} \\ G_{ba} & G_{bb} \end{pmatrix},$$

where $G_{aa} = -\langle T[a_k(\tau)a_k^\dagger(0)] \rangle$ and so on, with $\tau$ as the imaginary time. In the low energy sector of the spectrum, close to the Dirac points, the non-interacting Green’s function is $\hat{G}^{(0)}(k, i\omega) = [i\omega + v k \cdot \sigma]^{-1}$, or equivalently, in a chiral representation,

$$\hat{G}^{(0)}(k, i\omega) = \frac{1}{2} \sum_{s=\pm} \frac{1 + s\hat{\sigma}_k}{i\omega + \mu - sv|k|},$$

(2.11)

where $\hat{\sigma}_k = \sigma \cdot k/|k|$ is twice the quantum mechanical helicity operator for a Dirac fermion with momentum $k$, and $s = \pm$ labels the two branches with positive and negative energy in one cone. It is clear that the positive and negative branches within the same cone have also opposite helicities.

The polarization function in one loop is calculated directly from the bubble diagram shown in Fig. 2,

$$\Pi^{(1)}(q, \omega) = N \sum_p \sum_{s,s'} F_{s,s'}(p, q) \times \frac{f[\epsilon_{s'}(p + q)] - f[\epsilon_s(p)]}{\epsilon_{s'}(p + q) - \epsilon_s(p) - i\omega},$$

(2.12)

where $f(E) = (e^{E/T} + 1)^{-1}$ is the Dirac-Fermi distribution, with $T$ as temperature, $N = 4$ is the degeneracy for two spins and two valleys, and

$$F_{s,s'}(p, q) = \frac{1}{4} \text{tr}(1 + ss'\hat{\sigma}_p\hat{\sigma}_{p+q}),$$

(2.13)

are the matrix elements due to the overlap of wavefunctions for intraband ($s = s'$) and interband ($s = -s'$) transitions. ‘tr’ means trace over the sublattice indexes. In a more explicit form, $F_{s,s'}(p, q) = [1 + ss'\cos \theta_{p,p+q}]/2$, where $\theta$ is the angle between $p$ and $p + q$. The full momentum, frequency, and chemical potential dependence of (2.12) is shown in panels (a-d) of Fig. 3.

In metals, screening is a many-body property directly related to the polarizability of the electrons around the Fermi surface. In graphene, because the density of states (DOS) vanishes linearly around the Dirac points, $\rho(E) \propto |E - \mu|/v^2$, exactly at the neutrality point ($\mu = 0$) the screening of charge is completely suppressed, and the polarization function describes the susceptibility of the vacuum to particle-hole pair production, exactly as in the diagonal time component of the polarization tensor in massless Quantum Electrodynamics (QED), QED$_{2+1}$ (Appelquist et al., 1988; González et al., 1994; Pisarski, 1984),

$$\Pi^{(1)}(q, \omega) = -\frac{1}{4} q^2 \sqrt{\omega^2 - q^2},$$

(2.14)

Here we have performed a Wick rotation to real frequen-
cies, \( \omega \to \omega + 0^+ \). Since the Fermi surface in this case is just a point, there is no phase space for intraband excitations at zero temperature due to the Pauli principle. The process of creation of particle-hole pairs involves incoherent excitations of electrons from the lower to the upper band. The continuum of particle-hole excitations is well defined for all virtual transitions with \( \omega > v_F \).

For finite \( \mu \) there is a crossover in the behavior of the polarization function. The DOS around the Fermi level is finite and the intraband excitations dominate the infrared behavior of the polarization. For \( v_F \ll |\mu| \) and \( \omega \ll |\mu| \), the leading term in the polarization function is (Shung, 1986a)

\[
\Pi^{(1)}(q, \omega) \approx -\frac{2|\mu|}{\pi v^2} \left( 1 - \frac{\omega}{\sqrt{\omega^2 - v^2 q^2}} \right). \tag{2.15}
\]

As in a Fermi liquid, there is a particle-hole continuum

\[
\Pi^{(1)}(q, 0) = -\frac{2k_F}{\pi v} + \theta(q - 2k_F) \frac{q}{2\pi v} \left[ \frac{2k_F}{q} \sqrt{1 - \left( \frac{2k_F}{q} \right)^2} + \sin^{-1} \left( \frac{2k_F}{q} \right) - \frac{\pi}{2} \right], \tag{2.16}
\]

where \( k_F = |\mu|/v \) is the Fermi momentum, and \( \theta(x) \) is a step function. The static polarization is plotted in Fig. 3(e).

At \( q \approx 2k_F \) the static polarization exhibits a crossover from a two dimensional electron gas (2DEG) to Dirac fermion behavior. For details of the polarization function in the 2DEG please refer to Fig. 4. As in the 2DEG, the polarization of graphene is constant for \( q < 2k_F \). For \( q > 2k_F \), it eventually becomes linear in \( q \) for large momenta. At the crossover, the static polarization and its first derivative are continuous at \( q = 2k_F \). The discontinuity only appears in the second derivative. This is distinct from the 2DEG case, where the first derivative is discontinuous. The difference will affect the spatial dependence of the Friedel oscillations in the two systems.

In the opposite limit, for arbitrary \( \omega \) and \( q \to 0 \), the polarization function becomes

\[
\Pi^{(1)}(q \to 0, \omega) = \frac{q^2}{2\pi \omega} \left[ \frac{2|\mu|}{\omega} + \frac{1}{2} \ln \left( \frac{2|\mu| - \omega}{2|\mu| + \omega} \right) \right], \tag{2.17}
\]

which is shown in Fig. 3(f). The presence of a pocket of electrons (holes) around the Dirac points opens a gap in the particle hole continuum for interband excitations (\( \omega > v_F \)). From Eq. (2.17), it is clear that the imaginary part of the polarization function at small momentum is zero unless \( \omega > 2|\mu| \) [Fig. 3(h)]. This is so because the phase space for vertical interband excitations is Pauli blocked for \( \omega < 2|\mu| \), generating a gap for optical absorption in the infrared. At finite \( q \), the threshold for interband transitions is \( \omega > 2|\mu| - v_F \) for \( q < 2k_F \), as shown schematically in Fig. 5.

**D. Collective modes and screening**

The Coulomb interaction among the electrons in graphene gives rise to collective modes and metallic screening when the Fermi level is shifted away from the Dirac points. In a 2D system, the bare Coulomb interaction is given by

\[
V(q) = \frac{2\pi e^2}{\epsilon_0 q}, \tag{2.18}
\]

where \( e \) is the charge of the electron and \( \epsilon_0 \) is the effective dielectric constant of the medium. For graphene in contact with air and a substrate with dielectric constant \( \kappa, \epsilon_0 = (1 + \kappa)/2 \). In most of the experiments, graphene lies on top of some substrate like SiO2 or SiC, where dielectric effects are moderate (for instance, the dielectric constant of SiO2 is \( \kappa \approx 4 \)). The background dielectric constant can be significantly enhanced in the presence of substrates in contact with strong dielectric liquids such as ethanol (\( \kappa \approx 25 \)) or water (\( \kappa \approx 80 \)) (Jang et al., 2008; Ponomarenko et al., 2009).

As usual, the collective modes follow from the zeros of the dielectric function

\[
\epsilon(q, \omega) = \epsilon_0[1 - V(q)\Pi^{(1)}(q, \omega)], \tag{2.19}
\]
which follows the same dispersion as the plasmon encountered in the 2DEG. The \( \sqrt{q} \) dependence of the plasmon was recently confirmed by a high resolution energy loss spectroscopy (EELS) measurement in graphene (Liu et al., 2008). Additional corrections due to the interband excitations (which are absent in the 2DEG) can be absorbed into the definition of the background dielectric constant (Shung, 1986a),

\[
\epsilon_0(q) \approx \epsilon_0 - \frac{qe^2}{2\omega_p(q)} \ln \left( \frac{2|\mu| - \omega_p(q)}{2|\mu| + \omega_p(q)} \right),
\]

(2.21)

As in the 2DEG, the screened Coulomb interaction for \( q < 2k_F \) is

\[
\frac{V(q)}{\epsilon(q, 0)} = \frac{1}{\epsilon_0} \frac{2\pi e^2}{\epsilon_{RPA} q},
\]

(2.22)

where \( q_{TF} = 4\pi e^2 k_F/(\epsilon v_F) \) is the Thomas-Fermi momentum \( (k_F = |\mu|/v) \), which sets the size of the screening cloud. In the presence of an external charged impurity \( Z_e \), the induced charge, \( \delta Z \), has a non-oscillatory component coming from the \( q \to 0 \) limit of the polarization that decays as \( (k_F r^3)^{-1} \) (as in a 2DEG), and an oscillatory part which corresponds to the Friedel oscillations at \( q = 2k_F \). The Friedel oscillations in graphene decay as \( \cos(2k_F r)/k_F r^2 \), differently from the 2DEG case, where the decay is of the form \( \cos(2k_F r)/r^2 \). The difference is caused by the fact that the static polarization function in the 2DEG has a cusp at \( q = 2k_F \), whereas in graphene, the first derivative is continuous [cfr. Figs. 3(e) and 4(e)].

For undoped graphene, \( V(q)\Pi^{(1)} = -(\pi/2)[e^2/(\epsilon v_F)] \) [see Eq. (2.14)], and the static dielectric function is a constant. The effective Coulomb interaction in this case is

\[
\frac{V(q)}{\epsilon(q, 0)} = \frac{1}{\epsilon_{RPA} q},
\]

(2.23)

where \( \epsilon_{RPA} = \epsilon_0 - (\pi/2)[e^2/(\epsilon v_F)] \) is the effective background dielectric constant, renormalized by the interband transitions. Additional many body effects resulting from self-energy insertions in the bubbles logarithmically renormalize this correction to zero in the \( q \to 0 \) limit, as will be clear in Sec. III of this review. On the dynamical side, inserting Eq. (2.14) into Eq. (2.19), one can easily see that no collective modes are allowed in undoped graphene, at zero temperature, within the RPA framework. At half-filling, RPA is justified in the limit
of large number of fermionic species, \( N \), which favors diagrams with maximal number of bubbles at each order of perturbation theory. In graphene, the physical number of species is \( N = 4 \), and additional corrections beyond RPA coming from the exciton channel near the on-shell singularity of the bubble, \( |\omega| \sim vq \), were shown to generate a new acoustic plasmon mode (Gangadharaiah et al., 2008). In the static limit (\( \omega \to 0 \)), vertex corrections in the bubble are perturbatively small and RPA can be justified in the calculation of the dielectric function even at half-filling (Kotov et al., 2008b). The structure of perturbation theory in graphene will be discussed in detail in Sec. III.

In addition to the low energy acoustic mode due to intraband transitions, graphene has also two high energy optical plasmons generated by interband excitations around the Van-Hove singularities of the \( \pi - \pi^* \) bands, and also by optical transitions between \( \sigma - \pi^* \) and \( \pi - \pi^* \) bands (Eberlein et al., 2008; Kramberger et al., 2008). The measured optical gaps of the \( \pi \) and \( \pi - \sigma \) band plasmons in graphene are 4.5 eV and 15 eV, respectively. Similar modes were also observed in graphite, where they appear blue shifted to 7 eV and 24 eV respectively, according to optical data (Taft and Philipp, 1965), X-ray measurements (Shulke et al., 1988), and ab-initio calculations (Marinopoulos et al., 2004).

### E. Infinite stack of layers

In the case of an infinite stack of graphene layers, the Hamiltonian term for the Coulomb interaction among all the electrons can be written in real space as

\[
\mathcal{H}_C = \frac{e^2}{\epsilon_0} \int d^3 r \hat{n}(r) \frac{1}{|r-r'|} \hat{n}(r'), \tag{2.24}
\]

where \( \hat{n}(r) \) is the 3D particle density operator. In the absence of interlayer hopping, as in the case for example of several graphite intercalated compounds, the electrons remain confined in each layer, but the unscreened Coulomb lines fill the entire space in between the layers, coupling all the electrons in the system. In that case we may constrain the local density operator \( \hat{n} \) to be in the form (Visscher and Falikov, 1970)

\[
\hat{n}(r) \rightarrow d \sum_{l=-\infty}^{\infty} \hat{n}(r) \delta(z-ld), \tag{2.25}
\]

where \( l \) is an integer labeling the layers, and \( d \) is the distance between layers. In momentum space, making a discrete sum over the layers, the Coulomb interaction between all the electrons is

\[
\mathcal{H}_C = \frac{e^2}{\epsilon_0} \int \frac{d^3 k}{(2\pi)^3} \hat{n}(-k) V(k) \hat{n}(k), \tag{2.26}
\]

where

\[
V(k) = 2\pi d \frac{e^2}{\epsilon_0 q} S(q, k_z) \tag{2.27}
\]

with \( k = (q, k_z) \), \( q \) is an in-plane momentum, and (Fetter, 1974)

\[
S(q, k_z) = \frac{\sinh(qd)}{\cosh(qd) - \cos(k_z d)} \tag{2.28}
\]

is the structure factor for a stack with an infinite number of layers. In the limit when the distance between the layers \( d \) is small, Eq. (2.27) recovers the isotropic case \( V(k) = 4\pi(e^2/\epsilon_0)/(q^2 + k_z^2) \), whereas in the opposite limit \( d \to \infty \) one gets the 2D case, \( V(k) = 2\pi d(e^2/\epsilon_0)/q \). In any case, the polarization function must be integrated over a cylindrical Fermi surface of height \( 2\pi/d \), and so \( \Pi(q, \omega) \) acquires an additional factor of \( 1/d \) compared to the single layer case. The extension of this problem to include the interlayer hopping dispersion in the polarization was considered by Guinea, 2007.

Away from the neutrality point \( (\mu \neq 0) \), instead of a single acoustic mode as in the monolayer, the zeroes in the dielectric function of the multilayer generate a plasmon band, where the modes are labeled by \( k_z \in (-\pi/d, \pi/d) \). For \( q \ll 1/d \), the plasmon dispersion is (Shung, 1986a)

\[
\omega_p^2(q, k_z) = \frac{2\mu e^2}{\epsilon_0} q S(q, k_z). \tag{2.29}
\]

In the \( k_z = 0 \) mode, the charge fluctuations between different layers are in-phase, and the resulting plasmon mode is optical, \( \omega_p(q, 0) \approx (4\mu e^2/\epsilon_0 d) + \frac{2}{3}(vq)^2 \). For \( \omega_p(q) > 2\mu \), this mode is damped by the particle-hole continuum due to interband transitions (see Fig. 6), in agreement with energy loss spectroscopy data (Laitenberger and Palmer, 1996). The out-of-phase modes (for \( k_z \neq 0 \)) are acoustic. At the edge of the plasmon band, the mode \( k_z = \pm \pi/d \) disperses linearly with the in-plane momentum, \( \omega_p(q, \pm \pi/d) = \sqrt{\mu e^2 d/\epsilon_0 q} \), in contrast with the 2DEG dispersion \( (\omega_p \propto \sqrt{q}) \) present in the single layer. Except for the lack of an interband particle-hole continuum and the associated damping, similar plasmon band features are also expected in the 2D layered electron gas, for fermions with quadratic dispersion (Hawrylak, 1987).

### F. f-sum rule

The \( f \)-sum rule is a generic statement about conservation of the number of particles and results from the analytical properties of the retarded charge susceptibility. It can be generically defined as (Nozières, 1964)

\[
\int_{-\infty}^{\infty} d\omega \omega \text{Im} \chi_R(k, \omega) = 2\pi \text{Re} [\mathcal{H}, \hat{n}(-k)] , \tag{2.30}
\]

where \( \mathcal{H} \) is the Hamiltonian, \( \hat{n} \) is the particle density operator, \( \chi_R \) is a retarded charge susceptibility, \( \chi(k, \tau) = \langle T[\hat{n}(k, \tau) \hat{n}(-k, 0)] \rangle \), and \( \langle \ldots \rangle \) is an expectation value calculated in some basis.
As in any solid, the exact electronic Hamiltonian of graphene can be decomposed into a Hamiltonian of free electrons, plus a periodic potential due to the lattice, and interactions. If the interactions depend only on densities, the commutators in Eq. (2.30) can be calculated exactly, and the only term that survives is the Kinetic energy due to the free electrons,

$$\langle [\hat{H}, \hat{n}(-k)], \hat{n}(k) \rangle = N_e \frac{k^2}{m}, \quad (2.31)$$

where $m$ is the bare electron mass and $N_e$ is the number of fermions in the band. Choosing, for example, a basis of non-interacting fermions, the sum rule in graphene is

$$\int d\omega \omega \text{Im} \Pi^{(1)}(k, \omega) = \pi \frac{N_e k^2}{m}, \quad (2.32)$$

as in metals, where $\Pi^{(1)}(k, \omega)$ is the bare polarization bubble, calculated using the full non-interacting spectrum (dictated by the lattice symmetry). The validity of the $f$ sum-rule does not require Galilean invariance of the quasiparticles, but of the free electrons, which are not relativistic and hence obey the Schrodinger equation.

For low energy effective Hamiltonians, such as the Dirac Hamiltonian in graphene (which do not include the periodicity of the spectrum in the Brillouin zone), the $f$-sum rule above is still formally satisfied when applied for the electrons (holes) in the conduction (valence) band only, as can be explicitly checked by direct substitution of the polarization due to intraband transitions, Eq. (2.15), into Eq. (2.32). The number of electrons (holes) in this band, $N_e = k_F^2 A / \pi$, where $A = 3\sqrt{3}a^2 / 2$ is the unit cell area, is set by the size of the Fermi surface, and the verification of the sum rule follows as in a Fermi liquid.

The Dirac Hamiltonian, however, violates the $f$-sum rule (2.32) when interband transitions are taken into account. In that case, the left hand side of Eq. (2.32) becomes independent of the chemical potential, consistent with the fact that (Sabio et al., 2008)

$$\langle [\hat{H}, \hat{n}(-k)], \hat{n}(k) \rangle = k^2 \frac{D}{4} \quad (2.33)$$

for a Dirac Hamiltonian, where $D$ is the ultraviolet cut-off. A similar dependence with the cut-off also occurs in the true 3D relativistic problem, where the sum rule reflects the number of particles contained in the vacuum of the theory, which is formally divergent (Ceni, 2001; Goldman and Drake, 1982). In graphene, as in any two band semi-metal or semiconductor, the validity of the $f$-sum rule is physically recovered when the periodicity of the electronic spectrum is restored back into the Hamiltonian.

### III. Quasiparticles in Graphene

The quasiparticle properties of graphene are modified by the presence of long-range Coulomb interactions. Their effects are especially pronounced when the Fermi energy is close to the Dirac point ($\mu \approx 0$), and can result in strong renormalization of the Dirac band structure (the Fermi velocity $v$), and the quasiparticle residue ($Z$). Consequently, many physical characteristics, such as the compressibility, spin susceptibility and the specific heat can be strongly affected by interactions. Even when the Fermi surface is large and the system is a Fermi liquid, there are strong modifications of the physics near the Dirac point due to the presence of additional peaks in the quasiparticle decay rate, related to plasmon-mediated decay channels. Even reconstruction of the Dirac cone structure near the charge neutrality point appears possible, as indicated by recent Angle-Resolved Photoemission Spectroscopy (ARPES) measurements. All these effects are sensitive to the value of the Coulomb interaction constant in graphene, $\alpha$.

#### A. Low-energy behavior near the Dirac point

1. Weak-coupling analysis

The interaction parameter which characterizes the strength of the Coulomb interaction in graphene is (Eq. (1.4))

$$\alpha = \frac{e^2}{\epsilon_0 v}. \quad (3.1)$$

At $k_F = 0$ screening is absent, and the interaction potential in momentum space:

$$V(p) = \frac{2\pi e^2}{\epsilon_0 p}. \quad (3.2)$$

The value of $\alpha = 2.2 / \epsilon_0$ depends on the dielectric environment since, as previously discussed, $\epsilon_0 = (1 + \kappa)/2$ for graphene in contact with air and a substrate with dielectric constant $\kappa$. In vacuum, $\alpha = 2.2$.

In the case of small coupling, $\alpha \ll 1$, we can employ standard perturbation theory, involving the perturbative computation of the self-energy $\Sigma(k, \omega)$, which enters in a
standard way the Dirac fermion Green’s function (GF), for a given valley:
\[
G(k, \omega) = \frac{1}{\omega \sigma_0 - \nu \sigma \cdot k - \Sigma(k, \omega) + i \sigma_0 0^+ \text{sign} (\omega)}. \tag{3.3}
\]
It is convenient to decompose the self-energy into two pieces with different pseudo-spin structure
\[
\Sigma(k, \omega) = \Sigma_0(k, \omega) + \Sigma_v(k, \omega), \quad \Sigma_0 \propto \sigma_0, \quad \Sigma_v \propto \sigma \cdot k, \tag{3.4}
\]
where \(\sigma_0 = 1\) is the unit matrix, which from now on will not be written explicitly. Then we have
\[
G(k, \omega) = \frac{Z}{\omega - Z (\nu \sigma \cdot k + \Sigma_v)}, \tag{3.5}
\]
where \(Z\) is the quasiparticle residue
\[
Z^{-1} = 1 - \frac{\partial \Sigma_0}{\partial \omega}, \tag{3.6}
\]
and \(\Sigma_v\) is responsible solely for the velocity renormalization.

The first order diagram shown in Fig. 7(a) is the Hartree-Fock exchange contribution, and can be readily evaluated (we denote by \(G^{(0)}\) the non-interacting GF):
\[
\Sigma^{(1)}(k, \omega) = i \int \frac{d^2p d\varepsilon}{(2\pi)^3} G^{(0)}(k + p, \omega + \varepsilon) V(p), \tag{3.7}
\]
which at low external momenta exhibits a logarithmic singularity
\[
\Sigma^{(1)}(k, \omega) = \Sigma_v^{(1)}(k) = \frac{\alpha}{4} \nu \sigma \cdot k \ln (\Lambda/k), \quad \Lambda/k \gg 1. \tag{3.8}
\]
At this order we have \(\Sigma_0 = 0\), i.e. \(Z = 1\) due to the frequency independence of the interaction potential, and the quasiparticle velocity increases:
\[
v(k) = v \left(1 + \frac{\alpha}{4} \ln (\Lambda/k)\right), \quad \Lambda/k \gg 1. \tag{3.9}
\]
The ultraviolet cutoff \(\Lambda \sim 1/a\) represents the momentum scale up to which the spectrum is Dirac-like.

While the linearity of the spectrum in graphene was realized a long time ago (Wallace, 1947), in the context of studying graphite formed by layers of graphene, the self-energy correction Eq. (3.8) due to interactions was first investigated perturbatively much later by González et al., 1994. The non-trivial velocity renormalization is due to the unscreened, long-range Coulomb interactions. Similar logarithmic divergencies were also found in gapless 3D semiconductors, where the Dirac spectrum originated from special symmetries (Abrikosov and Beneslavskii, 1971).

The above calculation forms the basis of the Renormalization Group (RG) analysis. In the RG spirit one integrates out the high momentum degrees of freedom, i.e. regions of momenta \(\Lambda > |p| > \Lambda_1\), and the results vary with the quantity \(\ln (\Lambda/\Lambda_1) \equiv l\). Here we denote by \(l\) the RG parameter, so that the infrared limit corresponds to \(l \rightarrow \infty\) (i.e. one integrates down to the infrared scale \(k \rightarrow 0\), \(l = \ln (\Lambda/k)\)). From Eq. (3.9) we obtain
\[
\frac{dv}{dl} = \frac{\alpha}{4} v = \frac{\pi e^2}{4\alpha}. \tag{3.10}
\]
This equation has to be supplemented with an additional equation reflecting the absence of charge \(e^2\) renormalization:
\[
\frac{de^2}{dl} = 0. \tag{3.11}
\]
There are several ways to understand this. It was argued early on that the vertex function does not acquire any divergent contributions, which is related to the expected regular behavior of the polarization operator to all orders in graphene (González et al., 1994). More recently, explicit calculations up to two loop order were performed (de Juan et al., 2010; Kotov et al., 2008b); it was confirmed that the vertex function is finite in the low-energy limit. In addition, direct examination of the polarization function at two loop level (Kotov et al., 2008b) found that the self-energy correction, Fig. 8(a), acquires a logarithmic divergence which can be absorbed into the renormalized velocity \(v(k)\) (Eq. (3.9)), while the vertex correction of Fig. 8(b) is finite:
\[
\frac{2\pi e^2}{\epsilon_0 q} \Pi^{(2b)}(q, 0) = \text{finite} = -0.53\alpha^2. \tag{3.12}
\]
Incidentally, this contribution leads to enhancement of the dielectric static screening (i.e. the dielectric constant beyond linear (RPA) order becomes \(\epsilon = 1 + \frac{\pi}{2} \alpha + 0.53 \alpha^2\).
Alternatively, one can argue that in two-dimensional field theories with Coulomb interactions the charge $e^2$ does not flow because it appears as a coefficient in a nonanalytic term in the action (Herbut, 2006; Ye and Sachdev, 1998). The conclusion then is that only the quasiparticle velocity and residue (see below) are renormalized. In particular, at first order we can combine Eqs. (3.10), (3.11) into a single one reflecting the renormalization (running) of the coupling $\alpha$:

$$\frac{d\alpha}{dl} = -\frac{\alpha^2}{4}.$$  \hspace{1cm} (3.13)

Therefore we have an infrared stable fixed point at $\alpha = 0$, and the flow towards it is logarithmic:

$$\alpha(k) \sim \frac{4}{\ln(\Lambda/k)} \rightarrow k \rightarrow 0.$$ \hspace{1cm} (3.14)

Thus the Coulomb interactions are marginally irrelevant. This is equivalent to a logarithmically divergent velocity: $v(k) \sim (e^2/4) \ln(\Lambda/k), \ k \rightarrow 0$.

a. Two-loop results. It is instructive to examine corrections beyond first order (Mishchenko, 2007; Vafek and Case, 2008), since additional effects appear, such as renormalization of $Z$. For example the first diagram in the RPA series shown in Fig. 7(b) is

$$\Sigma^{(2b)}(k, \omega) = i \int \frac{d^dp}{(2\pi)^3} G^{(0)}(k+p, \omega+\varepsilon)(V(p))^2 \Pi^{(1)}(p, \varepsilon).$$ \hspace{1cm} (3.15)

An explicit evaluation at low energies and momenta gives a single logarithmic divergence

$$\Sigma^{(2b)}(k, \omega) = -\frac{N\alpha^2}{24}(\omega + v\sigma \cdot k) \ln(\Lambda/k), \ k/\Lambda \rightarrow 0,$$ \hspace{1cm} (3.16)

i.e. $\Sigma^{(2b)}_0 = -N\alpha^2/24(\omega) \ln(\Lambda/k)$, and $\Sigma^{(2b)} = -(N\alpha^2/24)v\sigma \cdot k \ln(\Lambda/k)$. Because the polarization bubble is proportional to the number of fermion flavors $N = 4$ (valley+spin), we have explicitly written the $N$ dependence. By comparing with Eq. (3.5), we find that the velocity is changed by an amount $-(N/24 - N/24)\alpha^2\ln(\Lambda/k)$.

In addition, other diagrams at second order have to be added, such as the vertex correction of Fig. 7(c). Most importantly, this diagram is also proportional to $\ln(\Lambda)$. Collecting all contributions one finds the RG equation for the velocity flow (Vafek and Case, 2008)

$$\frac{dv}{dl} = \frac{\alpha}{4} v - \left(\frac{N}{12} - \delta\right) \alpha^2 v,$$ \hspace{1cm} (3.17)

with $\delta \approx 0.03$. One observes that the contribution of the “RPA” diagram is numerically dominant at second order (it is larger than the rest by a factor of 10 for $N = 4$.) In addition, the second order tendency is a decrease of the velocity. Consequently a finite coupling fixed point is possible at $\alpha_c \approx 0.8$. This fixed point is infrared unstable since near $\alpha_c$, $\frac{dv}{dl} = -C(\alpha - \alpha_c) v, \ C > 0$, i.e. for $\alpha > \alpha_c$, $v$ flows towards zero ($\alpha$ flows to $\infty$) while for $\alpha < \alpha_c$, $v$ flows towards $\infty$ ($\alpha$ flows to zero.) Of course it is not clear that this estimate is reliable since the fixed point value $\alpha_c$ is not small, and we used perturbation theory ($\alpha \ll 1$) to derive this result. On the other hand, a flow towards strong coupling for $\alpha > \alpha_c$ is consistent with the formation of an excitonic insulator (mass generation), for which strong evidence has accumulated by now, as we discuss in Section III.B. Recent numerical simulations give the value $\alpha_c \sim 1$ (see Section III.B).

Finally, we also find that $Z$ is renormalized at second order, since the self-energy is frequency dependent. From Eq. (3.6) we can expand to second order of bare perturbation theory $Z \approx 1 - \frac{N\alpha^2}{24} \ln(\Lambda/k)$, which would lead us to an RG equation for $Z$: $\frac{dZ}{dl} = -\frac{N\alpha^2}{24} Z$, to be solved together with Eq. (3.13), or Eq. (3.17), depending on the desired level of approximation. Alternatively, Eq. (3.6) is already written in a “nonperturbative” way. Ignoring for the moment the running of $\alpha$, we have at low energies

$$Z = \frac{1}{1 + \frac{N\alpha^2}{24} \ln(\Lambda/k)} \rightarrow \frac{24}{N\alpha^2 \ln(\Lambda/k)}, \ k/\Lambda \rightarrow 0.$$ \hspace{1cm} (3.18)

This result, along with the previous one for $\Sigma^{(2b)}_0$, brings us to the infrared behavior (we use $\omega$ and $k$ interchangeably in the infrared limit):

$$Z \sim \frac{1}{\alpha^2 \ln(\omega)} \rightarrow \frac{\alpha^2 |\ln(\omega)|}{\Sigma_0}, \ \omega \rightarrow 0.$$ \hspace{1cm} (3.19)

This is characteristic of a marginal Fermi liquid (Das Sarma et al., 2007; González et al., 1994). However, this regime is never achieved if the running of $\alpha$ is taken into account, as is intuitively clear from the above equations. As we will see later from the solution of the RG equations for $Z$ and $\alpha$, in fact $Z$ tends to level off in the infrared, and the system has well-defined quasiparticles.

It is interesting to note that trigonal distortions, which change the band structure away from the Dirac equation, are modified by the electron-electron interaction, and their relevance at low energies is enhanced (Foster and Aleiner, 2008). As a result, the linear dispersion becomes an even more robust feature of graphene (Roldán et al., 2008).

b. Influence of disorder. Before we proceed, let us briefly address the effect of disorder. Two major sources of disorder are scalar potential random fluctuations (e.g. formation of electron-hole puddles), and vector gauge field randomness, related to formation of ripples. Starting with the latter, i.e. a gauge field coupled to the Dirac fermion pseudospin $\sigma \cdot A$, and characterized by variance $\Delta$, $\langle A_\mu(r_1) A_\nu(r_2) \rangle = \Delta \delta_{\mu\nu} \delta(r_1 - r_2)$, one can readily derive the corresponding RG equations in the
weak disorder and interactions limit (Herbut et al., 2008; Stauber et al., 2005)
\[ \frac{d\Delta}{dl} = 0, \quad \frac{d\alpha}{dl} = -\frac{\alpha^2}{4} + \frac{\Delta}{\pi} \alpha. \]  
(3.20)

Gauge field disorder itself is not renormalized, while the interplay of disorder and interactions leads to a line of attractive fixed points located at: \( \alpha = \frac{\Delta}{4} \), as shown in Fig. 9. Physically the variance is related to the characteristic height \( h \), and length \( L \) of the corrugations of the surface, \( \Delta \sim h^4/(L^2 a^2) \). Thus weak disorder generically shifts the fixed point away from \( \alpha = 0 \), while strong disorder can have an even more profound effect (Section VLC).

In addition, for weak interactions, the inclusion of scalar (density fluctuations) disorder turns out to be a relevant perturbation which grows under renormalization, and thus away from the perturbative regime (Aleiner and Efetov, 2006). Moreover, gauge field disorder, when combined with strong-enough interactions, can cause the interactions to grow (Vafek and Case, 2008). It has been argued that the strong-coupling regime for disorder and interactions generically occurs when all types of disorder consistent with graphene’s symmetries are included (Foster and Aleiner, 2008).

A detailed analysis of this complex situation is beyond the scope of this work, and from now on we continue our discussion of clean graphene.

### 2. Strong-coupling/RPA analysis

The full RPA treatment was performed by many authors (Das Sarma et al., 2007; Foster and Aleiner, 2008; González et al., 1999; Kotov et al., 2009; Polini et al., 2007; Son, 2007). Here we mostly follow Son, 2007. The RPA self-energy is shown diagrammatically in Fig. 10, and corresponds to the equation

\[ \Sigma^{(RPA)}(k, \omega) = i \int \frac{d^2p d\varepsilon}{(2\pi)^3} G^{(0)}(k + p, \omega + \varepsilon) V^{RPA}(p, \varepsilon). \]  
(3.21)

The RPA potential is given by

\[ V^{RPA}(p, \varepsilon) = \frac{2\pi e^2}{\epsilon_0 \mu - 2\pi e^2 \Pi^{(1)}(p, \varepsilon)}. \]  
(3.22)

Quite remarkably, at low momenta one can evaluate the singular contribution to the self-energy analytically

\[ \Sigma^{(RPA)}(k, \omega) = \frac{8}{N\pi^2} \left[ -F_0(\lambda)\omega + F_1(\lambda)\nu \sigma \cdot k \right] \ln(\lambda/k), \]  
(3.23)

where we have defined

\[ \lambda = \frac{\pi}{8} N\alpha. \]  
(3.24)

This parameter is measuring the importance of polarization loop contributions relative to the bare Coulomb term (i.e. the ratio of the second term to the first in the denominator of Eq. (3.22)). The RPA is generally expected to be valid when the loops dominate over other diagrams, i.e. \( N \gg 1 \). Provided this condition is satisfied, we can also analyze the strong-coupling regime \( \lambda \gg 1 \), and the crossover toward the weak-coupling one (\( \lambda \ll 1 \)), i.e. we can hope to cover a wide range of \( \alpha \) values.

The calculated functions \( F_0 \) and \( F_1 \) in Eq. (3.23) are

\[ F_1(\lambda) = \begin{cases} \frac{-\sqrt{1 - \lambda^2}}{\lambda} \arccos \lambda - 1 + \frac{\pi}{2\lambda}, & \lambda < 1, \\ \frac{\lambda^2}{\lambda^2 - 1} \ln \left( \lambda + \sqrt{\lambda^2 - 1} \right) - 1 + \frac{\pi}{2\lambda}, & \lambda > 1, \end{cases} \]  
(3.25)

\[ F_0(\lambda) = \begin{cases} \frac{-2 - \lambda^2}{\lambda\sqrt{1 - \lambda^2}} \arccos \lambda - 2 + \frac{\pi}{2}, & \lambda < 1, \\ \frac{\lambda^2 - 2}{\lambda\sqrt{\lambda^2 - 1}} \ln \left( \lambda + \sqrt{\lambda^2 - 1} \right) - 2 + \frac{\pi}{\lambda}, & \lambda > 1. \end{cases} \]  
(3.26)

This leads to the system of RG equations for \( \nu \) and \( Z \), to leading order in \( 1/N \)

\[ \frac{dv}{dl} = \frac{8}{N\pi^2} (F_1(\lambda) - F_0(\lambda)) \nu, \]  
(3.27)

\[ \frac{dZ}{dl} = -\frac{8}{N\pi^2} F_0(\lambda)Z. \]  
(3.28)

At strong-coupling, \( \lambda \gg 1 \), one finds

\[ \frac{dv}{dl} = \frac{8}{N\pi^2} \nu, \]  
(3.29)
\[
\frac{dZ}{dl} = -\frac{8}{N\pi^2} \ln(2\lambda) Z .
\]  

(3.30)

The first equation, after integration, leads to the low-energy result \((k \to 0)\)

\[ v(k)/v = \left( \frac{\Lambda}{k} \right)^\eta, \quad \eta = \frac{8}{N\pi^2}, \]  

(3.31)

which implies that the quasiparticle dispersion is of the form

\[ \omega(k) \sim k^z, \quad z = 1 - \frac{8}{N\pi^2}. \]  

(3.32)

The existence of the anomalous velocity dimension, \(\eta\), and consequently \(z \neq 1\), is characteristic of the strong-coupling regime \(N\alpha \to \infty\) (Son, 2007). However this strongly-coupled fixed point is infrared unstable, since, due to the velocity increase, the RG for \(\alpha\) flows towards weak coupling. (One also expects that for certain \(N < N_c\) and \(\alpha \gg 1\) an excitonic gap can appear, which will be discussed in Section III.B.) In this regime \(Z\) can be approximated perturbatively (in \(1/N\)) as

\[ Z \approx 1 - \frac{8}{\pi^2 N} \ln(N\alpha\pi/4) \ln(\Lambda/k), \quad N\alpha \gg 1, \]  

(3.33)

which can be obtained from Eq. (3.30) by ignoring the scale dependence of \(\lambda\).

In the weak-coupling limit \(\lambda \ll 1\), it is easy to verify that we recover the previous result (3.10) for the velocity \(v\) (leading to a flow for \(\alpha\) towards zero), and the previously encountered perturbative equation for \(Z\)

\[ \frac{dZ}{dl} = -\frac{8}{N\pi^2} \frac{\lambda^2}{3} Z, \quad \text{i.e.} \quad Z \approx 1 - \frac{N}{24} \alpha^2 \ln(\Lambda/k). \]  

(3.34)

The last formula is written to first order in \(N\alpha\).

Eqs. (3.33),(3.34) allow us to have a qualitative understanding of the behavior of \(Z\) as a function of the RG scale \(l\). If the initial value \(\alpha\) is large, at the initial RG steps \(Z\) decreases logarithmically fairly fast (due to the weak \(\ln(\alpha)\) dependence in Eq. (3.33), even though \(\alpha\) itself decreases). Eventually, when \(\alpha\) has decreased substantially \((\alpha \sim (\ln(\Lambda/k))^{-1}\), \(Z\) is governed by Eq. (3.34), meaning that \(Z\) will stop decreasing, and will level off for \(l = \ln(\Lambda/k) \to \infty\).

A numerical evaluation of the system of equations (3.27),(3.28) confirms the anticipated behavior and is shown in Fig. 11, (González et al., 1999). (The equation for the coupling \(\lambda = \frac{2}{N} Ne^2/(\epsilon_0 v)\) is obtained by observing that \((d\lambda/dl) = (-1/v^2)\frac{8}{24} N(e^2/\epsilon_0)(dv/dl)\), due to the lack of charge renormalization.) We conclude that the flow of \(\lambda\) is towards weak coupling, no matter how large its initial value is. \(Z\) does not renormalize to zero at low energy due to the RG decrease of \(\lambda\). Thus, near the weak-coupling infrared fixed point, the marginal Fermi liquid (Eq. (3.19)) is ultimately not reached, and the system behaves as a Fermi liquid (although the quasiparticle decay rate is non-Fermi liquid like, see below.)

At higher energies however (away from the fixed point but still much lower than the bandwidth \(v\Lambda\)), the system exhibits marginal Fermi liquid behavior.

At finite (but still small) density away from the Dirac point, i.e. \(k \neq 0\), the logarithmic behavior in the infrared is cut-off by the Fermi momentum, i.e. \(\ln(\Lambda/kF)\), \(k_F/\Lambda \to 0\), and the RG stops away from the fixed point. For comparison with experiments, the flow toward this stable fixed point should be stopped at a scale set by the (small) density, temperature, or frequency, whichever is higher.

One can also perform a numerical evaluation of the main RPA equation Eq. (3.21) (Polini et al., 2007). For small density, and with logarithmic accuracy \((\ln(\Lambda/kF))\), this is equivalent to evaluating, by using the notation of Eq. (3.23), and taking into account Eqs. (3.4),(3.5),(3.6)

\[ Z = (1 - \partial \Sigma^{(RPA)}/\partial \omega)^{-1} = \frac{1}{1 + \frac{8}{N\pi^2} F_0(\lambda) \ln(\Lambda/kF)}, \]  

(3.35)

\[ v^* / v = Z \left( 1 + \frac{8}{N\pi^2} F_1(\lambda) \ln(\Lambda/kF) \right). \]  

(3.36)

Here \(v^*\) is the renormalized velocity. At any finite density the numerical evaluation of \(\Sigma^{(RPA)}\) also picks up finite (subleading) contributions, while it can be shown (Polini et al., 2007) that the leading perturbative results
such as Eqs. (3.33), (3.34) are readily reproduced. The RPA results are shown in Fig. 12, and exhibit the natural density dependence tendency, i.e. the strongest renormalization occurs at the lowest densities. Similar RPA results have been obtained by Das Sarma et al., 2007.

A significant velocity enhancement was observed in the infrared conductivity (Li et al., 2008), which reported around 15% increase of the Fermi velocity, having value as high as $v^* \approx 1.25 \times 10^6 \text{m/s}$ at the lowest densities (compared to $v \approx 1.1 \times 10^6 \text{m/s}$ at higher density). The system is at a finite Fermi energy $\mu \approx 0.2 \text{eV}$. However the velocity renormalization is not logarithmic, and it is not clear what is the origin of this effect.

A recent study of suspended graphene which measures the cyclotron mass (Elias et al., 2011) has detected significant logarithmic renormalization of the Fermi velocity, having the high value $v^* \approx 3 \times 10^6 \text{m/s}$ at the lowest densities $n < 10^{10} \text{cm}^{-2}$, almost three times the value at high density ($n > 4 \times 10^{11} \text{cm}^{-2}$), Fig. 13(a). The logarithmic renormalization of the velocity predicted by theory fits the data fairly well, and thus offers a direct proof that the Dirac cones can be reshaped by long-range electron-electron interactions near the Dirac point, as schematically shown in Fig. 13(b). Finally, ARPES measurements of quasi-freestanding graphene grown on the carbon face of SiC have also detected logarithmic velocity renormalization (Siegel et al., 2011).

3. Quasiparticle lifetime

The inverse quasiparticle lifetime (decay rate) due to electron-electron interactions, $1/\tau_{ee}$, is an important quantity which is relevant to many properties of graphene (and Fermi systems in general). In particular the dependence of $1/\tau_{ee}$ on energy (or temperature) determines the importance of the electron-electron interaction contribution, relative to other processes, to transport, and interpretation of spectroscopic features, such as ARPES.

The decay rate is determined by the imaginary part of the self-energy, $\text{Im}\Sigma(k, \omega)$. The first diagram which has energy dependence, and thus a non-zero imaginary part, is the one bubble diagram of Fig. 7(b), whose real part is given by Eq. (3.16), i.e. behaves as in Eq. (3.19) at low energies. We can therefore deduce, for energies and momenta close to the mass shell (González et al., 1996),

$$\text{Im}\Sigma^{(2b)}(k, \omega) \sim \alpha^2 \theta(\omega - \nu k) \omega, \quad \omega \approx \nu k,$$

i.e. the decay rate is linear in energy. In addition, there is an on-shell (“light cone”, $\omega = \nu k$) discontinuity, where the rate experiences a jump. This on-shell behavior is due to the fact that, for $\omega < \nu k$, there is no phase space available for virtual interband particle-hole excitations (see Fig. 5), whereas such excitations are possible for $\omega > \nu k$. 

FIG. 12 (Color online) Exact evaluation of the RPA equations for (a) the quasiparticle residue, and (b) the Fermi velocity. On the horizontal axis $f$ is defined as $f \equiv N\alpha$. $\Lambda$ is in units of $k_F$. Values of $\Lambda$ from $\sim 10^6$ to $10^7$ correspond to density $n$ from $n \sim 10^{11} \text{cm}^{-2}$ to $n \sim 10^{12} \text{cm}^{-2}$ (while $\Lambda \sim 10^3$ is ultra low density $n \sim 10^9 \text{cm}^{-2}$). The values of $\Lambda$ (in units of $k_F$) can be converted into density $n$ via: $\Lambda/k_F \approx 220/\sqrt{n}$. The curves labeled 2DES refer to the case of 2DEG with parabolic bands, where $f = \sqrt{2}\tau_s$, and $\tau_s \sim 1/\sqrt{n}$. From (Polini et al., 2007).

FIG. 13 (Color online) (a) Density dependence of the velocity for suspended graphene, from (Elias et al., 2011). The solid line is the result of RG treatment within RPA (Eq. (3.27)). (b) Reshaping of the Dirac cone due to the interaction-driven renormalization (increase) of the Fermi velocity at low momenta. The outer cone represents the linear Dirac spectrum without many-body effects.
The above behavior is valid at the Dirac point and $T = \mu = 0$, while for small $T, \mu$, it is valid for energies of order\(^3\) max($T, \mu$). Notice also that the linear energy behavior of Eq. (3.37) is very different from the conventional Fermi liquid result $\text{Im} \Sigma \sim \omega^2$ (Das Sarma et al., 2007), which would occur for a finite Fermi surface ($\mu \neq 0$) and is due to intra-band particle-hole excitations.

The on-shell discontinuity present at the one-loop level Eq. (3.37) disappears when the full RPA self-energy is evaluated (Fig. 10). In this case one obtains (Khveshchenko, 2006)

$$\text{Im} \Sigma^{(\text{RPA})}(k, \omega) \sim (\pi \alpha) \theta(\omega - vk)(\omega - vk), \quad \omega \approx vk.$$  

Away from the mass shell, the energy dependence is naturally linear:

$$\text{Im} \Sigma^{(\text{RPA})}(k, \omega) \sim \ln(\pi \alpha) \omega, \quad \omega \gg vk.$$  

The full dependence $\text{Im} \Sigma^{(\text{RPA})}(k, \omega)$ has to be evaluated numerically (Das Sarma et al., 2007), and the results confirm the smooth rise of $\text{Im} \Sigma^{(\text{RPA})}$ from the point $\omega = vk$.

In the limit of zero doping $\mu \to 0$, when the system approaches the fixed point $\alpha = 0$, we argued previously that the residue $Z$ does not approach zero (i.e. the marginal Fermi liquid behavior ultimately does not manifest itself.) On the other hand the marginal Fermi-liquid behavior is expected to be much more robust as far as the inverse lifetime, $\text{Im} \Sigma \sim \omega$, is concerned, because the running of the coupling $\alpha(\omega)$ only introduces logarithmic variation on top of a much stronger linear energy dependence.

The linear decay rate discussed above is consistent with ARPES experiments (Bostwick et al., 2007; Zhou et al., 2008), and STM measurements of graphene on graphite (Li et al., 2009a) (see also the discussion in Grushin et al., 2009).

**B. Spontaneous mass generation**

It is an intriguing possibility that graphene can undergo a metal-insulator transition for strong enough Coulomb interaction $\alpha$, due to an excitonic pairing mechanism. We restrict ourselves to the charge neutrality point $\mu = 0$ since the excitonic pairing tendency decreases quickly beyond that.

1. Finite explicit mass

Before we outline the main results, let us mention that an explicit gap can also open in graphene under certain conditions that depend on graphene’s environment. For example there are suggestions of a detectable gap in situations when graphene is on a substrate with specific symmetry, creating sublattice asymmetry in the graphene plane, and thus making the graphene electrons massive (gapped) (Zhou et al., 2007). Gaps can also be produced by confining the electrons into finite-size configurations, such as quantum dots (Ponomarenko et al., 2008). In these cases the gap generation mechanism is not intrinsic to graphene, and the value of the gap depends strongly on the external conditions. However even in such situations interactions can play an important role by increasing the gap.

Consider a gap arising from an external potential that alternates between the two sublattices

$$\mathcal{H}_{\text{mass}} = \Delta_0 \sum_{\sigma, i \in A} n_\sigma(R_i) - \Delta_0 \sum_{\sigma, i \in B} n_\sigma(R_i).$$  

(3.40)

Consequently an additional pseudoscalar structure related to $\sigma_3$ is generated, and the new Green’s function has the form

$$G(k, \omega) = \frac{1}{\omega - v \sigma \cdot k - \Delta_0 \sigma_3 - \Sigma(k, \omega)}.$$  

(3.41)

Here $\Delta_0$ is the explicit “mass” of the graphene electrons (while $\Sigma(k, \omega)$ contains the information about interactions, assumed to perturbatively renormalize all the other terms.) The new spectrum is then $E(k) = \pm \sqrt{v^2 k^2 + \Delta_0^2}$, with a gap of $2\Delta_0$. Computing the Hartree-Fock interaction correction to $\Delta_0$ leads to a renormalized mass $\tilde{\Delta}_0$ (Kane and Mele, 2005; Kotov et al., 2008a)

$$\tilde{\Delta}_0/\Delta_0 \approx 1 + \frac{\alpha}{2} \ln(D/\Delta_0).$$  

(3.42)

The above enhancement can be substantial. For example for a bare gap due to spin-orbit coupling $\Delta_0 \sim 10^{-3}\text{meV}$ (Min et al., 2006; Yao et al., 2007), and taking into account the bandwidth $D = v\Lambda \approx 7eV$, the logarithmic factor is around 15. In fact one should integrate the RG equation for the renormalized mass $\Delta_0$ as a function of $\ln(\Lambda)$ simultaneously with the equation for the running coupling $\alpha(\ln(\Lambda))$, Eq. (3.13), down to the lowest infrared scale $\sim \Delta_0$ (bare gap). This leads to the stronger dependence $\tilde{\Delta}_0/\Delta_0 = (1 + \frac{3}{2} \ln(D/\Delta_0))^2$ (Kane and Mele, 2005), and the perturbative expansion of this result is Eq. (3.42). It is interesting to note that the logarithmic mass renormalization formula in graphene Eq. (3.42) is similar to the well-known expression for the electromagnetic mass of the electron (accounting for radiative corrections) in 3D relativistic QED (Weisskopf, 1939).

2. Excitonic mass generation

We now turn to the possibility of spontaneous gap generation due to long-range Coulomb interactions (we set the explicit gap $\Delta_0 = 0$ in Eq. (3.41)). In relativistic QED in two space (plus one time) dimensions, QED\(_{2+1}\), the study of this phenomenon, called chiral symmetry breaking, started quite a while ago (Appelquist et al., 1986; Pisarski, 1984), and is still going strong today. Graphene is actually different from QED\(_{2+1}\) because only
the fermions are confined to a 2D plane, while the field lines extend through the whole 3D space. In addition, the Coulomb interaction in graphene can be considered instantaneous since the speed of light $c$ is much larger than the Fermi velocity ($v \approx c/300$). Hence, Lorentz invariance is not respected, which reflects the non-relativistic, purely band origin of the Dirac quasiparticles. The analysis in relativistic QED reveals that dynamical mass can be generated below a critical number of fermion flavors $N_c$, with the mass scale set by the coupling itself, which has dimension of energy in pure QED $\alpha^{2+1}$. A transition is also found in non-relativistic graphene, where the generated mass scale is related to the ultraviolet energy cutoff ($D = \omega \Lambda$) since the coupling $\alpha$ is dimensionless in this case.

The gap equation can be obtained as a self-consistent solution for the self-energy within RPA (i.e. vertex corrections are neglected), and is referred to as the Schwinger-Dyson equation. It has the form

$$\Delta(p, \epsilon) = i \int \frac{d^2kd\omega}{(2\pi)^3} \frac{V^{RPA}(p-k, \epsilon - \omega)\Delta(k, \omega)}{(\omega^2 - v^2k^2 - \Delta^2(k) + i0^+)}.$$ (3.43)

The structure of the solution has been analyzed extensively (Gamayun et al., 2010; Gorbar et al., 2002; Khveshchenko, 2009; Khveshchenko and Leal, 2004; Liu et al., 2009) at different levels of approximation. The equation is simplified significantly if the static RPA potential is used $V^{RPA}(p, 0)$ (Khveshchenko and Leal, 2004), while the dynamical equation has also been studied on-shell ($\Delta(p, \epsilon = v\rho \pm)$) (Khveshchenko, 2009), as well as numerically (Liu et al., 2009).

The mass gap $\Delta(p)$ has strong momentum dependence, due to the long-range nature of the Coulomb interaction. $\Delta(p)$ decreases at large momenta and reaches maximum value at small momenta where it levels off. For fixed physical value of $N = 4$, a transition to a gapped state is found above a critical coupling $\alpha_c$. Some of the calculated values are: $\alpha_c = 0.92$ (Gamayun et al., 2010), $\alpha_c = 1.13$ (Khveshchenko, 2009). At strong coupling $\alpha \rightarrow \infty$ the gap is non-zero only below a critical number of fermion flavors (since the effective interaction scales as $1/N$ in this limit); for example $N_c \approx 7.2$ (Khveshchenko, 2009), $N_c \approx 7$ (Liu et al., 2009).

Near the critical coupling the low-momentum gap scales as

$$\Delta(0) \propto D \exp \left(-\frac{C}{\alpha_{eff} - \alpha_{eff,c}}\right), \quad (3.44)$$

where $C$ is a constant, the critical $\alpha_{eff,c} = 1/2$, and the form of the effective coupling $\alpha_{eff}$ depends on the level of approximation used — for example an improvement over the static RPA potential leads to: $\alpha_{eff} = \alpha/(1 + N\pi\alpha/8\sqrt{2})$ (which gives $N_c \approx 7.2$, $\alpha \gg 1$, and $\alpha_c = 1.13$, $N = 4$ (Khveshchenko, 2009)). The form of Eq. (3.44) suggests that the transition is of infinite order (Berezinskii-Kosterlitz-Thouless type). Even though Eq. (3.44) is only valid near the critical coupling, numerical results find that the gap in units of the bandwidth, $\Delta(0)/D$, is exponentially small in a wide range of couplings (Khveshchenko and Leal, 2004). Since $D \approx 7$ eV, this implies $\Delta(0) \sim$ meV, i.e. a rather small gap value.

Finally, recent work that takes into account the renormalization of the coupling constant and the quasiparticle residue suggests that $\alpha_c$ could be much larger than previously found (González, 2010; Sabio et al., 2010a).

The above results are based on various approximation schemes and it is therefore important to compare them with direct numerical simulations of the lattice field theory model. Recent Monte Carlo calculations (Drut and Łähde, 2009a,b,c; Hands and Strouthos, 2008) provide strong evidence that spontaneous mass generation does occur, and give comparable values for the critical couplings: $N_c \approx 9.6$, $\alpha \gg 1$ (Hands and Strouthos, 2008), $\alpha_c = 1.1$, $N = 4$ (Drut and Łähde, 2009b). Unfortunately the Monte Carlo simulations do not allow for an exact determination of the gap size, and for that we can only rely on the previously described Schwinger-Dyson equation (leading to small gaps). For graphene deposited on SiO the value of $\alpha_{SiO} \approx 0.79$ and is therefore not enough to generate a gap; only experiments on ultrahigh mobility suspended samples can potentially reveal the insulating state.

The overall phase diagram of graphene in the $\alpha - N$ plane is expected to look as shown in Fig. 14, with $\alpha_c \approx 1$ and $N_c \approx 7 - 9$. At finite temperature one expects the existence of a critical temperature $T_c \sim \Delta(0)$, while finite doping $\mu$ very quickly destroys the gap (Liu et al., 2009). Application of magnetic field perpendicular to the graphene layer leads to enhancement of the excitonic instability due to the formation of Landau levels (Gorbar et al., 2002; Gusynin et al., 2006; Khveshchenko, 2001a). In addition, it has been suggested that an in-plane magnetic field favors a gapped excitonic state (Aleiner et al., 2007), due to the instability of a system of electrons and holes polarized in opposite directions.
FIG. 15 (Color online) ARPES data from (Bostwick et al., 2010), showing strong features at the Dirac point, which is below the Fermi energy (at 0). The splitting shown in (H) is attributed to the presence of “plasmarons” — quasiparticles strongly bound to plasmons — and depends on the value of $\alpha$ ($\alpha \approx 0.5$ fits the data.)

The physical structure of the gapped state depends on the nature of pairing between the valleys — for example one can have charge density wave states (Khveshchenko, 2001b) with modulation of the electronic density around the two sublattices (which corresponds to intravalley pairing), or Kekule dimerization (Hou et al., 2007) which corresponds to tripling of the unit cell (intervalley pairing). One generally expects that interactions beyond the long-range Coulomb potential, such as short-range repulsion, would favor particular states, including time-reversal symmetry broken (spin) states. Further discussion appears in Section V.A.

C. Finite density Fermi-liquid regime

As the density increases above half-filling, i.e. graphene is at a finite, not necessarily small, chemical potential $\mu$, with a finite Fermi surface, a crossover towards a Fermi liquid regime takes place. In this case the lower (hole) band becomes irrelevant and the physics near the Fermi surface is dominated by intra-band transitions in the conduction (upper) band (assuming $\mu > 0$). However the physics near the Dirac point can still be very strongly affected due to the presence of plasmon and “plasmaron” features in the quasiparticle spectral function.

The quasiparticle width near $k_F$ is quite similar to the case of an ordinary 2D electron gas (Das Sarma et al., 2007; Hwang and Das Sarma, 2008b; Polini et al., 2008a), and is proportional to the second power of energy (or temperature), as in a Fermi liquid, while the quasiparticle residue is finite at the Fermi surface.

The existence of a plasmon-related peak in the quasiparticle decay rate, which originates from intraband transitions in which an electron can decay into a plasmon, was pointed out in the context of intercalated graphite, where the physics is dominated by graphene layers (Lin and Shung, 1996; Shung, 1986b). For n-doped graphene ($\mu > 0$), which is relevant to ARPES experiments, a double-feature is found in the decay rate $\text{Im}\Sigma$: a peak at positive energies, signaling an onset of plasmon emission, and a sharp spectral feature at negative energies, below the Dirac point, and separated from it by an amount proportional to the plasmon frequency (Hwang and Das Sarma, 2008b; Polini et al., 2008a). This is the so-called “plasmaron” — a resonance which consists of a quasiparticle strongly coupled to plasmons (Lundqvist, 1967). Plasmaron features have been previously detected for example in optical measurements of Bismuth (Tediosi et al., 2007).

The above calculations were done within RPA theory. Line widths have also been analyzed via ab-initio many-body methods (Park et al., 2009; Trevisanutto et al., 2008). Experiments generally show a well-pronounced linear quasiparticle spectrum (Bostwick et al., 2007; Sprinkle et al., 2009; Zhou et al., 2007, 2008), with additional features near the Dirac point which seem to depend on the way graphene is prepared, and its purity. For example, gap-like features have been observed near the Dirac point (Zhou et al., 2007), and attributed to external, substrate-related factors. Bending of the Dirac spectrum (kink-like feature) was attributed to plasmons (Bostwick et al., 2007). Most recently manifestations of the sharp plasmaron spectral intensities have been observed in quasi-freestanding graphene (Bostwick et al., 2010), where a reconstruction of the Dirac point crossing seems to take place, as shown in Fig. 15. A diamond-like shape appears due to crossing of charge and plasmaron bands. Comparison of the RPA calculation for the energy splitting with experiment leads to the value of $\alpha \approx 0.5$ (Fig. 15.) Bostwick et al., 2010 also suggest that the plasmaron features were obscured in earlier measurements on non free-standing graphene (Bostwick et al., 2007), due to the several times stronger screening (and consequently smaller $\alpha$.) Perhaps most importantly, all the current activity in ARPES on different graphene samples reveals that the electron-electron interactions can affect strongly the physics around the Dirac point, even for relatively large density (Fermi energy).

Tunneling spectroscopy measurements, combined with ab-initio calculations, have also found evidence for density-dependent interactions effects in the tunneling current (Brar et al., 2010) which arise from the sharp spectral features in the quasiparticle decay rate below the Dirac point, as discussed above.
D. Physical Observables

The interaction-driven singular logarithmic structure near the Dirac point (for \( \mu \approx 0 \)) encountered in the fermion self-energy, and in particular the renormalization of the Fermi velocity, can manifest itself in numerous physical observables, such as the charge compressibility and the spin susceptibility, which exhibit non Fermi-liquid behavior. Interactions can also affect the conductivity near the Dirac point, leading to deviations from the celebrated quantized value \( \sigma_0 = e^2/4\hbar \) expected for free Dirac fermions (Castro Neto et al., 2009a).

1. Charge and spin response

a. Compressibility. First we discuss the compressibility \( \kappa \), which was recently measured (Martin et al., 2008), Fig. 16, and it was concluded that no interaction effects were clearly visible in those samples. Theory predicts significant (\( \alpha \) dependent) deviations from the free electron behavior (Barlas et al., 2007; Hwang et al., 2007; Polini et al., 2008b; Sheehy and Schmalian, 2007).

The computation of the compressibility requires knowledge of the ground state energy, which contains the first order Hartree-Fock exchange contribution \( E_{\text{ex}} \), and the correlation energy \( E_{\text{corr}} \), describing all the higher order effects. Keeping in mind applications of the theory for fairly strong coupling (\( \alpha \approx 1 \)), the contribution of \( E_{\text{corr}} \) can be substantial. The correlation energy can be readily calculated within the RPA approximation, i.e. we take \( E_{\text{corr}} = E_{\text{RPA}} \). The total ground state energy \( E \), per unit area, is the sum \( E = E_{\text{kin}} + E_{\text{ex}} + E_{\text{RPA}} \). The kinetic energy \( E_{\text{kin}} = (2/3)v_kp_F n \), and \( n = (k_F)^2/\pi \) is the particle density. The inverse compressibility is then calculated as \( 1/\kappa = \partial^2 E/\partial n^2 \), which is equivalent to the usual definition involving the variation of the chemical potential with density, \( (1/\kappa) = \partial\mu/\partial n \). For free Dirac particles this gives \( (1/\kappa_0) = v\sqrt{\pi/(4n)} \) — behavior which can be clearly seen in experiment Fig. 16.

The interaction effects in the ground state energy acquire divergent contributions in the limit of small density \( k_F/\Lambda \approx 0 \), similarly to the previously discussed self-energy (velocity) renormalization. Ignoring any finite (non-diverging) terms, one finds (Barlas et al., 2007)

\[
E_{\text{ex}}/n = \frac{\alpha}{6} (vk_F) \ln(\Lambda/k_F), \quad (k_F/\Lambda) \to 0,
\]

\[
E_{\text{RPA}}/n = -\frac{N\alpha^2}{6} G(\alpha)(vk_F) \ln(\Lambda/k_F), \quad (k_F/\Lambda) \to 0,
\]

where the function \( G(\alpha) \) is defined as

\[
G(\alpha) = (1/2) \int_0^\infty dx (1+x^2)^{-2}(\sqrt{x^2 + 1} + N\pi\alpha/8)^{-1},
\]

and, in particular, at zero coupling \( G(0) = 1/3 \). The above results exactly follow the velocity renormalization, i.e. are equivalent to the substitution \( v \to v(k_F) \) in the free compressibility \( (1/\kappa_0) = v\sqrt{\pi/(4n)} \), where \( v(k_F) \) is the running velocity calculated within RPA at the infrared scale \( k_F \). The result is particularly simple at the Hartree-Fock (exchange) level (when the velocity follows Eq. (3.9)):

\[
\frac{1}{\kappa} = v\sqrt{\frac{\pi}{4n}} \left( 1 + \frac{\alpha}{4} \ln(\Lambda/k_F) + O(\alpha^2) \right),
\]

and was obtained by a number of authors (Barlas et al., 2007; Hwang et al., 2007; Sheehy and Schmalian, 2007).

The above results are valid at zero temperature. We also point out that exactly at zero density \( k_F = 0 \), but \( T \neq 0 \), the compressibility behaves as: \( \kappa^{-1} \sim (v^2/T)(1 + (\alpha/4)\ln(T_0/T))^2 \), where \( T_0 \) is the temperature related to the ultraviolet cutoff; since \( \Lambda v \approx 7 \text{ eV} \), then \( T_0 \approx 8 \times 10^3 \text{K} \). This is easily understood since in the infrared limit near the “critical point” \( n = T = 0 \) it’s the larger scale, either \( vk_F \), or the temperature \( T \), which enters the physical observables (Sheehy and Schmalian, 2007).

Of course Eqs. (3.45),(3.46) are valid only asymptotically \( (k_F \to 0) \), and at any finite density the compressibility should be calculated numerically. This was achieved by expressing the ground state energy via the charge response function (Barlas et al., 2007).

Fig. 17, upper panel, illustrates the variation of \( 1/\kappa \) with density for fixed interaction. Most notably, \( 1/\kappa \) is larger than the free value \( 1/\kappa_0 \). Also, the full RPA implementation weakens the first order Hartree-Fock (exchange) result, due to the different signs in Eqs. (3.45),(3.46). For example, at \( \alpha = 0.8 \) the RPA term is approximately 1/2 of the exchange, and thus has to be taken into account (although the RPA effects become weaker for \( \alpha \to 0 \)). Asymptotically, \( (\kappa^{-1}/\kappa_0^{-1}) \sim \ln(\Lambda/k_F) \), as \( k_F/\Lambda \to 0 \). The lower panel gives the variation \( \kappa/\kappa_0 \) as a function of the interaction for different densities; naturally the deviation from the free limit increases with increasing interaction and decreasing density.

The increase of the inverse compressibility, \( \kappa_0/\kappa \), as a function of the interaction \( \alpha \) (at fixed density), and
with decreasing density (for fixed interaction), represents non-Fermi liquid behavior, and reflects the lack of screening. By contrast, in a 3D (and 2D) Fermi liquid with a screened potential $\kappa_0/\kappa$ decreases; for example within Hartree-Fock, $\kappa_0/\kappa \approx 1 - r_s/6 < 1$, and eventually goes through zero, signaling an instability (Mahan, 2000) (although the critical value of $r_s$ depends strongly on the level of approximation.) Such an instability does not occur in graphene, which is related to the impossibility of Wigner crystallization (Dahal et al., 2006). It should be noted that for larger densities (larger than the density range shown in Fig. 17) the logarithmic corrections become unimportant and the system recovers the Fermi liquid behavior, i.e. eventually $\kappa/\kappa_0$ becomes larger than 1.

Fits of the experimental data for $\kappa$ with adjusted (slightly larger) velocity $v = 1.1 \times 10^6$ m/s show that $\alpha \approx 0$ (Fig. 16), while the use of $v = 10^6$ m/s by Sheehy and Schmalian, 2007 at the Hartree-Fock level produced $\alpha \approx 0.4$. On the other hand, the application of the full RPA analysis led us to conclude that $\alpha < 0.1$. It has also been argued that exchange and correlation effects vanish and do not manifest themselves at all in the compressibility (Abergel et al., 2009). These discrepancies indicate that the issue is still unsettled, while it’s also possible (indeed, quite probable) that interaction effects are obscured by charge inhomogeneities (electron-hole puddles) in these samples. Nevertheless theory predicts strong systemic (albeit logarithmic) deviations from Fermi-liquid theory, and it would be important to test these predictions in cleaner, more uniform, high-mobility, low-density samples.

b. Spin susceptibility. The paramagnetic spin susceptibility, $\chi_s$, shows behavior very similar to the charge compressibility, i.e. $(\chi_s/\chi_s,0)$ decreases as the interaction increases (Barlas et al., 2007). This is again related to the fact that $\chi_s,0^{-1}$ is calculated via the ground state energy, and is proportional to the Fermi velocity $v$. It was also pointed out that the same effect, i.e. the logarithmic growth of the exchange energy, Eq. (3.45), can lead to suppression of ferromagnetism in graphene at low densities (Peres et al., 2005). The full calculation of $\chi_s$ within RPA was carried out by Barlas et al., 2007.

On the other hand the orbital diamagnetic susceptibility, $\chi_{dia}$, is proportional to $v^2$, because the quasiparticle current that couples to the vector potential contains $v$ (the magnetic field is perpendicular to the graphene plane). Therefore interaction corrections lead to an increase of $\chi_{dia}$ (Sheehy and Schmalian, 2007) and, consequently, orbital effects are expected to dominate in the susceptibility. At the Dirac point, $k_F = 0$, one finds at finite temperature

$$\chi_{dia}/\chi_{dia,0} = \left(1 + \frac{\alpha}{4} \ln(T_0/T)\right)^2,$$

(3.48)

where the non-interacting $\chi_{dia,0} = -e^2v^2/(6\pi c^2T)$ (Ghosal et al., 2007). Here $c$ is the speed of light. At $T = 0, n \neq 0$, we have $\chi_{dia,0} \sim -e^2v/(c^2\sqrt{n})$, and interaction corrections readily follow from the $v$ dependence. This result is, strictly speaking, valid for $T \ll B \ll \mu = v\sqrt{n}$, whereas for $B = 0$ the orbital susceptibility is zero for $\mu \neq 0$ as $T \to 0$, and is finite only when the Fermi energy is at the Dirac point. It has been suggested that an interaction driven positive (paramagnetic) contribution to the orbital susceptibility can therefore become dominant in doped graphene, $\chi_{orb} \sim [e^2v^2/(\mu c^2)] |\alpha| \ln |\alpha|$, $\alpha \ll 1$ (Principi et al., 2010).

c. Specific heat. The specific heat is logarithmically suppressed due to the suppression of the DOS $\sim v^{-2}$. Consequently $C_V \sim C_{V,0}/(\ln(T_0/T))^2$, $T/T_0 \ll 1$, where $C_{V,0} \sim T^2/v^2$ is the free Dirac fermion specific heat. The full RPA calculation, valid also for large coupling, was carried out by Vafek, 2007.

![Graph of Inverse compressibility calculated at different levels of approximation as a function of density. The inset enlarges the low-density region. Lower panel (adapted from Barlas et al., 2007): Compressibility calculated within RPA, relative to the free level for different couplings and densities. Here $N = 4$ is the Dirac fermion degeneracy. The numbers refer to the values of $\Lambda/k_F$, which can be converted into density $n$ via: $\Lambda/k_F \approx 220/\sqrt{n}, \tilde{n} = n/(10^{10}\text{cm}^{-2})$. This implies $(\Lambda/k_F) \sim 10^2$ for $n \sim 10^{12}\text{cm}^{-2}$, and $(\Lambda/k_F) \sim 10$ for $n \sim 10^{13}\text{cm}^{-2}$.](image)
d. Graphene as a quantum critical system. A unified view of the above behavior is presented in Sheehy and Schmalian (2007), where it was stressed that the logarithmic corrections are manifestations of scaling behavior around the quantum critical point at $n = 0, T = 0$. As discussed previously, at finite chemical potential, $T = 0, n \neq 0$, graphene behaves as a Fermi liquid, whereas at $T \neq 0$, a quantum critical region fans out of the point $n = 0, T = 0$. In the critical region it is natural to call graphene a Dirac liquid, where the proximity to the Dirac point is important for physical phenomena at finite $T$. This puts graphene’s behavior into the general framework of quantum critical phenomena (Sachdev, 1999). In practical terms, it implies that the logarithmically divergent velocity contributions are cut-off by the largest scale: temperature $T$, $k_T \sim \sqrt{n}$, or magnetic field. Computing physical quantities in perturbation theory (Hartree-Fock or RPA) naturally involves these infrared scales. The separation between the Dirac liquid and the Fermi liquid regimes in the $n - T$ plane is defined by the crossover temperature $T^*(n) = v k_F (1 + (\alpha/4) \ln(\Lambda/k_F))$, $k_F = \sqrt{\pi n}$, and thus the temperature dependencies quoted previously, are valid for $T_0 > T > T^*(n)$. The ultraviolet temperature scale $T_0 \approx 8 \times 10^4$K, while for typical graphene densities $n \lesssim 10^{12}$cm$^{-2}$, $T^*(n) \sim 10^2$K.

2. Conductivity

The behavior of the electrical conductivity in graphene has been extensively reviewed (Das Sarma et al., 2011; Peres, 2010). It is believed that charged impurities and resonant scatterers are the main sources of scattering away from the Dirac point, and to extent the long- or short-range part of the Coulomb potential contributes to scattering is a matter of ongoing debate (Chen et al., 2008; Monteverde et al., 2010; Ni et al., 2010; Ponomarenko et al., 2009; Reed et al., 2010).

Here we will only mention effects related to long-range electron-electron interactions near the Dirac point. Interaction corrections to the minimum metallic conductivity of free Dirac fermions, $\sigma_0 = e^2/(4h) = \frac{2}{3} e^2/h$ (Fradkin, 1986; Lee, 1993), are more involved, because this expression does not contain the quasiparticle velocity, while the electric charge is not renormalized. The debate was fueled in part by electrical measurements of the minimum conductivity (at the Dirac point) which turned out to be somewhat larger than $\sigma_0$ (Geim and Novoselov, 2007; Tan et al., 2007). Theoretically, at $T = 0$ (or $T \ll \omega$ where $\omega$ is the external frequency), it is expected that any interaction effect should have sub-leading character, and the frequency can enter only through the running of the coupling $\alpha(\omega)$. Even though some debate still exists (Herbut et al., 2008; Juricic et al., 2010; Mishchenko, 2008; Sheehy and Schmalian, 2009) as to the implementation of the cut-off regularization procedure, the conductivity should have the form

$$\sigma(\omega)/\sigma_0 = 1 + \frac{\tilde{C}\alpha}{1 + \frac{2}{4}\ln(\Lambda\omega/\omega)} , \quad (3.49)$$

where the constant $\tilde{C} \approx 0.01$, as argued by Mishchenko, 2008; Sheehy and Schmalian, 2009. The smallness of $\tilde{C}$ reflects the near cancellation of self-energy and vertex corrections, and thus the effect of interactions is small. This value is also consistent with optical measurements on suspended samples (Nair et al., 2008), as well as graphene on a substrate (Li et al., 2008), which find $\sigma(\omega)$ to be very close to $\sigma_0$, and frequency independent in a wide range of energies.

In the strict DC limit $\omega = 0$, the presence of disorder, in combination with interactions, can alter the conductivity. For example, for weak gauge field disorder ($\Delta$) where an attractive line of fixed points exists (Fig. 9) with $\alpha^* = \frac{\pi}{2}\Delta$, calculations show that the conductivity (on the fixed line) increases relatively to the free limit (Herbut et al., 2008): $\sigma = [\pi/2 + (4 - \pi)\Delta]e^2/h$. For stronger scalar and vector disorder/interactions where the couplings run away to infinity the problem is non-perturbative, and a complex variety of behavior is expected (Foster and Alet, 2008).

For clean graphene at $\mu = v k_F = 0$ it was pointed out (Fritz et al., 2008; Kashuba, 2008; Müller et al., 2008) that at high temperature (compared to the frequency), the conductivity is expected to have the form

$$\sigma = \frac{0.76e^2}{\alpha^2 h}, \quad T\alpha^2 \gg \omega, \quad (3.50)$$

where $\alpha(T) = 4/\ln(\Lambda\omega/T)$ is the running Coulomb coupling. This form reflects electron-electron inelastic collisions with scattering rate $1/\tau_{ee} \sim \alpha^2 T$. The linear temperature dependence is characteristic for Dirac particles. The above formula is valid as long as $1/\tau_{ee}$ is the dominant scattering mechanism (collision-dominated transport), and implies that clean graphene at the neutrality point should exhibit a universal, interaction-limited conductivity, reflecting essentially the quantum critical behavior of graphene in this regime ($T \gg \mu$). With increased doping ($\mu/T$), a crossover takes place to a Fermi liquid regime with screened interactions, where $\tau_{ee}^{-1} \sim \alpha^2 T^2/\mu$, (Müller et al., 2008) and the conductivity is dominated by charged impurity scattering.

It has also been pointed out that for $\mu = 0$ graphene behaves as an almost “perfect” fluid, in a sense that its shear viscosity, $\eta$, relative to the entropy density $s$ is anomalously small: $\eta/s = (0.13/\alpha^2(T))(h/k_B)$ (Müller et al., 2009). This ratio measures how strongly the excitations in a fluid interact. At room temperature $\eta/s$ of graphene is smaller than $\eta/s$ of any known correlated quantum fluid, and is close to the lower bound of $\frac{1}{4\pi} \frac{h}{k_B}$ proposed to exist for a large class of strongly interacting quantum field theories (Kovtun et al., 2005). Therefore, due to its quantum critical nature near the Dirac point, graphene is suggested to behave as a strongly
correlated quantum liquid and should exhibit signatures of electronic turbulence (Müller et al., 2009).

E. Overview of main results

Before we proceed with further topics related to interactions in graphene, let us broadly summarize the main findings and questions raised so far:

1. For clean graphene at the neutrality point \( \mu = 0 \), interactions are not screened and are marginally irrelevant; the fixed point \( \alpha^* = 0 \) is approached logarithmically (or, equivalently, the quasiparticle velocity increases logarithmically). From a theory standpoint, the approach towards this fixed point is well understood both from weak and strong-coupling (RPA) perspectives. Since in graphene one can have \( \alpha \sim 1 \) under rather conventional experimental conditions, our understanding of RPA calculations is important. RPA is justified only in the limit of large number of fermion species \((N \gg 1)\), while for \( N = 4 \) it should work for weak to moderate coupling; however there are indications, coming mostly from two-loop calculations, that vertex corrections are numerically small, and thus RPA should work well. Disorder generally drives the system away from the clean fixed point, towards finite or even strong coupling, depending on disorder type.

2. The resulting behavior near the Dirac point is that of a non-Fermi-liquid with a quasiparticle decay rate which is linear in energy, and decreasing quasiparticle residue. All physical characteristics related to the quasiparticle velocity (which increases logarithmically) are affected, and predicted to exhibit systemic, interaction dependent, deviations from their non-interacting values as the Dirac point is approached, either as a function of density or temperature.

3. Can graphene be driven into an excitonic insulating state? At the Dirac point the long-range Coulomb interactions can lead to bound electron-hole pairs, creating a gap. There has been intense debate whether this can happen under realistic conditions — since the critical interaction strength appears to be \( \alpha_c \sim 1 \), it seems possible to occur in suspended samples (\( \alpha = 2.2 \)). So far no experimental indications have been observed.

4. What is the value of the interaction \( \alpha \)? Clearly, since \( \alpha = 2.2/\epsilon_0 \) is dielectric constant dependent, working with different substrates could lead to changes in interaction-dependent effects (Jang et al., 2008). There are also suggestions that graphene has an “intrinsic” value of \( \alpha \) (Reed et al., 2010), arising from dynamical dielectric screening. The polarizability of the Dirac fermions was found to be amplified by excitonic effects, improving screening of interactions between quasiparticles. This analysis leads to values of \( \alpha \) ranging from \( \alpha \approx 1/7 \) in the static limit to \( \alpha \approx 2 \) at high frequencies. Very recent measurements of the cyclotron mass in suspended graphene (Elias et al., 2011) have found logarithmic velocity renormalization and extract, within the RPA scheme, an effective value of graphene’s dielectric constant \( \epsilon_G \approx 3.5 \). One can also expect that near the Dirac point, where interactions lead to singular effects, additional factors can be important such as disorder, inhomogeneities, rippling, etc., and thus obscure the clean behavior.

5. In the Fermi-liquid regime, where interactions are screened, the physics near the Dirac point can still be strongly affected — this is due to resonant features in the quasiparticle self-energy, reflecting interactions of quasiparticles with plasmons.

IV. THE COULOMB PROBLEM AND CHARGED IMPURITIES

The consideration of non-interacting Dirac electrons in 2D under a Coulomb field is of paramount relevance for graphene, and for several reasons. First of all, the Coulomb problem for relativistic fermions has many features that are unfamiliar in condensed matter systems, and which resemble long standing predictions made in the context of QED in strong fields. As such, and given that having \( \alpha \sim 1 \) makes graphene intrinsically strongly coupled, it can provide the first experimental ground for testing many elusive predictions from strong-coupling QED.

On the other hand, the single particle Coulomb problem constitutes the first step in addressing nontrivial features of the full, many-body interacting problem. Characteristics like non-linear screening, or the supercritical instabilities, provide valuable insight in grasping some proposed many-body effects, like exciton condensation, or spontaneous mass generation in graphene.

Historically, however, the motivation for studying the Coulomb problem comes from the seminal experimental observations (Novoselov et al., 2004a) that the field effect in graphene prepared on SiO\(_2\) is characterized by carrier mobilities that do not depend on the Fermi energy or carrier density (the DC conductivity, \( \sigma = ne|v| \), with \( m \approx \text{const.} \), and that carriers are chiral Dirac fermions in 2D (Novoselov et al., 2005; Zhang et al., 2005). Early semiclassical investigations (Adam et al., 2007; Ando, 2006; Nomura and MacDonald, 2007, 2006) showed that such linear-in-density conductivity could be explained by scattering of unscreened Coulomb impurities, which are typically seen in silica in concentrations of \( \sim 10^{10} \text{cm}^{-2} \) (Ando et al., 1982). As a result, transport in the presence of charged impurities rapidly became one of the most studied topics in the quest for the ultimate mobility in graphene. Since, as we saw before, Coulomb’s law
is exactly preserved in undoped graphene, and approximately preserved for small and moderate doping, the scattering processes are essentially governed by the bare Coulomb problem, unlike conventional metals, where screening is perfect. A thorough understanding of this problem is therefore important not only for its theoretical relevance and its import on electron-electron interactions, but also for its experimental implications, and our understanding of transport in graphene.

Finally, it is highly significant that this is an exactly solvable problem. This means that most quantities can be obtained exactly, allowing us to unveil many interacting and non-interacting effects that are not within reach of the perturbative approaches already discussed. We proceed to show several such features. On account of the long range nature of the Coulomb field, inter-valley processes are not relevant, and hence we will solve the problem within each (independent) valley in the Dirac description of fermions in graphene.

A. Exact Solution of the Coulomb Problem

1. Wave Equations and Spectrum

A Coulomb center of charge $Z|e|$ generates the potential $U(r) = Ze^2/(e_0r)$ for the electrons. Without any loss of generality let us consider $Z > 0$. The electronic dynamics is governed by the wave equation

$$v \left( -i\sigma \cdot \nabla - \frac{g}{r} + \sigma_3 M v \right) \Psi(r) = E \Psi(r). \tag{4.1}$$

Here we use $g = Z\alpha = Ze^2/(e_0\nu)$, with $\epsilon_0$ reflecting the effective dielectric constant of the embedding medium, and the mass $M$ accounts for the more general possibility of a symmetry breaking gap. Throughout this chapter we shall use the scaled energy and mass $\varepsilon = E/\nu$, $m = M\nu$, and $k = \sqrt{\varepsilon^2 - m^2}$. Even though $m = 0$ for ideal graphene without interactions, nonzero $m$ can be induced in many ways. One of them is through interaction with suitable substrates, of which some experimental hints have been reported (Grüneis and Vyalikh, 2008; Li et al., 2009a; Martinazzo et al., 2010; Zhou et al., 2007). In terms of the original tight-binding Hamiltonian, the mass $M$ arising from a sublattice symmetry is related to the parameter $\Delta_0$ introduced in eq. (3.40) via $M\nu^2 = \Delta_0$. The axial symmetry of the potential allows us to use the eigenstates of the total pseudo angular momentum, $J_z = L_z + \sigma_z/2$, which is conserved (DiVincenzo and Mele, 1984). We write $\hat{\Psi}^j_z = r^{-1/2} F_j(r) \Phi_{j-1/2}^z(\theta)$, $iG_j(r) \Phi_{j+1/2}^z(\theta)$, where $j = \pm 1/2, \pm 3/2, \ldots$ are the eigenvalues of $J_z$, and the cylindrical harmonics read $\Phi_p^z(\theta) = e^{ip\theta}/\sqrt{2\pi}$. A detailed derivation of the 2D Dirac equation for general radial potentials is given by Novikov, 2007a. In our case, Eq. (4.1) reduces to the following radial equations (Khalilov and Ho, 1998; Novikov, 2007a)

$$[m - \varepsilon - g/r] F_j(r) + [\partial_r + j/r] G_j(r) = 0 \tag{4.2a}$$

$$[\partial_r - j/r] F_j(r) + [m + \varepsilon + g/r] G_j(r) = 0. \tag{4.2b}$$

This coupled pair of first order equations can be straightforwardly reduced to two decoupled second order equations. Free solutions ($g = 0$) of (4.1) exist when $|\varepsilon| > |m|$, and are simple spherical waves whose $k$-normalized version reads

$$\Psi_j = \sqrt{\frac{k}{2|\varepsilon|}} \left[ e^{i\varepsilon r/2} \sqrt{|\varepsilon + m|} J_{j-1/2}(kr) \Phi_{j-1/2} \right] \tag{4.3}$$

($s_\varepsilon \equiv \text{sgn}(x)$). For nonzero $g$, one readily sees from (4.2) that the solutions at $r \sim 0$ behave as

$$F(r), G(r) \sim r^{\pm \gamma}, \quad \gamma = \sqrt{\varepsilon^2 - g^2}. \tag{4.4}$$

The general exact solution is given in terms of confluent hypergeometric, or Whittaker’s functions, both in the massive (Gamayun et al., 2009; Gupta and Sen, 2008; Gupta et al., 2010; Khalilov and Ho, 1998; Novikov, 2007a; Pereira et al., 2008a), and massless cases (Gupta and Sen, 2009; Pereira et al., 2007; Shytov et al., 2007b). In the massless case, one can map (4.2) into the familiar Coulomb radial Schrodinger equation in 3D (Pereira et al., 2007):

$$\partial^2_{r^2} f_\pm + \left[ \varepsilon^2 + 2g\varepsilon/r - \gamma(\gamma \mp 1)/r^2 \right] f_\pm(r) = 0, \tag{4.5}$$

where the $f_\pm$ are linear combinations of $F$ and $G$, $\varepsilon^2$ takes the place of the Schrodinger energy, and $\gamma$ plays the role of angular momentum. Since the solution is formally the same, the appearance of $\varepsilon^2$ instead of $\varepsilon$ means that the massless case admits no bound solutions, as we expect on account of the absence of a spectral (mass) gap. The massive case, however, has a well defined infinite spectrum of bound solutions when $|\varepsilon| < |m|$, given by (Khalilov and Ho, 1998)

$$\varepsilon_{n,j} = s_g m \frac{n + \sqrt{n^2 - g^2}}{\sqrt{g^2 + [n + \sqrt{n^2 - g^2}]^2}}, \tag{4.6}$$

lowest level is given by $\varepsilon_G \equiv \varepsilon_{0,1/2} = s_g m \sqrt{1 - (2g)^2}$.

2. Supercritical Instabilities

Consideration of eq. (4.4) immediately reveals a complication if $g > c_\nu = 1/2$, because $\gamma$ becomes imaginary for the lowest angular momentum channels ($j = \pm 1/2$). The solution (4.4) is neither regular nor divergent, but rather oscillates endlessly towards $r = 0$. This is pathological because the space of solutions is of dimension 2, and we can no longer discard an irregular contribution since both linearly independent solutions are square integrable. In other words, there is no boundary condition.
Possibility of testing the supercritical instability in a con-

an infinite quasi-bound spectrum at \( g > g_c \), when its spectral fingerprint is rather featureless for \( g < g_c \); (iii) the infinite spectrum has the potential to over-screen the Coulomb center. In addition, unlike the massive case, here the critical coupling remains unchanged at \( g_c = 1/2 \), and no qualitative features (like how many, if any, states have dived) depend on the magnitude of the regularization distance. The spectrum of supercritical resonances behaves as (Gamayun et al., 2009; Gupta and Sen, 2009; Shytov et al., 2007b)

\[
\varepsilon_n \approx -\frac{a + ib}{R} e^{-\pi n/\sqrt{g^2 - g_c^2}}, \quad (a, b) \sim O(g),
\]

which has an essential singularity at \( g_c \), an energy scale/lower bound set explicitly by the regularization distance, \( R \), and diverging lifetimes close to the critical point. Since the width of these states vanishes linearly, they are practically bound states (hence the designation quasi-bound states). In real space, the localization scale is determined by the regularization distance \( R \) itself.

Since meso and nanoscopic devices are of high interest, it is pertinent pointing out that massless Dirac fermions in a finite-sized system mimic in all aspects the physics of massive electrons, as a result of the linearly vanishing DOS and the effective gap coming from finite-size quantization (Pereira et al., 2008a).

3. DOS, Scattering and Transport Cross Sections

Here and in the coming sections we shall be concerned mostly with massless Dirac fermions, except when explicitly stated otherwise. The local density of states (LDOS) and cross sections are useful quantities insofar as they are directly accessible in local probe and transport experiments. The LDOS per unit area and spin is isotropic, and can be written in closed form in terms of partial waves as

\[
N(\varepsilon, r) = \sum_{j} n_j(\varepsilon, r),
\]

(Pereira et al., 2007) with

\[
n_j(\varepsilon, r) = \frac{j^2}{2\pi^2} \sum_{\gamma} \frac{F^2_{\gamma - 1} + F^2_{\gamma} + 2gs_{x} |j| F_{\gamma} F_{\gamma - 1}}{\varepsilon - \varepsilon_{r, j}}
\]

for \( g < g_c \), and \( F_1 \) represents the Coulomb function \( F_1(-gs_{x}, |\varepsilon|) \) (Abramowitz and Stegun, 1964). The function \( N(\varepsilon, r) \) is plotted in Fig. 19(a) for different couplings and distances. Apart from the evident particle-hole asymmetry, the LDOS remains rather featureless, even at the shortest distances. If \( g > g_c \) the corresponding analytical expression obtained in the regularized potential is more complex, but still has a closed form (Pereira et al., 2007). In this case, supercritical channels \((|j| < 1/2)\) need to be isolated from undercritical ones \((|j| > 1/2)\), yielding two contributions to the LDOS:

\[
N(\varepsilon, r) = \sum_{|j| < |g|} \tilde{n}_j(\varepsilon, r) + \sum_{|j| > |g|} n_j(\varepsilon, r).
\]

The total LDOS for this case is shown in Fig. 19(c) for \( g = 1.0 \), and at different distances to the impurity. It is now clear that strong resonances, decaying rapidly with distance, appear in the vicinity of the Dirac point, signaling the presence of the quasi-bound levels (Pereira et al., 2007; Shytov et al., 2007b). Their exponential accumulation at \( \varepsilon = 0 \) is confirmed in Fig. 19(d) where we show the supercritical contribution \( \tilde{n}_j(\varepsilon, r) \) as a function of \( \log(|\varepsilon|) \). At positive energies the LDOS exhibits periodically decaying oscillations in \( \varepsilon r \) [inset of Fig. 19(c)], with extrema separated by \( \approx \pi \varepsilon r \), within logarithmic accuracy (Shytov et al., 2007a). When directly measured in STM such oscillations can be used to extract the electronic dispersion, as done by Ouyang et al., 2002.

We point out that, since the solution of the supercritical problem involves a nontrivial ad-hoc regularization, these results have been checked numerically against exact solution of the full tight-binding problem in the honeycomb lattice, being found that the analytical Dirac results reproduce the full lattice problem down to distances as small as the lattice scale (Pereira et al., 2007).

The striking differences between the two regimes and the violent modification of the ground state at strong coupling are likewise evident in the behavior of the scattering phase-shifts, \( \delta_j(\varepsilon) \). They admit closed formed expressions at both \( g < g_c \) (Novikov, 2007a; Pereira et al., 2007;
Shytov et al., 2007a) and $g > g_c$ (Castro Neto et al., 2009b; Shytov et al., 2007b). For example, the undercritical S-matrix reads (Novikov, 2007a)

$$S_j(\varepsilon) = e^{2i\delta_j(\varepsilon)} = \frac{je^{i(\varepsilon - g)} \Gamma(1 + \gamma - ig\varepsilon)}{\gamma - ig\varepsilon} \frac{\Gamma(1 + \gamma + ig\varepsilon)}{\Gamma(1 + \gamma - ig\varepsilon)}, \quad (4.11)$$

which is energy independent, but considerably asymmetric with respect to the sign of $g$. The corresponding $\delta_j$ are shown in Fig. 19(b)(inset) as a function of coupling strength. Note how $\delta_{1/2}$ (the most important partial wave) behaves rather differently from the others: only $\delta_{1/2}$ shows the expected sign for the attractive/repulsive situations. On the other hand, in the supercritical regime there is a strong $\varepsilon$-dependence of $\delta_j$. In the top row of Fig. 19(d) we present $(\delta_j \mod \pi)$ as a function of $\log(\varepsilon)$. In the attractive sector ($\varepsilon < 0$ if $g > 0$) the abrupt steps centered around $\pi/2$ mark the position of the infinite quasi-bound spectrum (which, as per (4.8), accumulates exponentially at $\varepsilon = 0$), whereas in the attractive sector $\delta_j(\varepsilon)$ is smooth.

Knowledge of the phase-shifts allows direct calculation of the full transport cross-sections for our 2D Dirac fermions:

$$\Lambda_{tr}(\varepsilon) = \frac{2}{\varepsilon} \sum_j \sin^2 \left( \delta_{j+1/2}(\varepsilon) - \delta_{j-1/2}(\varepsilon) \right) \quad (4.12)$$

(Katsnelson, 2006; Novikov, 2007a). The profile of $\Lambda_{tr} \times \varepsilon$ at weak coupling is shown in Fig. 19(b). When scattering is due only to unscreened charges, the marked asymmetry between $g > 0$ and $g < 0$ can be used to extract the density of positively and negatively charged impurities ($n^\pm$) from a single measurement of the electrical conductivity, $\sigma$, as a function of carrier density (Novikov, 2007b). This technique has been used in some experiments (Chen et al., 2009a,b, 2008), but the asymmetry effect can be easily masked by other spurious influences (Barraza-Lopez et al., 2010; Huard et al., 2008; Nouchi and Tanigaki, 2010). Moreover, on account of the $\varepsilon$-independence of $\delta_j$ in (4.11), the corresponding Drude conductivity, $\sigma = 4e^2\tau/\hbar v_n \Lambda_{tr} k^2$, is immediately seen to scale linearly with density: $\sigma \propto \mu^2 \propto n$. Therefore, the linear-in-density conductivity, which appears already in the first Born approximation, remains when the cross section is calculated exactly.

For supercritical potentials, and similarly to the LDOS, there will be undercritical and supercritical partial waves contributing to $\Lambda_{tr}(\varepsilon)$ [cfr. eq. (4.10)]. The latter give rise to strong peaks in the transport cross-section at densities for which the Fermi energy matches the levels $\varepsilon_n$ (Shytov et al., 2007b), tallying with the behavior of the DOS.

B. Induced Charge and Screening

First attempts at understanding screening in graphene date back to DiVincenzo and Mele, 1984, where it was recognized that conventional procedures of the theory of metals, like self-consistent screening, linear response or Friedel sum rules, are not straightforward in this system. For example, within the Dirac (effective mass) approximation, the ultraviolet cutoff scale enters explicitly in Friedel’s sum rule, and Levinson’s theorem is modified (Lin, 2006) (Levinson’s theorem is one of the fundamental results in quantum scattering theory, asserting that in the Schrödinger’s equation with a non-singular spherically symmetric potential the zero energy scattering phase-shift exactly counts the number of bound states: $\delta(0) = N\pi$). One consequence is that a naive application of Friedel’s sum rule can yield divergent displaced charges (DiVincenzo and Mele, 1984). Even though these divergences are artificial in the target lattice problem, they point, already at a single particle level, to the anomalous screening properties of graphene.

1. Weak Coupling ($g < g_c$)

a. Non-interacting Induced Charge. Knowledge of the exact LDOS within the Dirac approximation (Sec. IV.A.3) allows the straightforward calculation of the perturbation to the electronic density induced by the Coulomb center. The induced density is defined as $\delta n(r) = n(r) - n^0(r)$, and is related to the LDOS via (for undoped graphene at zero temperature) $n(r) = \sum_j n_j(r) = \sum_j \int_0^\infty n_j(\varepsilon, r) d\varepsilon$, where $D$ is the cutoff scale for the linearly dispersing band. The induced charge density is just $\delta \rho(r) = -e\delta n(r)$. Closed form expressions for $n_j(r)$ are provided in (4.9). One difficulty with this approach is that the resulting density per partial wave behaves asymptotically as

$$\delta n_j(r \to \infty) \sim \frac{1}{r} \left[ D - \frac{g}{r} - D^0 + O(r^{-2}) \right], \quad (4.13)$$

which diverges upon summation over $j$ (a reminiscence of the problems associated with the ultraviolet scale alluded to above). In the above expression $D$ and $D^0$ represent the cutoff in the presence and in the absence of the coulomb center, respectively. Since the subleading terms in (4.13) are convergent in $j$, we regularize it by taking a position dependent cutoff: $D \to D^0 + O(r^{-3})$. As a result, the total induced density acquires the form $\delta n(r) \sim H(D^0 r)/r^3$, where $H(x)$ is a constant-amplitude oscillating function (Pereira et al., 2007). Since it is desirable to have control over the validity of the regularization procedure outlined above, we have calculated the total induced density $\delta n(r)$ in the full tight-binding problem, via exact diagonalization. The result is plotted in Fig. 20(a), and unequivocally shows the predicted $1/r^3$ decay, with oscillations on the scale of the lattice. Such fast decay implies that the induced charge concentrates within a small vicinity of the impurity. Moreover, the numerical results in the lattice further suggest that such distance is of the order of the lattice parameter $a$: the inset in Fig. 20(a) reveals that the total charge pulled in-
side a region \( r < R_{\text{max}} \) saturates within very few lattice spacings. In fact, since \( D^0 \propto 1/a \), in the limit \( a \to 0 \) (where the effective mass description is meaningful) the analytical expression \( \delta n(r) \sim H(D^0 r)/r^3 \) can be seen as a representation of the 2D Dirac-delta function. In other words, we expect the induced charge density to behave as

\[
\delta \rho(r) = -|e| \delta n(r) \frac{a \to 0}{a} - Q|e| \delta(r). \tag{4.14}
\]

The same conclusion follows from a modified Friedel argument (Shytov et al., 2007a), and from the exact calculation of the non-interacting Green’s function in the Coulomb field (see below) (Terekhov et al., 2008). The induced charge has a screening sign, as expected, but the strongly localized distribution of the induced charge (4.14) implies that undoped graphene cannot screen in the usual sense, because it merely renormalizes the strength of the impurity: \( Z \to Z_{\text{eff}} = Z - Q \). This leaves Coulomb’s law unaltered, except for the substitution \( Z \to Z_{\text{eff}} \).

**b. Linear (RPA) Screening.** Single particle results, like the one above, are not generally sufficient to draw conclusions about screening. Consider now the same problem in linear response, at the RPA level, which is justified for small, undercritical couplings. Within the RPA, the Fourier transform of the statically screened potential is given by \( U_s(q) = U_0(q)/[1 - \Pi^{(1)}(q)V(q)] \) (Fetter and Walecka, 1971), where \( V(q) = 2q^2/|q| \) is the electron-electron interaction, and \( U_0(q) = ZV(q) \) the external impurity potential. From (2.14) we know that \( \Pi^{(1)}(q \to 0) \approx \sim -q/(4v) \), and hence \( U_s(q) \approx U_0(q) \left( 1 + \frac{\pi}{2} \right)^{-1} = \frac{U_0(q)}{\epsilon_{\text{RPA}}} \). Therefore linear response confirms the absence of screening, except for the trivial renormalization of the static dielectric constant: \( \epsilon_0 \to \epsilon_{\text{RPA}} = \epsilon_0(1 + \pi a/2) \) (Ando, 2006). Likewise, the induced density can be computed in linear response from \( \delta n(q) = -ZV(q)\Pi(q) \) or, in the RPA:

\[
\delta n(r) = -Z \int dq \frac{\Pi^{(1)}(q)V(q)}{1 - \Pi^{(1)}(q)V(q)} e^{-|q| r}, \tag{4.16}
\]

yielding \( \delta \rho(r \gg a) \sim -\delta(r) Z|e|\pi a/2 \) to linear order in \( a \) (Kolezhuk et al., 2006). This is exactly what was obtained in (4.14) from a single particle, wavefunction, perspective. In addition, the argument that the Fourier transform of \( \delta n(r) \) is dimensionless can be used to show that it should be a pure constant in undoped graphene, for which there is no natural length scale. As a result,

**FIG. 20** (Color online) (a) Induced electron density, \( \delta n(r) \), plotted as a function of distance to the Coulomb center, for different impurity strengths, \( g < g_c \). Data obtained from full diagonalization of the tight-binding Hamiltonian in a lattice with \( 124^2 \) atoms. Black lines are \( \propto 1/r^3 \), and guides for the eye. Inset shows the saturation of the integrated charge accumulated inside \( r < R_{\text{max}} \), as a function of \( R_{\text{max}} \). (b) Same as (a), but for the supercritical case, \( g > g_c \), and the dashed line is now \( \propto 1/r^3 \).

**FIG. 21** (Color online) (a) Total integrated charge in the vicinity of the impurity, \( Q \), obtained: from exact diagonalization in the lattice (dots), from RPA (4.16) (blue), and from the exact Green’s function in the Coulomb field (4.19) (red). (b) The self-consistent \( Z_{\text{eff}} \), obtained from Eq. (4.21) (Terekhov et al., 2008). Numerical data (dots) is plotted after accounting for finite-size renormalization of \( g_c \) (Pereira et al., 2008a).
that $\delta \rho(r) \propto \delta(r)$ remains true in all orders of perturbation theory (Biswas et al., 2007). For consistency, the total induced charge, $Q$, introduced in (4.14) is then given by

$$Q = \frac{\pi}{2} Z \alpha + (\text{higher orders in } Z \alpha). \quad (4.17)$$

To verify this correspondence we can compare (4.17) with the value of $Q$ extracted from the non-interacting exact diagonalization in the honeycomb lattice. As shown in Fig. 21(a), the numerical $Q$ for different values of $Z$ follows the relation (4.17) for most of the range $0 < g < g_e$, thereby confirming the correspondence, and showing how weakly undoped graphene screens (Pereira et al., 2007; Shytov et al., 2007a). Given that only the global dielectric constant is affected, one can say that undoped graphene screens like an insulator.

At finite densities, however, the system screens like a conventional metal. This derives at once from the fact that, at finite Fermi momentum, $\Pi^{(1)}(q \approx 0) \approx -2k_F/(\pi v)$, no longer vanishing, and leading to the screened potential

$$U_s(q) = \frac{U_0(q)}{\epsilon_{\text{RPA}}(q)}, \quad \epsilon_{\text{RPA}}(q) = 1 + \frac{q_s}{q}, \quad (4.18)$$

$q_s = 4\alpha k_F$ playing here the role of inverse screening length (Ando, 2006; Nomura and MacDonald, 2006). Contributions from interband transitions can be simply incorporated by renormalizing the background dielectric constant by the factor $(1 + \pi \alpha/2)$, as in eq. (4.15). Using (4.16), the total integrated charge is now seen to be $\int \delta \rho(r) dr = -Z|e|$. This means that, unlike the undoped situation, at finite electron densities the system completely screens the Coulomb center, just as expected in a metallic system (Castro Neto et al., 2009b).

For transport considerations it is important to underline that, even though at finite densities charged impurities have a finite range determined by $q_s$, the Boltzmann conductivity remains linear in density. This happens because the screened potential (4.18) entering in the relaxation time calculation, maintains the same dependence with $k_F$. From this perspective, the mobility remains constant in density for both screened and unscreened charges, differing only by an overall constant related to $\epsilon_{\text{RPA}}(k_F)$ (Nomura and MacDonald, 2006).

c. Nonlinear Screening. As Fig. 21(a) documents, even as linear response is acceptable at small values of $g = Z \alpha$, the approximation becomes increasingly unwarranted as $g$ nears the critical threshold, $g_c = 1/2$, which is non-perturbative. Rather than analyze this limit on the basis of exact wavefunctions in the Coulomb field, as was done in Sec. IV.B.1.a, we now describe the solution obtained by Terekhov et al., 2008. These authors bypass the solution of the Dirac equation, obtaining instead an exact integral expression for the Green’s function in a Coulomb field, using a proper-time approach common in QED (Mil’shtein and Strakhovenko, 1982). The main result is that

$$\delta \rho(r) = -Q \delta(r) + \delta \rho_{\text{dist}} \quad (4.19)$$

where $\delta \rho_{\text{dist}}(r)$ represents a positive charge distributed at $r = \infty$ (needed to satisfy the constraint of total zero induced charge). It is significant that this approach affords an exact expression for the dependence of $Q$ upon $g = Z \alpha$, which is shown in panel (a) of Fig. 21. A series expansion of this dependence yields the following:

$$Q(g) \approx \frac{\pi}{2} g + 0.783 g^3 + 1.398 g^5 + \cdots. \quad (4.20)$$

with each term corresponding to successive orders in perturbation theory. The linear term is the one that appeared already in (4.17), at the RPA level. The next term in the expansion was also calculated perturbatively by Biswas et al., 2007. Interestingly, even though this problem is analogous to conventional QED vacuum polarization of a point charge, the perturbative coefficients in $Q(g)$ are not small, and increase with order, in stark opposition with the behavior known in 3D QED (Brown et al., 1975). This offers another perspective upon the uniqueness of electron-electron interactions in graphene, for, even though the problem is on the surface analogous to the QED situation, the physics can be qualitatively different. In this particular case, the difference seems to arise from the 2D dimensionality of the problem and the absence of Lorentz invariance in graphene, which renders the Coulomb interactions instantaneous.

Inspection of the curve $Q(g)$ in Fig. 21(a) reveals that it reaches 1 at $g = 0.49$, slightly before $g_c$. This implies that, for a monovalent impurity ($Z = 1$), the non-interacting result predicts complete shielding before $g_c$, insofar as $Z_{\text{eff}}(Z, \alpha) = Z - Q(g) \to 0$. Such strong renormalization of the potential source immediately begs the consideration of interaction and correlation effects. They can be incorporated at the Hartree level by solving the self-consistent equation

$$Z_{\text{eff}} \alpha = Z \alpha - \alpha Q(Z_{\text{eff}} \alpha), \quad (4.21)$$

which encodes an infinite summation of a selected set of bubble diagrams (Terekhov et al., 2008). Since $Q(g)$ is obtained exactly, one obtains the renormalized effective potential strength, $Z_{\text{eff}} \alpha$, with an accuracy much beyond the RPA. In addition, the reduction of $Z_{\text{eff}}$ with respect to the bare $Z$ means that $g_c$ is also self-consistently renormalized to $\tilde{g}_c = Z_{\text{eff}} \alpha$. The effect is shown in Fig. 21(b), which reveals that, as $\tilde{g}_c > g_c$, self-consistent screening delays the supercritical threshold because the condition $Z_{\text{eff}} \alpha = 0.5$ requires a higher bare $Z$. This phenomenon is most striking for $Z = 1$, in which case the supercritical point disappears altogether ($\tilde{g}_c < 1/2$ even as $Z \to \infty$), whereas $g_{< c}^{Z=2} = 1.136$ and $g_{< c}^{Z=3} = 0.798$. The prediction of this self-consistent Hartree renormalization of $Z_{\text{eff}}$ would then be that impurities with $Z = 1$ can never become supercritical. In addition, Hartree screening is sufficient to suppress the tendency for over-shielding of the
Coulomb center: as seen in the inset of Fig. 21(b), $Z_{\text{eff}}$ remains always positive.

An alternative approach to the Hartree screening consists in treating the induced charge in linear response, $\delta \rho(q) = ZV(q)\Pi(q)$, but taking into account electron-electron interactions perturbatively, via the renormalization of the coupling constant (Biswas et al., 2007). This is valid for small $\alpha$ (weak interaction), and leads to a result formally equivalent to (4.19), but where $\delta \rho_{\text{dist}}$ now arises from the electronic correlations. The distributed charge in the interacting case also has an anti-screening sign, but decays as $1/r^2$, while the non-interacting $\delta \rho_{\text{dist}}(r)$ is zero everywhere, except at infinity.

Even though the above considerations pertain to undoped graphene, since all screening charge accumulates completely within a narrow distance, finite densities are not expected to alter the picture for as long as $q_s = 4ak_F$ remains large compared to the lattice scale $a$.

2. Strong Coupling ($g > g_c$)

In Sec. IV.B.1.c Hartree screening was shown to renormalize $g_c$ and delay the critical threshold. Two important questions naturally arise: (i) since the self-consistent solution of (4.21) is uncontrolled, how certain can one be that the critical regime is reachable at all? (ii) So far we looked only at screening from the undercritical side (i.e. as long as $Z_{\text{eff}} \alpha < 1/2$). How can one address screening from the supercritical side, given that this regime cannot be reached perturbatively?

The answer to these questions is far from trivial. In QED it is related to the ground state and stability of super-heavy nuclei ($Z \geq 170$), when the bound spectrum dived into the positron continuum (Fig. 18). Despite having received considerable attention throughout the 1970-80's (Greiner et al., 1985), the fact that these systems require such high $Z$'s, has turned it largely into an academic problem. The exciting prospect about graphene is that impurities with $Z = 1, 2$ might already display supercritical physics, in which case it would afford a benchmark test of some yet untested QED predictions.

The essence of the difficulties in treating the supercritical regime clearly lies in its non-perturbative nature. Graphene, being gapless, is even more pathological because of the infinite quasi-spectrum that appears in the hole channel [Fig. 18]. This quasi-spectrum is akin to an atom filled with infinitely many electrons and, as known from studies of heavy atoms (Landau and Lifshitz, 1981), it requires full consideration of correlations and interactions, and self-consistent techniques like Thomas-Fermi (Fermi, 1927; Thomas, 1927).

a. Non-interacting Induced Charge. In Sec. IV.A.3 we saw some unusual consequences for the DOS and cross-sections extracted from the exact solution of the Dirac equation for $g > g_c$. Now we address the corresponding induced charge obtained using the same procedure as in Sec. IV.B.1.a. Consideration of the exact wavefunctions (Pereira et al., 2007) or the exact phase-shifts (Shytov et al., 2007a) leads to the conclusion that the supercritical partial waves contribute with an induced charge $\propto 1/r^2$. This could be expected on dimensional grounds: $\delta(r)$ and $1/r^2$ are the only dimensionally consistent possibilities in the absence of any intrinsic length scale in massless graphene. The exact induced density per partial wave reads (Shytov et al., 2007a)

$$\delta n_j(r) = \frac{2s_g}{\pi^2 r^2} \sqrt{g^2 - j^2},$$

(4.22)

and, like the undercritical contributions, has a screening sign. The full induced charge is obtained from $\delta \rho(r) = -|e|\delta n(r), n(r) = \sum_{|j| < g_c} \delta n_j + \sum_{|j| > g_c} \delta n_j$, and has the general form

$$\delta n(r) = s_g A \frac{1}{r^2} + B_{\rho_{\text{g}}} \delta(r).$$

(4.23)

If $1/2 < g < 3/2$, Eq. (4.23) reduces to $\delta n(r) = (\pi g/2)\delta(r) + 2s_g \sqrt{g^2 - g_c^2}/(\pi r^2)$. The general behavior (4.23) is also confirmed numerically by exact diagonalization of the tight-binding Hamiltonian in the honeycomb lattice, whose results are plotted in Fig. 20(b).

b. Supercritical Protection. Unlike the undercritical regime, the additional power law decay in (4.23) causes a modification of Coulomb's law at large distances. But since we have a quasi-atom with all levels (4.8) filled, the non-interacting result in Eq. (4.23) cannot be the final answer. Each level is quasi-localized on the lattice scale, and should contribute significantly to shield the Coulomb center. For $g$ not too much above $g_c$ we can follow an argument advanced by (Shytov et al., 2007a) that assumes electrons at some distance $r$ feel the effect of a point charge consisting of the impurity subtracted from all the accumulated screening charge up to $r$. In other words, we introduce a distance dependent impurity strength, $Z_{\text{eff}}(r) = Z - \int_R^r \delta n(r) dr$, and substitute (4.23) for $\delta n(r)$:

$$Z_{\text{eff}}(r) = Z - \frac{\pi}{2} g - \frac{4\sqrt{g^2 - g_c^2}}{\pi} \log \frac{r}{R}.$$  

(4.24)

Since the log term represents the renormalization coming from screening at distances away from the center, we should replace ($g \equiv Z\alpha \rightarrow (Z_{\text{eff}} \alpha \equiv g_{\text{eff}}$). This leads to a self-consistent renormalization of the coupling that can be written in an appealing RG fashion as $dg_{\text{eff}}/d \log(r) = -4\alpha \sqrt{g_{\text{eff}}^2 - g_c^2}$. In this way, it can be immediately seen that the coupling $g_{\text{eff}}$ will “flow” to the constant value $g_c$ within a finite distance [see also (Gupta and Sen, 2009) for a related renormalization procedure]. As such, irrespective of the bare $Z$, the system self-consistently rearranges itself so that electrons at large distances never
feel a supercritical effective coupling. The undercritical (stable) situation is therefore protected. This reasoning agrees with expectations for the corresponding problem in QED, where it was shown that, within Thomas-Fermi, the vacuum polarization charge in super-heavy nuclei behaves in such a way as to reduce $Z$ to the threshold value (Müller and Rafelski, 1975).

This is quite different from a metal, to the extent that graphene always leaves an universal amount of charge ($Z_c = g_c/\alpha$) unscreened at large distances. Such behavior derives from the sharp transition between the under and supercritical regimes. On the one hand, the system wishes to screen as much charge as it possibly can. But, on the other, it cannot screen if $g < g_c$, therein lying the compromise that makes screening stop when $Z$ reaches $Z_c$.

c. **Nonlinear Thomas-Fermi and Beyond.** While the above approach is valid in principle only for $g \geq g_c$, the fact that qualitatively supercritical graphene resembles a super-heavy atom suggests the use of TF theory, which is exact for atoms with $Z \to \infty$ (Lieb, 1981), and affords an approximation from the opposite limit $g \gg g_c$. If we wish to calculate how Coulomb’s law is modified in this regime we can calculate the total potential

$$\delta V \equiv \frac{\epsilon^2}{\epsilon_0 r} \left[ \frac{Z}{1 + 2Z \alpha^2 \log(r/R)} \right], \quad (4.25a)$$

$$\delta V \equiv \frac{\epsilon^2}{\epsilon_0 (q_s r)^2} \left[ \frac{Z}{1 - 2Z \alpha^2 \log(q_s R)} \right], \quad (4.25b)$$

valid for $\mu = 0, r \gg R$ and $\mu \neq 0, r q_s \gg 1$ respectively, where $q_s = 4\alpha \mu / v$ is the screening length (4.18). One notes that the overall space dependence is formally the same as the one obtained within RPA, both at zero and finite density. Hence the bracketed coefficients in (4.25) can be interpreted as a renormalization of the valence. The important difference is that, in the limit $Z \to \infty$ of interest in the context of TF, the nominal valence $Z$ disappears from $\delta V(r)$, which thus becomes universal (and undercritical). Hence, even for strong impurities one can formally use perturbative expressions for the screened potential, corrected for this renormalization of $Z$.

It is important to emphasize that, since at this stage we are concerned with screening and corrections to the induced charge coming from electron-electron interactions, $g = Z \alpha$ is no longer the relevant parameter alone, but both $Z$ and $\alpha$ (that controls the interaction) independently. For this reason, Fogler et al., 2007 have argued that the result (4.25) is valid only for small $\alpha$. More precisely, it applies for $1/Z \ll \alpha \ll 1/\sqrt{Z}$, and provided that $\log(r/R) < 1/\alpha$. Otherwise, for intermediate electron-electron coupling ($\alpha \sim 1$), the asymptotic screened potential should follow $\delta V \approx Z_c \epsilon^2 / (\epsilon_0 r)$, with $Z_c = g_c / \alpha = 1/(2\alpha)$. This result embodies the undercritical protection discussed above in Sec. IV.B.2.b, insofar as the supercritical core is always self-consistently screened so that $\delta V \to Z_c$. Moreover, within the supercritical core region, $r < 2Z \alpha^2 R$, the effective potential decays as $\propto 1/r^{3/2}$. This obtains treating graphene as an ideal classical metal, under the assumption of quasi-complete screening in the core region (Fogler et al., 2007).

3. **Finite Mass**

We now briefly address the differences expected in the screening properties of charged impurities in massive graphene. We shall consider only the undoped situation, and assume $\mu = -m$, such that none of the bound levels (4.6) are occupied.

a. **Weak Coupling ($g < g_c$).** It is clear that at weak coupling one can directly rely on perturbative results (Sec. IV.B.1), and obtain the induced density from $\delta n(q) = -Z V_0(q) \Pi(q)$. $\Pi(q)$ has been calculated in (2.14), and simple substitution yields the following asymptotics:

$$\delta n(r) \sim Z \alpha \left\{ \begin{array}{ll}
\frac{\pi \delta(r)}{r} & r \approx a \to 0 \\
-\lambda_C^{-2} \log \frac{\lambda_C}{r} & a \ll r < \lambda_C \\
-\lambda_C r^{-3} & r \gg \lambda_C.
\end{array} \right. \quad (4.26)$$

where $\lambda_C = 1/(mv)$ is the Compton wavelength, and $a$ the lattice parameter of graphene. The short distance term is the same as found in the massless case (4.14,4.17), which makes sense given that when $r \ll \lambda_C$ the system does not “feel” the mass yet. It has a screening sign. However as the distance increases screening is increasingly suppressed, first weakly up to $\lambda_C$, and then strongly, beyond $\lambda_C$. In fact, since here $\delta n(q = 0) = 0$, we have exactly $\int \delta n(r) dr = 0$. The meaning of this is simple: the total induced charge is zero. The system cannot screen beyond $r \gtrsim \lambda_C$ because it is essentially an insulator (or a semiconductor with $\mu$ in the middle of the gap). Notwithstanding, unlike a conventional insulator, gapped graphene shows a novel screening behavior at short distances, reflected in the live dependence of $\delta n(r)$ on the distance up to $\lambda_C$.

b. **Strong Coupling ($g > g_c$).** In gapped graphene, screening in the supercritical regime is qualitatively easier to understand, at least when $g \gtrsim g_c$. If the first level has just merged inside to hole continuum, its effective
probability density, $|\Psi_r(r)|^2$, remains exponentially localized, as described in IV.A.2.a. Invoking completeness of the set of single-particle states, one can easily show that the non-interacting induced charge follows (Pereira et al., 2008a)

$$\delta n(r) \approx |\Psi_r(r)|^2 + \delta n_{pol}(r), \quad (4.27)$$

where $\delta n_{pol}(r) \approx \sum_{E < E_0} |\chi_{E}(r)|^2 - |\chi_{E}^0(r)|^2$ represents the vacuum polarization (i.e., the induced charge coming from the full set of plane wave states), and is the same quantity that obtains in RPA (4.26). Clearly, the contribution from the supercritical state alone makes $\delta n(r)$ in (4.27) highly localized within the Compton wavelength, $\lambda_C$. For all purposes, this state screens like a bound state would, and consequently one expects the impurity valence to be reduced by one unity times the degeneracy, $N$, of the level. But since $N = 4$, this would imply, for the experimentally significant cases of $Z \sim 1$, a tendency to over-screen the Coulomb center. This bring us again to the role of interactions. The above would be true in the limit of weak interaction $\alpha \ll 1$. But, in that case, the supercritical regime would require $Z \gg 1$, which is not feasible. In the end, if supercritical systems are to be produced, electron-electron interactions should be strong which, besides requiring the computation of the vacuum polarization in strong-coupling, brings the question of the renormalization of the bound levels themselves (Lamb shift). This situation, however, is completely analogous to the problem of super-heavy nuclei in QED, and an extensive account of its particular features and difficulties can be found in Greiner et al., 1985.

C. From Single to Many Particle Interactions

Coupling to an external Coulomb field can be seen as the zero-th order approach to the full many body electron interactions in graphene. The decisive difference that leaves graphene apart from standard electronic systems is the existence of the supercritical region, which, for the Coulomb field, has the peculiarities discussed so far. Since the coupling constant in vacuum is $\alpha \approx 2$, one can justifiably ask whether supercritical effects carry to electrons interacting among themselves. After all, even if a simplification, from a reference frame moving with an electron the problem becomes an impurity one again.

1. Interacting Two Body problem

The two particle problem has traditionally provided valuable insights into the full many-body phenomena in condensed matter [e.g. the Cooper pairing (Cooper, 1956)]. The chiral nature of the electronic states, however, precludes the usual decoupling between center-of-mass and relative coordinates, except for $s$-states in a quiescent center-of-mass (Sabio et al., 2010b). Even so, these authors show that the supercritical collapse is a general effect present in the two body problem. In this case the critical coupling occurs at $\alpha_c = 1$ and $\alpha_c = 2.24$ for $s$ and $p$ channels, respectively. The interacting two-body problem usually encodes much of the physics that the many-body system displays. One example is the study of pairing, pair condensation, and other processes which are dominated by two particle channel events. This has a clear relation with the issue of spontaneous gap generation, discussed in Sec. III.B. The prospect of exact solution of the two particle problem would afford more controllable means to explore this instability in graphene.

2. Excitons and Spontaneous Mass Generation

It is noteworthy that the value $\alpha_c = 1$ quoted above is tantalizingly close to recent calculations of the critical coupling which precipitates a spontaneous mass generation and metal-insulator transition in undoped graphene. Those values range from $\alpha_c = 0.8$ (Vafek and Case, 2008), to $\alpha_c = 1.1$ obtained within Monte Carlo (Drut and Lähde, 2009b) or by using the Schwinger-Dyson equation (Klivshchekno, 2009). As described at length in Sec. III.B, this metal-insulator transition in graphene has been ascribed to the emergence of an excitonic instability beyond $\alpha_c$.

Recently the excitonic problem has been considered vis-a-vis the supercritical instability of the Coulomb center. Instabilities in the particle-hole channel appear at critical couplings consistent with the above (Gamayun et al., 2009; Wang et al., 2010). For example, Gamayun et al., 2009 show that solving the Bethe-Salpeter equation in graphene leads to instability-prone tachyonic states ($E^2 < 0$) at $\alpha_c = 1.6$. Such states are the analogue in the two channel many-body language of the quasi-bound resonances for supercritical impurities, and a glimmer of supercritical effects in the fully interacting problem.

D. Supercritical Physics in Experiments

The non-perturbative nature of supercritical Coulomb impurities, and the associated analytical difficulties, preclude unequivocal predictions regarding the possibility of crossing the supercritical threshold. Experimental investigation of this problem requires the ability to vary the strength of the Coulomb impurity and/or the electron-electron interactions. Control over the dielectric environment provides a handle to tune interactions and impurity strength at the same time, via selection of $\varepsilon$. Experiments in this vein have been performed by Jang et al., 2008 and Ponomarenko et al., 2009, showing that it is possible to controllably tune the value of $\varepsilon$ by exploring substrates with different dielectric properties. Variation of $Z$ is a more delicate issue. Chen et al., 2008 have devised a way to add monovalent ions to graphene via K-irradiation, in quantities that can be controlled...
with some precision. But exploration of the supercritical regime might require higher valences. For real impurities, the valence is determined by the nature of the impurity atom and the host system, and cannot be changed. One can, in principle, use ions of different valence, but here the difficulty lies in the fact that valences higher than \(Z = 2\) are very unlikely. One possible alternative to this constraint imposed by nature, would be to resort to sharp STM tips, whose strong local field could mimic a strong local charge. As mentioned in the beginning of this chapter, the experimental exploration/confirmation of the supercritical state would be rather important a milestone. Not only in understanding the physics of graphene, but because it would afford a glimpse to what might happen in the more fundamental QED situation.

V. STRONG CORRELATIONS IN GRAPHENE

A. Mass gaps in the honeycomb lattice

Graphene is a semi-metal (SM) with gapless quasiparticles. The Dirac points in graphene are protected by the combination of sublattice and translational symmetries of the honeycomb lattice. The point group symmetry of the honeycomb lattice, \(C_{6v}\), can be decomposed into the point group of the triangular sublattice and the \(Z_2\) sublattice symmetry group, \(C_{3v} \otimes Z_2\). Violation of sublattice symmetry leads to the opening of a mass gap in the Dirac Hamiltonian. This broken symmetry can be physically implemented either by the Semenoff gap (Semenoff, 1984), which is induced by a staggered scalar potential that breaks the sublattice inversion symmetry, as previously discussed in Eq. (3.40), or by the Haldane gap (Haldane, 1988), where there is an additional broken time reversal symmetry (TRS) induced by the inclusion of circulating current loops with zero magnetic flux per unit cell, corresponding to a staggered magnetic field. In particular, a system that breaks inversion and TRS is susceptible to a “parity” anomaly, where the application of an electric field generates a net axial current flowing between the two valleys in graphene (Jackiw, 1984).

In the presence of mirror symmetry along the \(z\)-axis, the spin-orbit interaction in graphene has the form (Kane and Mele, 2005)

\[
\mathcal{H}_{SO} = \Delta_{SO} \sum_{k,\sigma} \Psi_{k,\sigma}^\dagger \tau_0 \otimes \sigma_3 \otimes s_3 \Psi_{k,\sigma},
\]

(5.1)

where \(\Delta_{SO}\) is the spin orbit coupling gap, and \(s_3\) is the diagonal Pauli matrix in spin space. The other matrices follow the convention in the Dirac Hamiltonian (2.6). The spin-orbit interaction in graphene breaks the spin degeneracy in the valleys, giving rise to spin polarized currents that flow along the edge states of the system — a quantum spin Hall state (Kane and Mele, 2005). Although the spin orbit coupling gap in graphene is rather small, \(\Delta_{SO} \approx 10^{-3}\) meV, (Huertas-Hernando et al., 2006; Min et al., 2006; Yao et al., 2007), it can be drastically enhanced either by curvature effects (Huertas-Hernando et al., 2006), or by impurities (Castro Neto and Guinea, 2009). The spin-orbit coupling is also logarithmically enhanced by Coulomb interactions (Kane and Mele, 2005), as discussed in Sec. III.B. When the mirror symmetry is broken either by a substrate or external electric field, an additional Rashba term is allowed

\[
\mathcal{H}_R = \lambda_R \sum_{k,\sigma} \Psi_{k,\sigma}^\dagger \tau_3 \otimes (\sigma_1 \otimes s_2 - \sigma_2 \otimes s_1) \Psi_{k,\sigma},
\]

(5.2)

where \(\lambda_R > 0\) is the Rashba coupling. The induced gap is \(2(\Delta_{SO} - \lambda_R)\) for \(\lambda_R < \Delta_{SO}\), closing to zero when \(\lambda_R > \Delta_{SO}\) (Kane and Mele, 2005).

Kekule lattice distortions (Hou et al., 2007), which break the translational symmetry of the lattice, also lead to the opening of gaps in graphene, whereas lowering the rotational symmetry of the \(C_{3v}\) group, by stretching the honeycomb lattice in one direction, does not. In the presence of topological defects in the order parameter, such as vortices, the midgap states which are bounded to them allow the emergence of excitations with fractional statistics under vortex exchange (Chamon et al., 2008a,b; Hou et al., 2007; Seradjeh and Franz, 2008). In the superconducting case, the vortex core may sustain a quantum Hall state in the presence of a strong Zeeman coupling of the electrons with the magnetic field, which lifts the spin degeneracy (Herbut, 2010). In the most general case, where any spin, valley and pairing symmetries are allowed, 36 different types of instabilities that generate mass gaps in graphene have been classified (Ryu et al., 2009).

B. Charge and magnetic instabilities

Although no evidence of mass gaps has been found in graphene, numerical results have predicted a semi-metal-insulator (SM-I) transition in the presence of strong correlations. Quantum Monte Carlo (QMC) calculations on the Hubbard model for the honeycomb lattice at half filling predicted the opening of a Mott gap above the critical ratio \(U/t > 5\) (Martelo et al., 1997; Paiva et al., 2005; Sorella and Tosatti, 1992), where \(t \approx 2.8\) eV is the hopping energy and \(U\) is the on-site electronic repulsion. A more recent QMC calculation has found a gapped AF state at half filling for \(U/t > 4.3\), preceded by an intermediate coupling insulating phase for \(3.5 < U/t < 4.3\), which has been attributed to a gapped spin liquid state formed by short-range resonating valence bonds (Meng et al., 2010). An insulating antiferromagnetic (AF) ground state has been also predicted above \(U/t > 4\) (Furukawa, 2001; Martelo et al., 1997). Variational (Hanish et al., 1995) and mean field calculations (Peres et al., 2004) predicted the possibility of Nagaoka ferromagnetism (where the polarization is maximal) above a critical coupling both in the half filled and in the doped regimes. Although the validity of the Hub-
bord model in graphene may be questioned since it does not include long range Coulomb interactions, it could be in principle justified if one accounts for strong screening effect from a substrate which can deplete the long range part of the interactions (or also, perhaps, by accounting for dynamical screening effects from graphene itself (Reed et al., 2010)), leaving only the short-range part of the electron-electron interactions. The extent of validity of the Hubbard model in graphene is a subject of ongoing debate.

The bare spin polarization in graphene is a $2 \times 2$ tensor (Peres et al., 2004),

$$\Pi_{x,y}^{\pm}(q, \tau) = \langle S_{x}^{\pm}(q, \tau)S_{y}^{-}(q, 0) \rangle,$$  \hspace{1cm} (5.3)

where $S_{x}^{+}$ and $S_{x}^{-}$ are the spin raising and lowering operators in the two sublattices, $x = a, b$. Written in terms of the Green’s function (2.11) with additional spin labels,

$$\Pi_{x,y}^{(1)+}(q, i\omega) = -\frac{1}{4} \sum_{k,s,s' = \pm} A_{x,y}^{s}(k)A_{y,x}^{s'}(k + p) \times \frac{f \left[ E_{s',\uparrow}(k) \right] - f \left[ E_{s',\downarrow}(k + q) \right]}{i\omega + E_{s',\uparrow}(k) - E_{s',\downarrow}(k + q)},$$  \hspace{1cm} (5.4)

where $\hat{A}^{s} = 1 + sk \cdot \sigma / k$, and $E_{s,\sigma}(k) = sv |k| - \mu$ describes the two branches of the spectrum near the Dirac points. Since $\Pi_{a,a} = \Pi_{b,b}$ and $\Pi_{a,b} = \Pi_{b,a}$ by the honeycomb lattice symmetry, the eigenvalues of the spin polarization are $\Pi_{F/AF}^{(1)} = \Pi_{a,a}^{(1)} \pm \Pi_{b,b}^{(1)}$, which correspond to ferromagnetic (+) and AF (−) states. In RPA, the spin susceptibility is $\chi = \left[ 1 - U\Pi^{(1)} \right]^{-1}\Pi^{(1)}$, and the critical Hubbard coupling required for a divergence in the spin susceptibility in graphene is (Peres et al., 2004)

$$U_{c}^{F/AF} = \frac{1}{\Pi_{F/AF}^{(1)}(0)}.$$  \hspace{1cm} (5.5)

The ferromagnetic transition translates in the condition $U_{c}^{F} = 2 / \rho(\mu) \approx D^{2}/|\mu|$, which is the Stoner criterion, where $\rho(E)$ is the DOS and $D$ the band width. The AF transition occurs at $U_{c}^{AF} \approx D^{2}/(D - |\mu|)$.

The application of an in plane magnetic field, $B$, splits the spin degeneracy at the Dirac points, creating two Fermi surface (FS) pockets with opposite spins. Including the Zeeman coupling, $H_{B} = \sum_{k,\sigma} B_{k}^{\sigma}n_{k,\sigma}$ into the Hamiltonian, the spin polarized energy spectrum is $E_{s,\sigma}(k) = sv |k| + \sigma B - \mu$. The nesting between the two Fermi surface sheets can produce a logarithmic divergence in the spin polarization in the limit $|B| \gg \max(T, |\mu|)$ (Bercx et al., 2009),

$$\Pi_{AF}^{(1)}(0) \sim \rho(B) \ln \left( \frac{|B|}{\max(T, |\mu|)} \right).$$  \hspace{1cm} (5.6)

This instability brings the possibility of a canted AF state in graphene. In the presence of Landau level quantization due to the application of an out of plane magnetic field, electronic interactions may lead to the formation of quantum Hall ferromagnetic states at integer values of the filling factor (Nomura and MacDonald, 2006). The magnetic field has been also proposed as a source of a charge density wave (CDW) Peierls distortion in the zero Landau level in graphene, breaking the parity symmetry between the valleys (Fuchs and Lederer, 2007). For a discussion of interaction effects at strong magnetic fields, see sec. VIII.

For Dirac fermions in 2+1 dimensions, a CDW instability translates into the phenomenon of chiral symmetry breaking (CSB), with spontaneous generation of a mass term that breaks the sublattice symmetry. The AF state is favored by strong on site repulsion and competes with the long range part of the Coulomb field, which can favor either strong coupling ferromagnetism (Peres et al., 2004) or else excitonic CDW instabilities at strong coupling (Drut and Lähde, 2009a,b; Khveshchenko, 2001a,b; Khveshchenko and Leal, 2004; Liu et al., 2009).

At large $N$, with $N$ the number of fermionic flavors, the continuum limit of the Hubbard model in the honeycomb lattice falls in the universality class of the Gross-Neveu model (Gross and Neveu, 1974) for massless Dirac fermions in 2+1 dimensions, with four-fermion contact interactions. The extended version of this model accommodates the short range piece of the Coulomb interaction involving the repulsion between nearest neighbor sites, $V$ (Herbut, 2006). In addition to the Gaussian fixed point, which controls the semi-metal (SM) phase, the RG flow of the extended model was shown to be controlled by two other fixed points at large $N$: an AF fixed point, and a CDW fixed point, both unstable towards the Gaussian fixed point at weak coupling, and having a runaway direction to strong coupling when $U$ or $V$ are sufficiently large. The two fixed points compete, resulting in the phase diagram shown in Fig. 22. The fact that the AF fixed point has only one unstable direction to leading order in $1/N$ motivated the conjecture that the SM-I transition to the AF state is continuous and of the Gross Neveu type (Herbut, 2006). The symmetry analysis of the possible quartic terms has been discussed by Herbut et al., 2009.

The $1/N$ results were confirmed qualitatively by numerical renormalization group (NRG) calculations for
the extended Hubbard model in the honeycomb lattice (Raghu et al., 2008). In the presence of next-nearest neighbors repulsion, the NRG calculations suggested the possibility of competition between the CDW and spin density wave (SDW) phases with non-trivial topological insulating states, such as the quantum spin Hall (QSH) state, where TRS is spontaneously broken (Raghu et al., 2008). Functional renormalization group (FRG) calculations for the $t-J$ model on the honeycomb lattice with on site and nearest neighbor repulsion also suggested the possibility of strong coupling CDW and SDW instabilities in graphene at half filling (Honerkamp, 2008). In the doped regime, the $t-J$ model can favor the formation of superconducting states for $J > 2t$, either in the triplet or in the $d$-wave singlet channels (Honerkamp, 2008).

In the high doping regime, the proximity of the Fermi level to the Van-Hove singularities, where the graphene DOS diverges logarithmically, may favor a Pomeranchuck instability (PI), rather than a gapped state. In that case, the redistribution of the electronic density generates a deformation of the Fermi surface, which lowers the lattice $C_{3v}$ point group, instead of breaking the $Z_2$ sublattice symmetry. In the extended Hubbard model at high doping, the PI is favored by the repulsion between nearest neighbor sites, which renormalizes the kinetic energy at the mean field level, and competes with the on-site repulsion, which favors a ferromagnetic state when the Stoner criterion is satisfied (Valenzuela and Vozmediano, 2008).

When coated with metallic atoms that have a strong tendency to hybridize with the carbon $p_z$ orbitals, graphene can induce strong itinerant ferromagnetism in the metallic bands (Uchoa et al., 2008b).

C. Local magnetic moments

For massless Dirac particles, the formation of localized states is usually harder than in usual Fermi systems due to the Klein paradox, in which the fermions can easily tunnel through a barrier regardless of its height. Defects such as vacancies, where a carbon atom is knocked out from the plane, have been shown to generate localized states in graphene (Pereira et al., 2006; Vozmediano et al., 2005), and were recently observed in STM experiments (Ugeda et al., 2010). Vacancies have also been found to host local magnetic states (Chen et al., 2011; Yazyev and Helm, 2007).

Short range interacting impurities can generate local resonances, which are quasi-localized states. At half-filling, the energy of the resonance, $\varepsilon_0$, is given by (Skrypnyk and Loktev, 2006; Wehling et al., 2007)

$$U_0 = \frac{D^2}{\varepsilon_0 \ln \left| \varepsilon_0^2 / (D^2 - \varepsilon_0^2) \right|},$$

where $U_0$ is the scattering potential of the impurity and $D$ is the bandwidth. The resonance induces accumulation of LDOS at the Fermi level around the impurity, $\rho(r, \omega)$, which decays as $1/r$ (Bena and Kivelson, 2006), whereas the Friedel oscillations decay as $1/r^2$ for intracone scattering and as $1/r$ for intercone scattering (Bena, 2008).

Besides defects, zigzag edges also lead to local magnetism in the presence of interactions (for a more detailed discussion, see Sec. VI). In bulk graphene, a simple way to generate localized magnetic states is provided by the adsorption of adatoms with inner shell electrons. On the lattice, the adatoms can stay in different locations relative to the two sublattices in graphene. Transition metals are usually more stable sitting in the hollow site, at the center of the honeycomb hexagon (Chan et al., 2008), whereas simple molecules and atoms such as hydrogen (H) tend to hybridize more strongly with the carbons, sitting on top of them and generating a large local moment (Yazyev and Helm, 2007). In particular, H adsorption creates a midgap state (Boukhvalov et al., 2008; Wehling et al., 2010c) and distorts locally the $sp^2$ carbon bonds, which acquire $sp^3$ character (Elias et al., 2009). This distortion can induce a strong local enhancement of the spin-orbit coupling up to $\approx 7$ meV, as in diamond, and generate a strong local magnetic anisotropy (Castro Neto and Guinea, 2009). Adatoms can also form local moments from substitutional defects on single and double vacancies in graphene (Krasheninnikov et al., 2009; Venezuela et al., 2009).

The heuristic criterion that describes the formation of a local magnetic moment is addressed at the mean field level by the Anderson impurity model (Anderson, 1961). In the top carbon case, assuming that the adatom sits on a carbon (see Fig. 23), say on sublattice $B$, the hybridization Hamiltonian is $H_V = V \sum_\sigma[ f^\dagger_\sigma b_\sigma(0) + h.c.]$, where $f_\sigma$ ($f^\dagger_\sigma$) annihilates (creates) an electron with spin $\sigma = \uparrow, \downarrow$ at the impurity. In momentum space, this translates into:

$$H_V = V \sum_{p, \sigma} (f^\dagger_{p, \sigma} b_{p, \sigma} + f^\dagger_{p, -\sigma} f_{p, \sigma}).$$

If $n_\sigma = \langle f^\dagger_{p, \sigma} f_{p, \sigma} \rangle$ is the occupation of the localized level for

![FIG. 23 (color on line) (a) Honeycomb lattice with an impurity atom. Black: sublattice A; White: sublattice B. Intersection of the Dirac cone spectrum, $E(k) = \pm v|k|$, with the localized level $E_I = \varepsilon_0$: (b) $\varepsilon_0 > 0$, (c) $\varepsilon_0 < 0$.](image-url)
a given spin, the effective Hamiltonian of the level is
\[ \mathcal{H}_f = \sum_{\sigma} \varepsilon_{\sigma} f_\sigma^{\dagger} f_\sigma, \]  
(5.9)
with \( \varepsilon_{\sigma} = \varepsilon_0 + U n_{-\sigma} \), after a proper mean field decomposition of the Hubbard term \( H_U = U f_\uparrow^{\dagger} f_\uparrow f_\downarrow^{\dagger} f_\downarrow \), which accounts for the charging energy \( U \) to doubly occupy the level. The hybridized level becomes magnetic when \( n_f \neq n_i \). The occupation is derived self-consistently by integrating the \( f \)-electron DOS from the bottom of the graphene band up to the Fermi level \( \mu \),
\[ n_{\sigma} = -\frac{1}{\pi} \text{Im} \int_{-\infty}^{\mu} \frac{d\omega}{\omega - \varepsilon_{\sigma} - \Sigma_{ff}(\omega)}, \]  
(5.10)
where \( \Sigma_{ff}(\omega) \) is the self-energy of the localized electrons. In the cone approximation of the spectrum in graphene, for the top carbon case,
\[ \Sigma_{ff}(\omega) = \omega \left[ 1 - Z^{-1}(\omega) \right] - i \Delta |\omega| \theta(D - |\omega|), \]  
(5.11)
where \( \Delta = \pi V^2 / D^2 \) is the dimensionless hybridization, \( D \) is the effective band width, and
\[ Z^{-1}(\omega) = 1 + \frac{V^2}{D^2} \ln \left| 1 - \frac{D}{\omega^2} \right| \]  
(5.12)
gives the quasiparticle residue, \( Z(\omega) \), which vanishes logarithmically at the Dirac points (\( \omega \to 0 \)).

Because of the vanishing DOS, the level broadening [given by \( \text{Im} \Sigma_{ff}(\omega) \)] scales linearly with the energy around the Dirac points (González-Buxton and Ingersent, 1998; Skrypnyk and Loktev, 2006; Uchoa et al., 2008a; Zhang et al., 2001). The DOS induced around the bare level, \( \varepsilon_{\sigma} \), does not decay like a Lorentzian as in usual metals, but shows a long tail proportional to \( 1/\omega \). This tail induces several peculiar features in the magnetic states. For instance, a local moment is allowed to exist when the bare level is empty (\( \varepsilon_0 < \mu \)) or doubly occupied (\( \varepsilon_0 + U > \mu \)) (see Fig. 24). The presence of the Dirac point also breaks the symmetry around the line \( \mu - \varepsilon_0 = U/2 \), and makes the scaling of the curves shown in Fig. 24 non-universal. Furthermore, there is a physical asymmetry between the cases where the level is above (\( \varepsilon_0 > 0 \)) or below (\( \varepsilon_0 < 0 \)) the Dirac point. When \( \varepsilon_0 = 0 \), as in the case of a vacancy, the level decouples from the bath and becomes magnetic for any \( \mu > 0 \), regardless of the value of \( U \) (Pereira et al., 2006; Uchoa et al., 2008a).

Since the chemical potential in graphene can be tuned, the formation of local magnetic states can be controlled by the application of a gate voltage (Uchoa et al., 2008a). The low density of states around the localized level also makes the formation of local moments in graphene much easier than in usual metallic hosts. As a result the adatoms can achieve high magnetic moments at relatively small \( U \) (Cornaglia et al., 2009; Uchoa et al., 2008a).

The formation of local moments is also affected by the specific location of the adatom in the lattice (Fig. 25). For instance, when the adatom sits in the center of the honeycomb hexagon (\( H \)-site), the tight-binding hybridization Hamiltonian is (Uchoa et al., 2009)
\[ H_V = \sum_{\sigma,i} \left[ V_{a,i} a^{\dagger}_{\sigma} (\mathbf{a}_i) + V_{b,i} b^{\dagger}_{\sigma} (-\mathbf{a}_i) \right] f_\sigma(0) + \text{h.c.}, \]  
(5.13)
where \( \mathbf{a}_i \) (\( i = 1, 2, 3 \)) are the three nearest neighbor vectors of the honeycomb lattice, and \( V_{x,i} \) (\( x = a, b \)) is the hybridization strength of the adatom with each of the nearest surrounding carbon atoms. In momentum representation,
\[ H_V = \sum_{\sigma,\mathbf{p}} \left( V_{x,\mathbf{p},\sigma} a^{\dagger}_{\mathbf{p}\sigma} + V_{b,\mathbf{p},\sigma} b^{\dagger}_{\mathbf{p}\sigma} \right) f_\sigma + \text{h.c.}, \]  
(5.14)
where
\[ V_{x,\mathbf{p}} = \sum_{i=1}^{3} V_{x,i} e^{i\mathbf{p}\cdot\mathbf{a}_i}. \]  
(5.15)
The top carbon case is recovered by setting \( V_{a,\mathbf{p}} \equiv V \) and \( V_{b,\mathbf{p}} = 0 \) or vice-versa. For \( s \)-wave orbitals, \( V_{x,i} \equiv V \), whereas for in-plane \( f \)-wave orbitals the hybridization is anti-symmetric in the two sublattices, \( V_{a,i} = -V_{b,i} \equiv V \). In the case of substitutional impurities (\( S \)-sites), either \( V_{a,i} = 0 \) or \( V_{b,i} = 0 \). The quantum interference between the different hybridization paths of the electrons can modify the energy scaling of the level broadening in Eq. (5.11) (Uchoa et al., 2009), and can also change the shape of the Fano resonances in scanning tunneling spectroscopy (STS) measurements, allowing a clear identification of the adatom position with an STS tip (Saha et al., 2010; Uchoa et al., 2009; Wehling et al., 2010b).
D. Kondo effect

The formation of a Kondo screening cloud around a magnetic moment is described by the Anderson Hamiltonian (5.8) in the strong coupling limit, $U \to \infty$, where the valence fluctuations are suppressed and the local moment becomes a good quantum number. In the standard mean field approach, the spin 1/2 fermionic fields are replaced by fermionic fields with larger degeneracy, $N > m$, which corresponds to an SU($N$) extension of the problem, with a corresponding Kondo Hamiltonian (Coqblin and Schrieffer, 1969)

$$\mathcal{H}_K = J_K \sum_{m m'} \sum_{k k'} \psi_{k m}^\dagger f_{m}^\dagger \psi_{k', m'},$$

(5.16)

where $J_K \sim V^2/|\varepsilon_0 - \mu|$ is the Kondo coupling, $\psi_m$ ($\psi_m^\dagger$) are annihilation (creation) operators of the itinerant electrons, and the local $f$ fields are constrained to a fixed occupancy. At the mean field level, which is asymptotically exact at large $N$, the Kondo order parameter can be extracted either from the standard slave boson approach to the Anderson model (Coleman, 1983; Newns and Read, 1987), or else by an equivalent path integral approach starting from the Kondo Hamiltonian (5.16) (Read and Newns, 1983).

The application of these methods to semi-metals with a vanishing DOS, $\rho(\omega) = \rho_0 |\omega|^r$, with $r > 0$, resulted in the prediction of a Kondo quantum critical point (QCP) at half-filling ($\mu = 0$). In that case, a Kondo cloud is expected for $J_K > J_K^c = r/(\rho_0 D^r)$, below the Kondo temperature (Withhoff and Fradkin, 1990)

$$T_K \approx |J_K - J_K^c|^r,$$

(5.17)

where $\nu = 1/r$, and $D$ is the ultraviolet cut-off. Since the scaling dimension of the hybridization $V$ in the Anderson model is $\dim[V] = (1 - r)/2$, the case $r = 1$ acts as an upper critical scaling dimension in the problem, where the scaling is marginal (Vojta and Fritz, 2004). In the marginal case, the Kondo temperature may have an additional logarithmic scaling with the coupling, upon implementation of an ultraviolet cut-off smoothly connected to the metallic case ($r = 0$) (Cassanello and Fradkin, 1996). Away from half-filling, there is a crossover to the usual

Fermi liquid case in the weak coupling regime, $J_K < J_K^*$, where (Withhoff and Fradkin, 1990)

$$T_K \approx \mu \exp[r^{-1} (D/\mu)^r (1 - J_K^c/J_K) - 1/r].$$

(5.18)

Further studies based on NRG techniques (Fritz and Vojta, 2004; González-Buxton and Ingersent, 1998; Vojta, 2001) predicted a variety of fixed points. At half-filling, in the particle-hole symmetric case, $\varepsilon_0 = -U/2$, the Kondo problem has a metallic Kondo screened fixed point at $r = 0$, which evolves into a strong coupling fixed point for $0 < r < 1/2$. In this case, the strong ($J_K > J_K^c$) and weak coupling ($J_K < J_K^c$) regimes are separated by a symmetric quantum critical point (SCP), whereas for $r > 1/2$ the local moment remains unscreened for all initial values of the Kondo coupling (Chen and Jayaprakash, 1995). In the particle-hole asymmetric case ($\mu = 0$, $U \neq -2\varepsilon_0$), for $r > r^* \approx 0.375$, the weak and strong coupling regimes are separated by an asymmetric critical point (ACP). For $r < r^*$, the particle-hole symmetry is dynamically restored (Fritz and Vojta, 2004; González-Buxton and Ingersent, 1998).

The phase diagram around the QCP is schematically shown in Fig. 26. The critical local moment fluctuations were studied by Ingersent and Si, 2002, who found linear $\omega/T$ scaling of the dynamical spin susceptibility at the critical point for $0 < r < 1$. In the marginal case, $r = 1$, there are logarithmic corrections to scaling (Cassanello and Fradkin, 1997). The Kondo problem for gapless excitations was also extensively studied in the context of magnetic impurities in $d$-wave superconductors (Borkowski and Hirschfeld, 1992; Cassanello and Fradkin, 1996, 1997; Polkovnikov, 2002; Polkovnikov et al., 2001; Vojta and Bulla, 2001; Zhang et al., 2001; Zhu and Ting, 2000). For a review, see Balatsky et al., 2006.

In the graphene case, where $r = 1$, the Dirac fermions in the bath have an additional pseudospin structure, which motivated several proposals for multichannel Kondo physics (Cassanello and Fradkin, 1996; Dell’Anna, 2010; Sengupta and Baskaran, 2008; Zhu et al., 2010). The Kondo resonance in graphene has been calculated with NRG by Cornaglia et al., 2009.

FIG. 26 Schematic phase diagram around the Kondo QCP at half filling: temperature vs Kondo coupling. LM: local moment phase, where the Kondo cloud is suppressed. In the critical LM phase, quantum critical fluctuations dominate (Ingersent and Si, 2002).

FIG. 25 Two adatom configurations in graphene: a) the adatom (red circle) sits on top of a carbon atom, and b) the adatom (blue circle) sits at the center of the honeycomb hexagon, hybridizing equally with the two sublattices. Red arrows: nearest neighbor vectors.
At half filling, the local DOS around the impurity can be spontaneously enhanced by the formation of midgap states due to the scattering potential of the impurity (Hentschel and Guinea, 2007), frustrating the Kondo QCP.

At finite doping, the Kondo temperature has an exponential dependence with the DOS at weak coupling, allowing the Kondo cloud to be tuned by gating (Sengupta and Baskaran, 2008). In the crossover regime, at \( J = J_c \), the scaling of the Kondo temperature with doping becomes power law, \( T_K \propto |\mu|^x \). Recent NRG calculations in graphene have found a particle-hole asymmetric scaling of the Kondo temperature with doping, \( T_K \propto |\mu|^x \), where \( x = 1 \) for \( \mu > 0 \) and \( x = 2.6 \) for \( \mu < 0 \) (Vojta et al., 2010), in contradiction with the mean field and poor man scaling analysis for the marginal case (Vojta et al., 2010). In the presence of Landau level quantization, the Kondo temperature has reentrant behavior as a function of the chemical potential (Dora and Thalmeier, 2007).

Looking at the problem on the lattice, ab initio calculations on Cobalt have found that the interplay of spin and orbital degrees of freedom can give rise to an SU(4) Kondo effect in graphene when the spin orbit coupling is strong enough (Wehling et al., 2010a). Another ab initio calculation accounting for dynamic correlations, also on Co, has identified the possibility of a spin 3 \( ^1S_0 \) Kondo regime (Wehling et al., 2010b). From a tight-binding perspective, for a spin 1/2 impurity, the hybridization Hamiltonian (5.14) can be written in the diagonal basis

\[
\mathcal{H}_V = V \sum_{\alpha = \pm} \sum_{p, \sigma} \left[ \Theta_{\alpha, p} c_{\alpha, p, \sigma}^\dagger f_\sigma + \text{h.c.} \right],
\]

(5.19)

where \( c_{\pm, k \sigma} = (1/\sqrt{2})[b_{k \sigma} \pm (\phi_k^e/|\phi_k|)a_{k \sigma}] \) are the fermionic operators that diagonalize the graphene Hamiltonian (2.2), \( \phi_k = \sum_{\sigma = \pm} \epsilon_{p, \sigma} \alpha_{\sigma, k} \) is the tight-binding hopping matrix element defined by Eq. (2.3), and \( \alpha = \pm \) labels the conduction and valence bands. \( \Theta \) is a phase factor, which accounts for the symmetry and position of the localized orbital with respect to the sublattices (Uchoa et al., 2009),

\[
\Theta_{\alpha, p} = \frac{1}{\sqrt{2V}} \left( V_{k, p} + \alpha V_{p, k}^* \phi_p^e / \phi_p \right),
\]

(5.20)

where \( V_{x, p} \) is the hybridization as defined in Eq. (5.15).

As in metals, the Anderson Hamiltonian in graphene can be mapped onto the spin exchange Hamiltonian by a canonical transformation (Schrieffer and Wolff, 1966). In the large \( U \) limit, the spin exchange Hamiltonian between the magnetic adatom and the graphene electrons is (Uchoa et al., 2011)

\[
\mathcal{H}_e = -J \sum_{k k'} \sum_{\alpha \alpha'} \Theta_{\alpha, k} \Theta_{\alpha', k'} S \cdot c_{\alpha', k'}^\dagger c_{\alpha, k}^\dagger \sigma \Sigma_{\alpha, \sigma},
\]

(5.21)

where \( \sigma = (\sigma_1, \sigma_2, \sigma_3) \) are the Pauli matrices, \( S = \frac{1}{2} f_a^\dagger f_b \) is the localized spin, and

\[
J(\mu) \approx \frac{V^2 U}{(\varepsilon_0 - \mu)(\varepsilon_0 + U - \mu)} < 0,
\]

(5.22)

is the exchange coupling defined at the Fermi level, \( \mu \). Within the tight-binding description, we realize that the determinant of the exchange coupling matrix in Eq. (5.21) is identically zero, \( \det[J_{\alpha \alpha'}] = 0 \), and hence the exchange Hamiltonian (5.21) can be rotated into a new basis where one of the hybridization channels is decoupled from the bath (Pustilnik and Glazman, 2001). The eigenvalues in the new diagonal basis are \( J_{u, k, k'} = J \sum_{\alpha} \Theta_{u, k} \Theta_{\alpha, k'} \) and \( J_v = 0 \), implying that the one-level exchange Hamiltonian (5.21) maps into the problem of a single channel Kondo Hamiltonian, \( \mathcal{H}_e = -2 \sum_{k, k} J_{u, k, k} S \cdot s_{k, k'} \), where \( s \) is the itinerant spin, in spite of the implicit valley degeneracy. A multi-channel description of the one-level problem is nevertheless possible for example in graphene quantum dots, in the continuum limit, where valley and angular momentum channels become good quantum numbers.

Unlike the situation in metals, the exchange coupling in graphene can be controlled by gating (Jacob and Kotliar, 2010; Uchoa et al., 2011), as shown in Fig. 27, in particular when the chemical potential is brought to the proximity of the localized level, where the Kondo coupling becomes resonant. This effect opens the possibility of tuning \( J \) to the vicinity of the critical coupling that sets the crossover between the weak and strong coupling regimes. In this region, at finite doping, quantum criticality is reminiscent of the frustrated QCP at \( \mu = 0 \). Since the width of the Kondo peak in the spectral function is set by the Kondo temperature only, the gating effect permits measuring the quantum critical scaling of the Kondo temperature with doping (Uchoa et al., 2011; Vojta et al., 2010) directly with STM probes (Saha et al., 2010; Uchoa et al., 2009; Wehling et al., 2010b; Zhuang et al., 2009).
E. RKKY interaction

The Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction between two local spins is obtained by integrating out the itinerant fermions in Eq. (5.21), which gives

\[ \mathcal{H}_{\text{RKKY}} = -J^2 \chi_{ij} S_i \cdot S_j, \]

where \( \chi_{ij} \) is a two point correlation function, with \( i, j \) indexing the positions of the local spins. In momentum space (Brey et al., 2007; Saremi, 2007; Uchoa et al., 2011),

\[ \chi^{xy}(q) = \sum_{k, \alpha} \mathcal{M}_{k, q}^{xy} \frac{f[E_{\alpha}(k+q)] - f[E_{\alpha}(k)]}{E_{\alpha}(k) - E_{\alpha}(k+q)}, \]

where (omitting the \( \alpha' \) labels for simplicity)

\[ \mathcal{M}_{k, q}^{xy} = \Theta_{\alpha, k}^{x} \Theta_{\alpha', k+q}^{y} \Theta_{\alpha', k+q}^{x} \Theta_{\alpha, k}^{y}, \]

(5.23)

with \( x, y = A, B, H, S \) etc, indexing the position of the spins on the lattice, \( E_{\alpha}(k) = \alpha/|k| - \mu \), and \( f \) is the Fermi distribution. \( \mathcal{M}_{k, q}^{AA} = \mathcal{M}_{k, q}^{BB} = 1/4 \) for spins on the same sublattice whereas

\[ \mathcal{M}_{k, q}^{AB} = \frac{1}{4} \alpha' x^{\phi}_{k} x^{\phi}_{k+q}, \]

(5.25)

for spins on opposite sublattices. In the continuum limit, where the spectrum is linearized around the Dirac points, \( \mathcal{M}_{k, q}^{AB} = \frac{1}{4} \alpha' e^{i \theta_{k+q}} \), where \( \theta \) is the angle between \( k \) and \( k + q \) (Brey et al., 2007).

At half-filling, \( k_F = 0 \), the Fermi surface collapses into points and the RKKY interaction is mediated by interband transitions, which polarize the vacuum as in QED. In this case, the Friedel oscillations disappear and the sign of the interaction is ferromagnetic for spins on the same sublattice and anti-ferromagnetic for spins in opposite sublattices (Brey et al., 2007; Saremi, 2007). In the overdoped regime, at \( \mu = t \), the nesting among the Van Hove singularities in graphene reverses the sign of the RKKY interaction compared to the \( \mu = 0 \) case (Uchoa et al., 2011).

At long distances, the spatial decay of the RKKY is \( r^{-3} \) when \( \mu \) is at the neutrality point (Brey et al., 2007; Cheianov and Fal’ko, 2006; Saremi, 2007; Vozmediano et al., 2005; Wunsch et al., 2007). Away from half filling, the Friedel oscillations are restored by the intraband transitions and the RKKY interaction decays at \( r \gg 1/k_F \) as \( 1/r^2 \), similarly to the 2DEG case (Brey et al., 2007; Wunsch et al., 2007). For \( H \) or \( S \) site spins formed in \( C_{3v} \) symmetric orbitals, the RKKY interaction decays with a fast power law \( 1/r^4 \) at half filling (Uchoa et al., 2011). In carbon nanotubes, the RKKY interaction decays as \( 1/r \) for top carbon spins and as \( 1/r^3 \) for \( H \) site spins in isotropic orbitals (Kirwan et al., 2008).

When distributed regularly on top of graphene, magnetic adatoms such as hydrogen (H) can form macroscopic magnetic states at room temperature (Zhou et al., 2009). In the disordered case, H atoms in particular can cluster on top of graphene due to rippling. On top of a ripple, the \( sp^2 \) carbon (C) bonds are spontaneously stretched by the curvature and acquire \( sp^3 \) character. Contrary to the perfectly flat case, the adsorption of H atoms on top of the hills helps to stabilize the ripples (Boukhvalov and Katsnelson, 2009). The interplay between the correlations due to the ripples and the RKKY interaction among the H spins can generate magnetoresistance hysteresis loops and a variety of magnetic spin textures (Rappoport et al., 2009).

F. Superconductivity

The observation of proximity induced superconductivity in graphene junctions has stirred a lot of excitement in the field of mesoscopics (Heersche et al., 2007). The Dirac nature of the quasiparticles gives rise to ballistic transport on a micron scale and allows graphene to sustain supercurrents in long junctions, the size of the coherence length in the superconducting metallic leads (Du et al., 2008; Heersche et al., 2007; Miao et al., 2007; Ojeda-Aristizabal et al., 2009). The experimental realization of the proximity effect motivated theoretical studies of the differential conductance (DC) in normal-superconductor (NS) interfaces in graphene (Beenakker, 2006; Burset et al., 2008), graphene nanoribbons (Rainis et al., 2009), and in graphene normal-insulator-superconductor (NIS) junctions (Bhattacharjee and Sengupta, 2006). Due to the Dirac nature of the spectrum, at half-filling, the Andreev conversion of an electron into an hole at the interface between a normal and a superconducting region involves specular reflection rather than retro reflection (Beenakker, 2006). The specular Andreev reflection leads to the presence of Andreev modes in SNS junctions that propagate along the graphene edges at the interface with the superconductor (Titov et al., 2007). The Josephson current in graphene SNS junctions was studied by Titov and Beenakker, 2006, followed by Bergman and Hur, 2009; Maiti and Sengupta, 2007; Moghaddam and Zareyan, 2006, and Black-Schaffer and Doniach, 2008. Possible applications involving the proximity effect in graphene include proposals for valley sensors (Akhmerov and Beenakker, 2007), current switches (Linder et al., 2008; Lutchyn et al., 2008), and a spin current filter (Greenbaum et al., 2007). A review on Andreev and Klein tunneling processes in graphene can be found in Beenakker, 2008.

These experimental developments in transport motivated a surge of interest in the possibility of making graphene an intrinsic superconductor. Graphene parent compounds, such as the graphite intercalated materials CaC\(_2\) and KC\(_8\), are low temperature superconductors, although neither graphite nor alkaline metals alone superconduct (Csanyi et al., 2005; Hamay et al., 1965; Weller et al., 2005). Even though intrinsic superconductivity has not been observed in the single
Regarding the microscopic origin, the superconducting state in graphene can be analyzed based on the symmetries of the order parameter in the honeycomb lattice. On the lattice, the electrons in graphene carry spin, angular momentum and sublattice quantum numbers. There are four possible pairing channels: singlet/triplet spin channels, and same/opposite sublattices. In the singlet case, if we restrict the analysis to nearest neighbor site interactions only, two competing order parameters can be identified:

\[\Delta_0 = g_0 \langle a_{i \uparrow} a_{j \downarrow} \rangle = g_0 \langle b_{i \uparrow} b_{j \downarrow} \rangle, \]

which corresponds to an \(s\)-wave state, and \(\Delta_1\), defined as

\[\Delta_{1,ij} = g_1 \langle a_{i \uparrow} b_{j \downarrow} - a_{i \downarrow} b_{j \uparrow} \rangle \]

for nearest neighbors and zero otherwise, where \(g_0\) and \(g_1\) are the coupling strengths. In momentum space, the latter state is described by

\[\Delta_{1,k} = \sum_{i=1}^{3} \Delta_{1,i} e^{i \mathbf{a}_i \cdot \mathbf{k}}, \]

where \(\Delta_{1,i} \equiv \Delta_1 (\mathbf{a}_i)\) are the real space pairing amplitudes along the three different bond directions in the honeycomb lattice (see Fig. 28). In the simplest case the pairing amplitudes are the same, \(\Delta_{1,i} = \Delta_1\), and \(\Delta_1\) is real, giving

\[\Delta_{1,k} = \Delta_1 \phi_k, \]

where \(\phi_k = \sum_{i=1}^{3} e^{i \mathbf{k} \cdot \mathbf{a}_i}\), gives the hopping matrix element in the single particle tight-binding spectrum (Uchoa and Castro Neto, 2007). This order parameter represents the pairing between electronic states in opposite sides of the BZ, and preserves all the physical symmetries of the honeycomb lattice, including point group and time-reversal symmetry, \(\Delta_{1,k} = \Delta_{1,-k}^*\), where the momentum \(\mathbf{k}\) is measured with respect to the center of the BZ, at the \(\Gamma\) point. In real space, this order parameter (OP) has extended \(s\)-wave symmetry. If expanded around the Fermi surface centered at the Dirac point \(\mathbf{K}\), from the perspective of the quasiparticle excitations near the Fermi level,

\[\Delta_{1,K+p} = \Delta_1 e^{i \theta} (p_x + ip_y) \]

describes a \(p + ip\) state in one valley and \(p - ip\) in the opposite one (Uchoa and Castro Neto, 2007). This state is therefore a \(p + ip\) state with additional valley degeneracy. Unlike the case of conventional \(p + ip\) superconductivity, the time reversal operation involves an additional exchange of valleys, preserving the TRS of this state, and we shall refer to it as \(p + ip\).

Another possible paring symmetry is the state (Black-Schaffer and Doniach, 2007; Jiang et al., 2008)

\[\Delta_{1,j} = \Delta_1 e^{(2\pi/3)j}, \]

FIG. 28 Superconducting order parameter \(\Delta_{1,j} = \Delta_1 e^{i \theta_j}\) (\(j = 1, 2, 3\)), with phases along the three different bond directions in the lattice.

layer so far, a few different superconducting mechanisms have been proposed. One possibility is a plasmon mediated mechanism in graphene coated with metallic adatoms, in which the plasmons of the metallic band mediate the attraction between the graphene electrons (Uchoa and Castro Neto, 2007). When isolated islands of metallic atoms are adsorbed on top of graphene, superconductivity can also be induced by proximity effect (Feigel’man et al., 2008). Another possibility is the Kohn-Luttinger mechanism, which explores the proximity of the Fermi surface to the Van-Hove singularities in the high doping regime (Kohn and Luttinger, 1965). In this scenario, the superconductivity can be mediated by a purely electronic mechanism, when the interactions become attractive along a specific direction of the BZ near the Van-Hove singularity (González, 2008). The superconductivity can also be mediated by in plane or out of plane flexural phonons (Lozovik and Sokolik, 2010). In graphene, strong doping regimes can be currently achieved by chemical adsorption of alkaline metals, such as potassium (Grüneis et al., 2009; McChesney et al., 2010; Uchoa et al., 2008b), or with metal contacts (Giovannetti et al., 2008).

Alternative proposals include edge state superconductivity, induced by the large DOS at the edges (Sasakia et al., 2007), or strong correlations, which so far have not been observed in graphene. As in the cuprates, the antiferromagnetic attraction between spin singlets on nearest neighbor sites has been proposed as a possible pairing channel in graphene, provided the on site Hubbard repulsion is strong enough to suppress the local fluctuations (Pathak et al., 2010). González et al., 2001 considered the possible competition between ferromagnetic and superconducting states in graphene sheets through a renormalization group analysis accounting for Coulomb interactions. A recent functional renormalization group calculation has proposed the possibility of a strongly correlated SDW state that gives way to a singlet superconducting instability in the \(d\)-wave channel, or else a CDW solution that allows a triplet pairing instability in the \(f\)-wave channel (Honerkamp, 2008). In two-layer graphene, the possibility of excitonic pairing of electrons in one layer with holes in the other one has been considered (Kharitonov and Efetov, 2008; Min et al., 2008).
$j = 1, 2, 3$, which describes on the lattice a real space pairing wavefunction with $d_{x^2-y^2} + id_{xy}$-wave symmetry, breaking TRS. This broken symmetry is caused by the circulation of plaquette current loops, which amounts to global circulation along the edges. The low energy description of this state around the Dirac points is a combination of $s$-wave in one valley and $p + ip$ state in the opposite valley (Jiang et al., 2008), as shown in Fig. 29. At the mean field level, this state was shown to have lower energy than the pure $p + ip$ state (Black-Schaffer and Doniach, 2007). Due to the broken TRS, disorder and quantum fluctuations, which are paramount in a 2D system, may strongly inhibit the coherence of the $d + id$ state. Other alternatives are the degenerate states with $d_{x^2-y^2}$ and $d_{xy}$-wave symmetries, represented by the $\Delta_{1, i}$ pairing amplitudes $(2, -1, -1)$ and $(0, 1, -1)$, respectively (Black-Schaffer and Doniach, 2007). These states conserve TRS but lower the crystal point group symmetry.

In the spin triplet channel, the OP is a superposition of $S_z = -1, 0, +1$ states. Since on-site pairing is forbidden by the Pauli principle, for nearest neighbors interaction the triplet superconducting states are $\Delta_{i, \sigma \sigma} = \langle a_{i\sigma} b_{j\sigma} \rangle$, with $\sigma = \uparrow, \downarrow$ for $S_z = \pm 1$, and $\Delta_0 = \langle a_{i\uparrow} b_{j\downarrow} + a_{i\downarrow} b_{j\uparrow} \rangle$, in the $S_z = 0$ channel. The OP in this case is commonly defined as a $2 \times 2$ tensor,

$$\Delta_{ij} = i\sigma_2 \sigma \cdot d_{ij}, \quad (5.32)$$

where the Pauli matrices act in spin space, and $d_{ij} = -d_{ji}$ is an anti-symmetric tensor, violating parity. The case where the OP $d$ has a single vector component describes the spinless fermionic case, discussed by Bergman and Hur, 2009. The possibility of spin triplet states beyond nearest neighbors in the $S_z = 0$ channel was recently examined in a variational cluster approximation calculation (Sahebsara and Sénchal, 2009). Another possibility is a Kekule superconducting state in the triplet channel, which breaks the translational symmetry of the lattice and allows the presence of topological excitations (Roy and Herbut, 2010).

At the level of nearest neighbor sites, the electron-electron interaction can be decomposed into an effective local Hubbard term,

$$H^0_j = \frac{g_0}{2} \sum_{i\sigma} \left( a_{i\sigma}^\dagger a_{i\sigma} a_{i+\sigma}^\dagger a_{i-\sigma} + b_{i\sigma}^\dagger b_{i\sigma} b_{i+\sigma}^\dagger b_{i-\sigma} \right), \quad (5.33)$$

and a non-local part,

$$H^1_j = g_1 \sum_{\langle ij \rangle \sigma} a_{i\sigma}^\dagger a_{i\sigma} b_{j\sigma}^\dagger b_{j\sigma}, \quad (5.34)$$

In the singlet pairing channel, the non-local term can be decomposed into $H^1_j = g_1 \sum_{\langle ij \rangle} \left( -B_{ij}^\dagger D_{ij} + D_{ij}^\dagger B_{ij} \right)$, plus one body terms that can be absorbed into the chemical potential $\mu$. $D_{ij} = a_{i\sigma}^\dagger b_{j\sigma} - a_{i\sigma} b_{j\sigma}$ is a standard singlet pair operator and $B_{ij} = \sum_{\sigma} a_{i\sigma}^\dagger b_{j\sigma}$ is a bond operator. Decomposition of the interaction at the mean field level with $\langle B_{ij} \rangle = 0$ results in the graphene tight-binding Hamiltonian for the superconducting phase, $\hat{H} = \sum_k \Psi^\dagger_k \hat{H}^S_k \Psi_k + E_0$, where

$$E_0 = -|\Delta_0|^2 / g_0 - 3\Delta_1^2 / g_1, \quad (5.35)$$

and

$$\hat{H}_k^S = \begin{pmatrix} -\mu & -t\phi_k^\dagger & \Delta_0 & \Delta_{1,k} \\ -t\phi_k & -\mu & \Delta_{1,-k} & \Delta_0 \\ \Delta_0 & \Delta_{1,-k} & -\mu & t\phi_k \\ \Delta_{1,k} & \Delta_0 & t\phi_k & -\mu \end{pmatrix} \quad (5.36)$$

is the Bogoliubov-de Gennes matrix written in the sublattice and Nambu basis $\Psi_k = (ak^\dagger, b_k^\dagger, a_{k\uparrow}, b_{k\downarrow})$.

The Hamiltonian (5.36) can be diagonalized in a basis of Bogoliubov quasiparticles: $H = \sum_{k,\alpha} E_{k,\alpha} \hat{n}_{k,\alpha}^B + E_0$, where $\hat{n}_{k}^B$ is the quasiparticle number operator and $s, \alpha = \pm 1$. In the isotropic case, $\Delta_{1,k} = \Delta_1 \phi_k$, the spectrum is $E_{k,\alpha} = \alpha E_{k,\alpha}$, with (Uchoa and Castro Neto, 2007),

$$E_{k,s} = \sqrt{(l|\phi_k| + s\mu)^2 + (|\Delta_0| + s\Delta_1|\phi_k|)^2}, \quad (5.37)$$

$|\Delta_0|$, $\Delta_1$, $\phi_k$, $\mu$, and $\Delta_1$, $\phi_k$, $\mu$ are parameters of the system, and $l$, $s$ are the indices of the quasiparticle states.
where the phase of the OP $\Delta_0$ is locked in with $\Delta_1$, and $\Delta_1$ is real. The electronic gap described by the spectrum (5.37) is

$$E_g = 2|t\Delta_0 - \mu\Delta_1|/\sqrt{t^2 + \Delta_1^2}.$$  

(5.38)

In the $p + ip$ state ($\Delta_0 = 0$, $\Delta_1 \neq 0$), $E_g$ is proportional to the deviation of the chemical potential away from half-filling, and at $\mu = 0$ this state becomes quantum critical and gapless. The instability in this case translates into the renormalization of the Fermi velocity, where $t = t\sqrt{1 + \Delta_1^2}$ is the renormalized hopping amplitude, instead of the opening of a gap (Uchoa and Castro Neto, 2007). Minimization of the free energy

$$F = -T \sum_{k,s} \ln [2 + 2\cosh(E_{k,s}/T)] + E_0,$$

(5.39)

with respect to $\Delta_0$ and $\Delta_1$ gives a set of two coupled BCS-like equations, and leads to the phase diagram shown in Fig. 30. At half-filling, $\mu = 0$, the emergence of superconductivity is controlled by quantum critical lines in the parameters $g_0$ and $g_1$, with critical values $g_0' = -\pi v^2/D$ and $g_1' = -4\pi v^4/D^3$, in the linear cone approximation, where $D$ is an ultraviolet cut-off and $v$ is the Fermi velocity near the Dirac point (Castro Neto, 2001; Marino and Nunes, 2006; Uchoa and Castro Neto, 2007; Zhao and Paramekanti, 2006). For finite $\mu$, there is a crossover to the standard Fermi liquid case at weak coupling, as shown in Fig. 30.

When $\Delta_{1,j} = \Delta_1 e^{(2\pi/3)}$ [see Eq. (5.28)], the electronic wavefunctions collect different phases along the different bond links, which gives rise to a current flow, and the $d + id$ state cannot coexist with an isotropic TRS $s$-wave state. The gap properties of the $d + id$ state and the differential conductance in SN junctions were derived by Jiang et al., 2008. The Josephson current for this state in SNS junctions was calculated by Linder et al., 2009.

In the $s$-wave state (we assume $\Delta_0$ to be real), the gap variation with the coupling at half filling, near the quantum critical point $g_0' = -\pi v^2/D$, is (Castro Neto, 2001)

$$\Delta_0 = D(1 - g_0'/g_0).$$  

(5.40)

Away from half-filling, the gap crosses over to (Uchoa et al., 2005)

$$\Delta_0 = 2|\mu|\exp[D(1 - g_0'/g_0)/|\mu| - 1]$$  

(5.41)

for $|\mu| > \Delta_0$, which corresponds to the weak coupling BCS limit, where $g < g_c$. As shown in Fig. 31. The $|\mu|/\Delta_0 < 1$ limit corresponds to the strong coupling regime ($g > g_c$), and the intermediate coupling region near $g \approx g_c$ sets the crossover scale between the two regimes at finite $\mu$. Non-equilibrium effects in the presence of a dissipative environment may also lead to a dissipation driven quantum phase transition away from half filling (Takei and Kim, 2008).

At mean field level, the critical temperature at $\mu = 0$ is $T_c = \Delta_0/2\ln 4$, whereas in the opposite limit, $|\mu| \gg \Delta_0$, $T_c = \gamma\Delta_0/\pi$, as in the BCS case, where $\ln \gamma \approx 0.577$ is the Euler constant (Uchoa et al., 2005). Of course, in two dimensions there is no true long range order. The superconducting transition is of Kosterlitz-Thouless (KT) type and coherence is actually lost at much lower temperatures due to the role of thermal fluctuations, which unbind vortex and anti-vortex pairs above the KT transition temperature, at $T_{KT} < T_c$. The mean field result indicates the onset of critical fluctuations where the amplitude of the Cooper pairs is completely destroyed, although the phase coherence is suppressed much earlier, at $T_{KT}$. The KT fluctuations of the SC order parameter have been considered by Loktev and Turkowski, 2009, without accounting, nevertheless, for the chiral nature of the quasiparticles in graphene.

Zero field thermodynamic properties, such as the specific heat at fixed volume, $C_V = -T (\partial^2 F/\partial T^2)$, can be extracted from the free energy (5.39). For an isotropic condensate of Dirac fermions, the jump of the specific heat at the phase transition, normalized by the specific heat on the normal side, is (Uchoa et al., 2005)

$$\delta C_V = 2(\ln 4)^2/|\zeta(3)| \approx 0.35,$$

(5.42)

at half-filling. In the $|\mu|/\Delta_0 \gg 1$ limit, the jump grows to the standard BCS value $\delta C_V = 12/|7\zeta(3)| \approx 1.43$.

The Meissner effect in graphene, which describes the expulsion of an external magnetic field by the circulation of diamagnetic supercurrents, has been recently examined by Kopnin and Sonin, 2008 and Uchoa and Castro Neto, 2009. In the presence of vortices, the Bogoliubov de Gennes equations for Dirac fermions in $2+1$ dimensions allow the presence of zero energy modes (Jackiw and Rossi, 1981) which are bound to the vortex cores. For a vortex with vorticity $n$ (the winding number of the OP), $\Delta_n = |\Delta_n(r)| e^{in\phi}$, with $(r, \phi)$ as cylindrical coordinates. The physical solutions allowed by the boundary conditions at the center of the vortex and at infinity result in $n$ zero modes at half filling (Ghaemi and Wilczek, 2012). The subgap spectrum and the wavefunctions in the vortex core have been derived by Bergman and Hur, 2009; Seradjeh, 2008. Away from half filling, for odd vorticity $n$, there is only one energy
branch that crosses zero energy for zero angular momentum. For n even, no subgap branch intersects zero energy, and no exact zero modes exist (Bergman and Hur, 2009; Khymmovich et al., 2009). Because of the fermionic degeneracy in the valleys, the topological zero modes do not lead to fractional statistics under vortex exchange, as in conventional p+ip superconductors, unless additional interactions that lift the fermionic degeneracy are included (Herbut, 2010). Vortex zero modes for excitonic condensates in bilayers have been discussed by Seradjeh et al., 2008.

VI. INTERACTIONS AT BOUNDARIES AND LATTICE DEFECTS

A. Surface states

The vanishing density of states of graphene at the neutrality point implies that localized states can exist at the Dirac energy, much in the same way as localized states appear inside a forbidden energy gap in semiconductors and insulators. In order for these states to be normalizable, special boundary conditions are required. These conditions imply the breaking of the translational symmetry of the lattice, so that they can only exist near edges or defects.

The most extensively studied examples are the surface states which exist at graphene zigzag edges, where the lattice is abruptly terminated (Fujita et al., 1996; Nakada et al., 1996). Such edges have been observed in graphene flakes (Girit et al., 2009; Jia et al., 2009), and also in graphite (Niimi et al., 2005). As the localized states form an energy band of zero width, the local density of states at the Dirac energy near a zigzag edge changes from zero to infinity, and the electron compressibility becomes divergent. Interactions of arbitrarily small strength lead to instabilities when the Fermi energy lies at the Dirac point. A mean field analysis showed that a short range Hubbard interaction can lead to a ferromagnetic ground state (Harigaya, 2001; Harigaya and Enoki, 2002). In zigzag ribbons with two edges, the spins at the two edges are aligned antiferromagnetically, see Fig. 32. These early theoretical results, based on the tight binding approximation, were later confirmed by calculations based on the Local Density Approximation (Pisani et al., 2007; Son et al., 2006). The ferromagnetic order remained when the dangling bonds at the zigzag edges where saturated by hydrogen, which probably is closer to the actual experimental situation. The optimization of the atomic positions at the edges leads to reconstructed phases with gaps, where the spin up and spin down bands do not overlap near the gap, suggesting a half metallic phase (Son et al., 2006). Other phases, with ferroelectric properties (Fernández-Rossier, 2008) or canted moments have been studied (Jung and MacDonald, 2010). A sketch of the magnetization induced near a zigzag edge of a graphene ribbon is shown in Fig. 32. Recent experiments (Enoki and Takai, 2009; Joly et al., 2010) confirm the existence of magnetic moments at graphene edges.

The effects of the electron-electron interaction on the midgap states has also been studied beyond the mean field approximation. The calculations show that the ferromagnetic phase is stable when the band of localized states is half filled. Both a local onsite interaction or the long range exchange effect lead to this phase. At very low fillings, electrons tend to form a charge density wave state, similar to a Wigner crystal (Wunsch et al., 2008a,b). More complex correlated states are possible at other fillings. The fact that the midgap states at a zigzag edge resemble the wavefunctions of Landau levels, in that the momentum parallel to the edge and the spatial extension are coupled, leads to the intriguing possibility of states similar to the Laughlin wavefunctions which describe the Fractional Quantum Hall Effect (Wunsch et al., 2008a).

At long distances, straight graphene edges of arbitrary orientation other than armchair can support midgap states, as zigzag edges (Akhermov and Beenakker, 2008). Hence, local magnetic moments can be a generic property of abrupt graphene edges. Zigzag edges and vacancies in bilayer (Bernal) graphene also give rise to midgap states, at least when only the direct nearest neighbor interlayer hopping is included (Castro et al., 2008a), and magnetic moments can be formed at the edges of bilayer graphene (Sahu et al., 2008). Models which include other interlayer hoppings lead to sharp resonances near edges and vacancies. These results suggest that moderate interactions can produce local moments in graphene bilayers or in three dimensional graphite. The combination of the Zeeman field associated with magnetic ordering, and the spin orbit coupling can lead to phases characterized by quantized spin currents at the edges (Soriano and Fernández-Rossier, 2010).
B. States at vacancies and cracks

Midgap states can occur in other situations where the translational symmetry of the lattice is broken. Similarly to the case of surface states at a zigzag edge, interactions will lead to the spin polarization of these states. The simplest situation where the existence of a partially localized midgap state can be demonstrated is a lattice vacancy (Pereira et al., 2006, 2008b). This analysis can be extended to multilayer samples (Castro et al., 2010).

The existence of these states has been confirmed by STM spectroscopy on vacancies in irradiated graphite (Ugeda et al., 2010). It can be expected that interactions lead to the formation of a magnetic moment around the vacancy. The formation of local moments near vacancies is consistent with the observation of ferromagnetism in irradiated graphite (Barzola-Quíquía et al., 2007; Chen et al., 2011; Esquinazi et al., 2003; Ohldag et al., 2007; Ramos et al., 2010). Absorption of hydrogen leads to similar effects to those of a vacancy, including the formation of magnetic moments (Yazyev, 2008). Other dopants, like carbon atoms and NO$_2$, also lead to the formation of spins (Lehtinen et al., 2003; Wehling et al., 2008b).

A sketch of the magnetization induced near a graphene vacancy is shown in Fig. 33. The moment associated with the localized level around the vacancy is coupled to the extended states, leading to the possibility of the Kondo effect. Some differences between usual magnetic impurities and the situations described here can be expected: i) The vacancy or adatom modifies significantly the electronic density of states, rendering invalid perturbative treatments which relate the magnitude of the exchange coupling to the unperturbed electronic structure. The phase shift induced in the conduction band remains significant, even near the Dirac energy (Hentschel and Guinea, 2007). ii) The localized state is orthogonal to the extended states. Hence, the coupling between the local moment and the conduction band does not take place via virtual hops between the two types of states. Instead, it can be expected that the electron-electron interaction favors a ferromagnetic alignment of the local moment and the spins of the conduction electrons.

Spins at different vacancies interact ferro- or antiferromagnetically (Brey et al., 2007; Palacios et al., 2008), depending on whether the vacancies occupy the same or different sublattices. At half filling, the RKKY interaction mediated by the $\pi$ band decays as $1/|\mathbf{r} - \mathbf{r}'|^3$, and it goes to the $1/|\mathbf{r} - \mathbf{r}'|^2$ dependence typical of a two dimensional electron gas at finite carrier concentrations (Cheianov and Fal’ko, 2006). Voids or cracks can be considered an intermediate case between vacancies and edges (Vozmediano et al., 2005). They also support localized spins at the boundaries.

C. Midgap States and Random Gauge Fields

Midgap states in bulk graphene can also be induced by magnetic fields (see below), or by strains which mimic the effect of a magnetic field (Guinea et al., 2008b). These states have been analyzed using the tight binding approximation (Guinea et al., 2008b), or by means of the Local Density Functional method (Wehling et al., 2008a). Corrugations and wrinkles also induce midgap states in graphene (Katsnelson and Prokhorova, 2008; Pereira et al., 2010). The presence of these states enhances the effects of the interactions. Mean field calculations suggest the formation of magnetic moments, which will order ferro- or antiferromagnetically (Guinea et al., 2008a,b).

A random strain distribution leads to a random gauge field acting on the electrons. The changes in the electronic density of states induced by a random gauge field have been studied by RG techniques (Horowitz and Doussal, 2002; Ludwig et al., 1994). Related problems arise at the transition between plateaus in the Quantum Hall Effect, and in d-wave superconductors. It can be shown that, above a certain disorder strength, a random gauge field leads to a divergent density of states at the Dirac energy (Horowitz and Doussal, 2002; Riu and Hatsugai, 2001). This divergence leads to a vanishing electron compressibility, and enhances the effects of interactions in the same way as the midgap states considered earlier. A random gauge field, $\mathbf{A}(\mathbf{r})$, can be characterized by a dimensionless number, $\Delta$,

$$
\langle A_\mu(r)A_\nu(r') \rangle = \Delta \delta_{\mu\nu} \delta^2(r - r').
$$

If the gauge potential is assumed to arise from random corrugations of average height $h$ and length $\ell$, then $\Delta \sim h^4/(a^2\ell^2)$, where $a$ is the lattice constant (Guinea et al., 2008a,b). A similar parameter can be defined if the gauge potential is due to topological defects, such as dislocations (González et al., 2001). The regime $\Delta \sim 1$ corresponds to ripples large enough to accommodate midgap states, leading to a divergence in the density of states. The changes in the density of states induced by a gauge field can be written as a logarithmic renormalization of
FIG. 34 (Color online). Sketch of the magnetization induced at the edges of a quantum dot.

the Fermi velocity

$$v \rightarrow v \left[1 - c\Delta \log \left(\frac{\Lambda}{|k|}\right)\right], \quad (6.2)$$

where $c$ is a numerical constant, and $\Lambda$ is a high momentum cutoff of the order of the inverse of the lattice constant.

The scaling towards lower Fermi velocities in eq. 6.2 can be combined with the RG analysis of the long range Coulomb interaction (Foster and Aleiner, 2008; Foster and Ludwig, 2006a,b; Stauber et al., 2005). Disorder tends to increase the density of states near the Dirac energy, while interactions lead to the opposite effect. To lowest order, this analysis leads to a line of fixed points characterized by a finite disorder and finite interactions, as discussed in Sec. III.A.1, see Fig. 9. The temperature and frequency dependence of properties such as the conductivity or the specific heat acquire anomalous exponents (Herbut et al., 2008). For high disorder, $\Delta \gtrsim 1$, it can be shown that a gapped state is more stable than the gapless density of states expected in the absence of interaction effects (Guinea et al., 2008a).

Certain strain configurations lead to effects similar to those induced by a constant magnetic field (Guinea et al., 2010). The possible ways in which the degeneracies of these states are lifted by the interactions have been studied (Herbut, 2008), and new phases, with properties similar to those of topological insulators may exist. It is worth noting that STM experiments suggest the existence of very large effective fields due to strains, $B_{eff} \sim 300$T, in small graphene bubbles under high strains (Levy et al., 2010). The effects of electron-electron interactions in this regime remain unexplored.

FIG. 35 (Color online). Single energy peaks and Coulomb diamonds in a graphene quantum dot, see (Ponomarenko et al., 2008).

VII. INTERACTION EFFECTS IN MESOSCOPIC SYSTEMS

A. Magnetism in quantum dots

Mesoscopic samples have a large ratio between the perimeter and the area. Midgap states localized at the edges can have a significant weight in the total density of states, and interaction effects are enhanced. Early calculations for planar carbon molecules (Stein and Brown, 1987; Tyutyulkov et al., 1998) showed gaps associated with the electron-electron interaction, and magnetic moments at the edges. A large magnetic moment can be found in triangular graphene flakes (Fernández-Rossier and Palacios, 2007), where the three boundaries have the zigzag orientation, and the carbon atoms at the edges belong to the same sublattice.

As mentioned previously, edges of arbitrary orientations, except the armchair direction, support midgap states (Akhmerov and Beenakker, 2008). Hence, local moments and magnetism can be expected in graphene...
quantum dots of any shape, provided that the termination at the edges is abrupt. Model results suggest that this is the case, and the orientation of the moments at the edges depends on the type of sublattice at the edge (Fernández-Rossier and Palacios, 2007), as sketched in Fig. 34. Away from half filling, correlated states with unsaturated magnetization, and charge density wave states are also possible (Romanovsky et al., 2009; Wunsch et al., 2008a). The charging of a quantum dot leads to a substantial rearrangement of the electronic levels, in a similar way to the well studied orthogonality catastrophe in metals (Anderson, 1967; Wunsch et al., 2008a). The conductance can acquire a non trivial voltage or temperature dependence, as in a Luttinger liquid (Kane and Fisher, 1992).

A simple estimate of the number of magnetic moments in a quantum dot can be obtained by assuming that the average density of edge states is of order \( \rho_{\text{edge}} \approx c \times [R/(aW)] \), where \( c \approx 1 \) is a numerical constant, \( R \) is the radius of the dot, \( a \) is the lattice spacing, and \( W \) is the bandwidth of the band of edge states (Wimmer et al., 2010). The Coulomb interaction within each state, which leads to the formation of local moments is \( E_c \approx c^2/R \times \log(R/a) \), see below. Naturally, one has to replace \( c^2/R \) in all formulas, but we do not write the dielectric constant explicitly in this section. The states which are spin polarized are those whose distance from the Fermi energy is less than \( E_c \). This condition, combined with the estimate for \( \rho_{\text{edge}} \), gives a maximum number of magnetic moments within the dot, \( N \approx E_c \rho_{\text{edge}} \approx c \times [c^2/(aW)] \times \log(R/a) \). This number is not too large. For \( W \sim 0.3 - 0.5 \text{eV} \) and \( R \sim 100 \text{nm} \) we obtain \( N \sim 10 - 20 \). The total magnetic moment of the dot depends on the sign of the couplings between the edge spins, see Fig. 34.

Experimentally, there is evidence which suggests the formation of local moments in small graphene flakes, of dimensions 10 – 50 nm (Sepioni et al., 2010).

B. Charging effects. Coulomb blockade

Graphene quantum dots of many shapes and dimensions are being extensively studied (Avouris et al., 2007; Bunch et al., 2005; Guettinger et al., 2008; Güttinger et al., 2009; Han et al., 2007; Huard et al., 2007; Molitor et al., 2009a; Moser and Bachtold, 2009; Özyilmaz et al., 2007; Ponomarenko et al., 2008; Stampfer et al., 2008; Williams et al., 2007). Single electron effects have been observed in many of them. Experiments show clear evidence of charging effects in graphene quantum dots, as evidenced in the diamond patterns formed by the resonances in the conductance through the dot as a function of gate and bias voltages (Guettinger et al., 2008; Güttinger et al., 2009; Molitor et al., 2009a,b; Moriyama et al., 2009; Moser and Bachtold, 2009; Ponomarenko et al., 2008; Ritter and Lyding, 2009; Schnez et al., 2009; Stampfer et al., 2008), see Fig. 35.

The electrostatic interaction between electrons leads to Coulomb blockade, which modulates the energy difference between levels, and induces non Ohmic features in the conductance through the dot. In a graphene quantum dot of dimension \( R \), the electrostatic energy required to add a unit of charge scales as \( e^2/R \). The mean level spacing between extended states in a ballistic dot scales as \( v/R \). As the dimensionless parameter \( \alpha = e^2/(\epsilon_0 v) \) in graphene is of order unity, the energy scales associated with charging and confinement effects are comparable.
The edge states discussed earlier can lead to charging energies larger than those for extended states. Assuming that these states are delocalized along the perimeter of the ribbon, over a scale \( L \sim R \), see Fig. 36, and width \( a \) comparable to the lattice spacing, see Fig. 36, the charging energy becomes \((e^2/R) \times \log(R/a)\) (Wimmer et al., 2010).

Charging effects can also modify the transport properties of narrow graphene ribbons. Irregularities in the edges may induce the formation of constrictions and quantum dots, as sketched in Fig. 37, where charging effects will lead to a transport gap. In a nanoribbon of width \( W \), the typical size of these dots will also be \( W \), and the transport gap will be of order \( e^2/W \). In the absence of charging effects, a ribbon will have confined subbands, separated by gaps of order \( v/W \). Hence, the similarity between the energy scales arising from quantum confinement and charging effects, which exists in a quantum dot, also exists in a graphene ribbon. An experimental realization of an all graphene circuit with a point contact coupled to a quantum dot (Stampfer et al., 2009) is shown in Fig. 38. This setup can be used to count the passage of charges through the quantum dot.

Experiments in graphene nanoribbons are compatible with the relevance of charging effects (Han et al., 2010, 2007; Todd et al., 2009). Some observations can be explained by a model of dots formed in the ribbon connected through many channels with the rest of the structure. Such a strongly coupled dot always shows Coulomb blockade effects, unless there is a perfect transmission through one or more of the channels. The effective charging energy, however, is strongly renormalized by the coupling between the dot and the rest of the system (Sols et al., 2007), \( E_c \approx e^2/W e^{-g} \), where \( g \) is the conductance, in dimensionless units, of the junction between the dot and the electrodes. In general, \( g \sim \langle |T|^2 \rangle \times k_F W \), where \( T \) is the transmission amplitude of a given channel.

The electron-electron interactions can be studied in mesoscopic samples through their effect on the magnetoconductance at low magnetic fields. These experiments probe the phase coherence of electrons at low temperatures. This quantum effect is suppressed due to the dephasing induced by the interactions. Electronic quantum coherence also gives rise to the universal conductance fluctuations observed in disordered metals, which are also reduced by the dephasing due to interactions. The dephasing length shows a temperature dependence consistent with the expected behavior in a dirty metal, \( \ell_\phi \sim (qhv)/[T \log(g)] \), where \( g \) is the conductivity in dimensionless units (Tikhonenko et al., 2009) (see also (Chen et al., 2010)). This dependence is replaced by \( \ell_\phi \propto T^{-2} \) in high mobility samples (Tikhonenko et al., 2009), as expected in a clean Fermi liquid. Experiments that tune the ratio between the dephasing length and the mean free path (Moser et al., 2010) show a variety of regimes, interpolating between weak and strong localization.

VIII. INTERACTIONS IN STRONG MAGNETIC FIELDS

A comprehensive review of graphene in magnetic field has recently appeared (Goerbig, 2011), and here we only mention some of the main effects. The electronic energy bands of graphene in a strong magnetic field collapse into Landau levels. In the absence of disorder,
the electronic compressibility diverges when the chemical potential coincides with the energy of a Landau level, and the effects of the interactions are enhanced, as in other two dimensional metallic systems. The typical scale of the electronic wavefunctions is the magnetic length, \( \ell_B = \sqrt{\hbar/(eB)} = \sqrt{\Phi_0/(2\pi B)} \), where \( B \) is the applied field and \( \Phi_0 \) is the quantum unit of flux. The separation between levels is of order \( v/\ell_B \), while the relevant scale for interaction effects is \( e^2/\ell_B \).

There are two sets of Landau levels in graphene, one for each valley. In addition, graphene has the \( n = 0 \) level, which combines electron and hole features. Hence, interactions can break either the valley degeneracy or the spin degeneracy. The long range part of the Coulomb interaction is independent of the valley index. The \( n = 0 \) Landau level is localized in a given sublattice, and its degeneracy can be lifted by interactions which break the symmetry between sublattices, like the coupling to out of plane optical phonons (Fuchs and Lederer, 2007). Hence, the removal of the spin and valley degeneracies of the Landau levels due to interactions depends on other energy scales (Goerbig, 2011), such as the Zeeman splitting, or the nearest neighbor repulsion, for the case \( n = 0 \). A sketch of the possible symmetry breaking patterns as a function of magnetic field is shown in Fig. 39. Early observations of splittings between Landau levels are shown in Fig. 40, see (Zhang et al., 2006).

It is usually assumed that the Zeeman splitting is much smaller than the other energy scales. Calculations suggest that the spin degeneracy is lifted first, leading to excitations with combined spin and valley indices (Abanin et al., 2007; Alicea and Fisher, 2006; Goerbig et al., 2006; Gusynin et al., 2009; Nomura and MacDonald, 2006; Shibata and Nomura, 2008; Wang et al., 2008; Yang et al., 2006). The fourfold spin and valley degeneracy when the Zeeman coupling is neglected gives a new \( SU(4) \) symmetry, which may lead to new features, not observable in other two dimensional electron gases (Goerbig and Regnault, 2007; Töke and Jain, 2007). The formation of Landau levels favors the excitonic transition which can also exist in the absence of a magnetic field (Gusynin et al., 2006). The spin split \( n = 0 \) level leads to spin polarized edge states (Abanin et al., 2006, 2007; Fertig and Brey, 2006; Shimshoni et al., 2009) where the orientation of the spin depends on the sign of the current, as in topological insulators (Hasan and Kane, 2010; Qi and Zhang, 2011).

A magnetic field oriented parallel to the plane does not give rise to Landau levels. In neutral graphene, it leads to metallic states with electrons and holes polarized in opposite directions, providing another route towards an excitonic transition (Aleiner et al., 2007).

Experiments show that, indeed, the spin and valley degeneracies of Landau levels in graphene are lifted (Giesbers et al., 2007, 2009; Jiang et al., 2007; Zhang et al., 2006). The opening of a gap in the \( n = 0 \) level in graphene has been extensively studied, and a metal insulator transition with critical features consistent with a Berezinskii-Kosterlitz-Thouless transition has been reported (Amado et al., 2009; Checkelsky et al., 2008, 2009).

The most striking manifestation of the interactions in the presence of a strong magnetic field is the Fractional Quantum Hall Effect. Early theoretical calculations showed that the FQHE could be stable in graphene (Apalkov and Chakraborty, 2006; Castro Neto et al., 2006; Töke et al., 2006). The conditions for the FQHE are the existence of sharp Landau levels and sufficiently strong electron electron interactions. The analysis of FQHE states in graphene can be done in a similar way to that of a two dimensional electron gas. The main difference is a change in the pseudopotentials which describe the interactions between electrons in a given Landau level, because the wavefunctions in graphene and in a two dimensional electron gas differ.

This Fractional Quantum Hall Effect was extensively, but unsuccessfully, sought in samples deposited on SiO\(_2\). Suspended samples, which showed a much higher electron mobility, did not exhibit the FQHE, using the standard experimental four terminal setup. The observation of the IQHE in suspended bilayer graphene using a two terminal setup (Feldman et al., 2009) led quickly to the discovery of the FQHE in single layer graphene (Bolotin et al., 2009; Du et al., 2009), using the same technique. More recently, four terminal measurements in high mobility suspended samples (Ghahari et al., 2011), and also samples deposited on a new substrate, boron nitride (Dean et al., 2011, 2010), also show the FQHE. In two terminal measurements, the existence of the FQHE is inferred from plateaus of the longitudinal resistance at carrier densities which correspond to fractional fillings of Landau levels, see Fig. 41. The \( \nu = 1/3 \) state turns out to be more robust than in other materials, like GaAs, which
exhibit the FQHE, and it can be observed at temperatures greater than 10K. Fractional plateaus at $\nu = 2/3$ and $\nu = 1/2$ have also been reported. Theoretical calculations suggest that the so called Moore-Read ground state at fillings with even denominators, which leads to the existence of non Abelian anyonic quasiparticles, is not favored in graphene (Wojs et al., 2011).

IX. INTERACTIONS IN BILAYERS

Bilayers are the building blocks for 3D stacks of graphene, such as graphite. In a bilayer one has two parallel graphene sheets, separated by an equilibrium distance similar to the interlayer distance of graphite (3.35Å) (Dresselhaus and Dresselhaus, 1981). The relative position of the two graphene layers is not unique, and this leads to different stacking arrangements of the bilayer, and even more possibilities for multilayers, or graphite. The most stable configuration seems to be the so-called Bernal AB stacking, in which the two layers are rotated by 60°. As a consequence, one of the the sublattices in the lower layer (say, sublattice A) is vertically aligned with one of the sublattices of the upper layer (say, sublattice B) [see Fig. 42(a)]. Notice that this particular rotation leads to a breaking of sublattice symmetry between layers. As a first approximation, the electronic coupling between the layers can be described in terms of the hopping of electrons between the nearest neighbor atoms in different layers with an energy $t_\perp$ (also known as $\gamma_1 \approx 0.39$ eV in the graphite literature (Castro Neto et al., 2009a). Another possible arrangement between the layers is the fully aligned configuration, also called AA stacking. In both AB and AA stacking, the unit cell is comprised of 4 atoms, and has the same 2D extension as the unit cell of a single layer; this implies that the Brillouin zone is precisely the same as in monolayer graphene.

Notice, however, that these configurations are just a few of an infinite series of commensurate structures between two layers, the so-called twisted bilayer graphene (Lopes dos Santos et al., 2007). The problem of commensurate and incommensurate structures always appears when two crystalline materials are superimposed, as in the case of bilayers. For commensurate structures, the angle between the layers is not arbitrary but follows a well defined sequence (Lopes dos Santos et al., 2007). Obviously, different angles lead to different broken symmetries and hence to different electronic states. When the angle of rotation is 60 degrees, as in the case of the Bernal structure, the sublattices are nonequivalent, which leads to a broken sublattice symmetry and hence to a putative gap opening. For other angles, there is no broken sublattice symmetry but the unit cell is enlarged as the rotation angle becomes smaller. In this case the massless Dirac dispersion has to be preserved for symmetry reasons (Li et al., 2010; Lopes dos Santos et al., 2007; Mele, 2010). From this perspective, the Bernal configuration is an exception. The twisted bilayer graphene presents a very rich physics of its own that we will not cover in this review. Instead, we will focus on the Bernal configuration which is the most studied case.

We will start from the minimal tight-binding model for Bernal bilayers, which includes a basis with two additional layer flavors (denoted by an overbar),

$$\Psi_{k,\sigma} = (a_{k,\sigma}, b_{k,\sigma}, \bar{a}_{k,\sigma}, \bar{b}_{k,\sigma}) , \quad (9.1)$$

with $\sigma = \uparrow, \downarrow$ representing the spin. The resulting Bloch Hamiltonian is then a 4 × 4 matrix with two sublattice, and two layer degrees of freedom,

$$\mathcal{H}_\beta = \sum_{k\sigma} \Psi_{k,\sigma}^\dagger \begin{pmatrix} 0 & -t\phi_k & -t_\perp & 0 \\ -t\phi_k^\dagger & 0 & 0 & 0 \\ -t_\perp & 0 & 0 & -t\phi_k^\dagger \\ 0 & 0 & -t\phi_k & 0 \end{pmatrix} \Psi_{k,\sigma} , \quad (9.2)$$

where $t_\perp \approx 0.39$eV is the interlayer hopping, and $t \approx 2.8$eV is the in-plane, nearest neighbor, hopping amplitude. The momentum dependence is contained in $\phi_k$, which is as for a monolayer (2.3). The band structure associated with eq. (9.2) consists of four non-degenerate bands given by

$$E(k) = \pm \frac{1}{2} (t_\perp \pm \sqrt{t_\perp^2 + 4t^2|\phi_k|^2}) . \quad (9.3)$$

An expansion $k = K + p$ around the $K$ points of the BZ when $v|p| \ll t$ shows that the four-band tight-binding spectrum (9.3) resolves into four hyperbolic
bands (Nilsson et al., 2006), as shown in Fig. 42(b), and whose form reads:

\[ \pm E_{\gamma}(p) = \pm \frac{t_1}{2} \left[ 1 + \gamma \sqrt{1 + 4(v|p|/t_{\perp})^2} \right], \tag{9.4} \]

with \( v \approx 6 \text{ eVÅ} \) being the Fermi velocity (the same Fermi velocity of a monolayer), and \( \gamma = \pm 1 \). The Bernal stacking explicitly breaks the sublattice symmetry in each layer, causing an energy splitting of \( t_{\perp} \) between the two \( \gamma = \pm 1 \) branches, \( E_+ \) and \( E_- \), at \( p = 0 \) (see Fig. 42). Due to a degeneracy at the \( K \) points, the two symmetric branches \( +E_- \) and \( -E_+ \) touch there, resulting in a gapless spectrum. Just as in a monolayer, the Fermi surface of an undoped bilayer reduces to only two points, at \( K \) and \( K' \); but now the valence and conduction bands have a finite curvature and, hence, notwithstanding the absence of a gap, the effective electronic degrees of freedom are massive, but still chiral. The degeneracy at \( K \) is protected by the \( Z_2 \) symmetry between the two layers only (McCann, 2006), and can be lifted with arbitrarily small perturbations, such as the ones induced by a bias voltage, by polarizing the two sheets (Zhang et al., 2009), or else by independently changing the carrier concentration in each layer (Ohta et al., 2006). This property opens the exciting prospect of using graphene bilayers as materials with a gate-tunable band gap (Castro et al., 2007; Castro Neto et al., 2007; Min et al., 2007).

We stress that the low energy effective theory of bilayers remains Lorentz invariant, in the following sense. The rotation of \( \pi/3 \) between layers breaks the sublattice symmetry leading to 2 pairs of massive Dirac particles at the \( K (K') \) point. Nevertheless, the system remains metallic because two bands, belonging to different pairs, touch in a point. More explicitly, the non-interacting bands (9.4) have the form:

\[
E_1(k) = -E_-(k) = -mv^2 + E(k), \tag{9.5a}
\]
\[
E_2(k) = +E_-(k) = mv^2 - E(k), \tag{9.5b}
\]
\[
E_3(k) = +E_+(k) = mv^2 + E(k), \tag{9.5c}
\]
\[
E_4(k) = -E_+(k) = -mv^2 - E(k), \tag{9.5d}
\]

where \( E(k) = \sqrt{(mv^2)^2 + (vk)^2} \), and \( m = t_{\perp}/(2v^2) \). Hence, \( E_1(k) \) and \( E_4(k) \) describe a massive relativistic dispersion with rest energy given by \( mv^2 \). Again, the gapless nature of the full spectrum of this problem is due to an accidental degeneracy of the simplest tight binding parametrization. Additional hopping terms (Castro Neto et al., 2009a) in the Hamiltonian or many body interactions can easily lift this degeneracy. This implies that the Bernal bilayer problem is unstable from the electronic point of view. In contrast, the twisted bilayer (Lopes dos Santos et al., 2007) is stable because it does not rely on this particular accidental degeneracy. Just like in the case of monolayer graphene, the introduction of the instantaneous Coulomb interaction does not preserve this Lorentz invariance.

At very low energy, below \( \Delta_w \approx 1.5 \text{ meV} \), additional trigonal warping effects take place due to the influence of next-nearest neighbor hopping matrix elements [which we are neglecting in (9.2)]. Trigonal warping introduces an asymmetry in the conductivity under electron or hole doping (Li et al., 2009b), and leads to a remarkable Lifshitz transition at low densities, whereby the lowest energy bands split into 4 Dirac cones (Cserti et al., 2007; McCann and Fal’ko, 2006). These effects, however, happen at very low densities (around 1 electron per flake for typical 1\( \mu \text{m}^2 \) samples), and hence are experimentally very challenging. A detailed description of the spectral properties of graphene bilayers can be found in Castro Neto et al., 2009a, and Nilsson et al., 2008.

When \( \Delta_w < v|p| < t_{\perp} \), we recover the so-called classical limit of the “relativistic” problem. This means that the presence of the uppermost band is not too relevant, and the energy disperses quadratically with momentum (the opposite limit of \( v|p| \gg t_{\perp} \) corresponds to the “ultra-relativistic” regime, where the bandstructure is essentially linear in momentum, like in the monolayer). In this case the Hamiltonian (9.2) near the \( K \) points can be projected onto an effective two-band model, written in terms of the two valleys and a mixed sublattice-layer basis (McCann and Fal’ko, 2006):

\[
\tilde{\Psi}_{p,\sigma} = (\alpha_{K+p,\sigma}, \tilde{b}_{K+p,\sigma}, \tilde{b}_{-K+p,\sigma}, \alpha_{-K+p,\sigma}). \tag{9.6}
\]

In such a basis, the effective kinetic Hamiltonian is

\[
\mathcal{H}_B = \sum_{p \sigma} \sum_{s=\pm} \tilde{\Psi}_p \tilde{\Psi}_p^\dagger \frac{p_a^2}{2m} [\tau_0 \otimes \sigma_s] \tilde{\Psi}_p \sigma, \tag{9.7}
\]

where \( p_{\pm} = p_x \pm ip_y \), \( \sigma_{\pm} = (\sigma_1 \pm i\sigma_2)/2 \) operating in the sublattice basis, and \( \tau \) operates in the valley space. The resulting energy spectrum is parabolic,

\[
E(p) = \pm \frac{p^2}{2m}, \tag{9.8}
\]

with \( m = t_{\perp}/(2v^2) \approx 0.054 m_e \) as the effective mass of the electron. From now on we will omit the valley indexes and assume the two component basis \( \tilde{\Psi}_{p,\sigma} \rightarrow (\alpha_{p,}\tilde{b}_{p,}) \) with a total degeneracy \( N = 4 \) in valley and spin.

The electronic Green’s function in this two band model, \( \tilde{G}^{(0)}(k, \tau) = -(T[\tilde{\Psi}_k(\tau)]\tilde{\Psi}_k^0(0)) \), is given by

\[
\tilde{G}^{(0)}(k, i\omega) = \frac{1}{2} \sum_{s=\pm} \frac{1 + s\sigma_k}{\omega - s|E(k)|} \tag{9.9}
\]

in the chiral representation, where

\[
\tilde{\sigma}_k = \sum_{a=\pm} \frac{1}{|k|^2} \sigma_a. \tag{9.10}
\]

Although the fermions are chiral, in bilayers the wavefunctions of the quasiparticles acquire a \( 2\pi \) phase when winding around the \( K \) points, rather than a \( \pi \)-phase, as for Dirac fermions. This property is an admixture of the
FIG. 43 (Color online) The polarization $\Pi^{(1)}(q, \omega)$ of bilayer graphene, obtained within the two-band approximation, for finite chemical potential, and zero temperature. All panels are normalized to the DOS at the Fermi energy, $\mu$. Panel (a) shows a density plot of the imaginary part, for $\omega/\mu = 0.5, 1.0, 1.5, 2.0, 2.5, 3.0$. Panel (c) corresponds to the static limit $\Pi^{(1)}(q, 0)$ in eq. (9.12), and includes the intra-band contribution (dashed), the inter-band contribution (dotted), and the full polarization (solid). In (d) we represent the real and imaginary parts of the polarization in the undoped case (9.14) as a function of $\nu = 2n\omega/q^2$.

behavior of Dirac particles, which are chiral, with conventional electrons, which disperse quadratically. The combination of chirality and a trivial Berry phase has a clear experimental signature in the suppression of the zero-level plateau in the quantum Hall effect of the bilayer, whose plateaus are quantized by integer numbers (McCann and Fal’ko, 2006; Novoselov et al., 2006).

A. Charge polarization

Within the two band model, the one loop polarization function has the generic form given in Eq. (2.12) for the single layer. The adaptations for the present case consist in considering the bilayer spectrum, and a new overlap factor, which, for the bilayer, reads

$$\mathcal{F}_{s,s',p,q} = \frac{1}{2} [1 + ss' \cos(2\theta_{p,p+q})].$$

In this expression $\theta_{p,p+q}$ is, again, the angle between the vectors $p$ and $p+q$. Below we shall focus our discussion in terms of the effective two-band Hamiltonian (9.7), and dispersion (9.8).

The polarization function $\Pi^{(1)}(q, \omega)$ at finite density was obtained by Hwang and Das Sarma, 2008a in the $T = 0$ static limit. The full dynamical case was calculated by Sensarma et al., 2010 at $T = 0$, and by Lv and Wan, 2010 at finite temperature. The finite density result can be obtained in closed analytical form for $T = 0$; but, in order to avoid reproducing here those lengthy expressions, we simply present $\Pi^{(1)}(q, \omega)$ graphically in Figs. 43(a,b). The explicit form of the static limit reads (Hwang and Das Sarma, 2008a; Lv and Wan, 2010)

$$\frac{-\Pi^{(1)}(q, 0)}{\rho(\mu)} = g\left(\frac{q}{k_F}\right) - f\left(\frac{q}{k_F}\right) \theta(q - 2k_F)$$

at zero temperature, with

$$f(x) = \frac{2 + x^2}{2x} \sqrt{x^2 - 4} + \ln\left(\frac{x - \sqrt{x^2 - 4}}{x + \sqrt{x^2 - 4}}\right)$$

$$g(x) = \frac{1}{2} \sqrt{4 + x^2} - \ln\left(\frac{2 + \sqrt{4 + x^2}}{4}\right).$$

The DOS at the Fermi energy, $\rho(\mu) = Nm/(2\pi)$, is constant and density independent, by virtue of the parabolic nature of the low energy approximations (9.7) and (9.8) [note, however, that the consideration of the full 4-band spectrum leads to a DOS which is linear in energy; in this sense, the correction to the DOS that arises from considering the 4 versus the 2 band model is negligible (Ando, 2007)]. In this sense the bilayer is similar to the conventional 2DEG. However, just as in the monolayer, the existence of two symmetric bands adds an inter-band channel, leading to a rather different quasiparticle spectrum, in comparison with the 2DEG. This can be seen by directly comparing Figs. 4(b) and 43(a). The behavior of $\Pi^{(1)}(q, 0)$ is shown in Fig. 43(c), together with its decomposition into intra- and inter-band contributions, which are respectively associated with the choice $ss' = 1$, or $ss' = -1$ in eq. (9.11). As intuitively expected, the inter-band contribution dominates at large momenta/small densities, whereas the intra-band transitions dominate the low momenta/large density regime. Unlike the monolayer, or the 2DEG, the polarization is constant for both $q \ll k_F$ and $q \gg k_F$. The former limit makes the bilayer similar to the conventional 2DEG and monolayer graphene, while the latter is neither akin to the 2DEG (for which the polarization decreases rapidly with $q/k_F$ [Fig. 4(e)]), nor to the monolayer (for which it increases linearly [Fig. 3(e)]). Moreover, at precisely $q = 2k_F$, $\Pi^{(1)}(q, 0)$ is sharply cusped, which contrasts with the behavior of a monolayer, whose derivative is continuous. According to the standard theories of linear response, this feature at $2k_F$ has important implications for the behavior of the induced charge, the associated decay of the Friedel oscillations around charged impurities, the effective RKKY interaction among magnetic impurities, Kohm’s anomaly in the phonon dispersion, etc. For example, one expects qualitative differences between the
resistivity arising from Coulomb scattering in mono- and bilayer graphene: it should be stronger in the bilayer, and have a more pronounced temperature dependence (Hwang and Das Sarma, 2008a; Lv and Wan, 2010).

At long wavelengths, the RPA screened potential reads \( V^{\text{RPA}}(q) = V(q) / [1 - V(q) \Pi^{(1)}(q)] \approx 2\pi e^2 / [\epsilon_0 (q + q_{TF})] \), with a Thomas-Fermi momentum \( q_{TF} = N m e^2 / \epsilon_0 \). Notice that \( q_{TF} \) is the same for the bilayer as in the 2DEG, i.e. it is constant (no density dependence), and also temperature independent (Lv and Wan, 2010). The temperature independence of \( q_{TF} \) at long wavelengths is another trait that distinguishes this system from both the monolayer and the 2DEG. In real space the statically screened potential decays asymptotically as \( V(r) \propto 1/|r|^3 \) (Hwang and Das Sarma, 2008a).

At half-filling (undoped situation) and zero temperature, the form of the polarization bubble simplifies further, and can be cast as

\[
\Pi^{(1)}(\nu) = -\frac{N m}{2\pi} \left[ \frac{1}{\nu} \ln \left( \frac{1 + \nu}{1 - \nu} \right) - \frac{1}{2\nu} \ln \left( \frac{1 + 2\nu}{1 - 2\nu} \right) \right. \\
\left. + \ln \left( \frac{1 - \nu^2}{4 - \nu^2} \right) \right] 
\]  

(Barlas and Yang, 2009; Nandkishore and Levitov, 2010a; Nilsson et al., 2006), where \( \nu = 2\pi \omega / q^2 \) is the only scaling parameter. This function is plotted in Fig. 43(d). It follows at once that the static limit \( (\omega \to 0) \) is simply

\[
\Pi^{(1)}(q, 0) = -\frac{N \ln 4}{2\pi} m, \quad (9.15)
\]

consistent with the above discussion when \( k_F = 0 \). Despite the absence of a Fermi surface at half-filling, the Coulomb interaction among the quasiparticles is screened due to the finite density of states at the K points. However, an important difference here is that \( \Pi^{(1)}(q, 0) \) is constant for all momenta, unlike traditional 2D systems, and stems from the presence of the interband channel. Hence, the Thomas-Fermi wavevector is exactly \( q_{TF} = N m \ln(4)e^2 / \epsilon_0 \) for all wavelengths, and Friedel oscillations are suppressed at half-filling (Hwang and Das Sarma, 2008a). The additional numerical factor \( \ln(4) \) means a slight increase in the screening strength of undoped bilayer, with respect to the doped situation. One way to interpret this \( \ln(4) \) enhancement is the following: the factor \( N m e^2 / \epsilon_0 \) being exactly the same as in a simple 2DEG, is attributable to the finite density of states, while the extra \( \ln(4) \) arises from the virtual inter-band transitions. In real space, the statically screened potential of undoped bilayer will decay as \( 1/|r|^3 \), which contrasts with the corresponding behavior in the monolayer, where the decay is \( 1/r \) (as we saw before this is due to the fact that, in the RPA, the effect of interactions in the monolayer is to simply renormalize the background dielectric constant, keeping the Coulomb form of the potential). Inspection of Fig. 43(d) reveals that the real part of the RPA dielectric function \( \epsilon_{RPA}(q, \omega) = \epsilon_0 [1 - V(q) \Pi^{(1)}(q, \omega)] \) will be always nonzero. This means that, although the lack of a Fermi surface does not prevent screening in bilayers \( (q_{TF} \neq 0) \), the formation of zero temperature infrared plasmons is suppressed at half-filling.

The screened Coulomb interaction between the layers is \( V(q) = 2\pi e^2 e^{-q d} / [\epsilon_0 (q + q_{TF} e^{-q d})] \), where \( d = 3.35 \) Å is the interlayer distance. At long wavelengths, \( q \ll \ell_\perp / \nu < 1/\pi \approx 0.3 \) Å\(^{-1}\), \( d \) can be effectively replaced by zero in first approximation, and the screened interaction among electrons belonging to the same or different planes can be treated on the same footing.

At this point we should pause to point out that the behaviors discussed so far at large \( q \) have to be interpreted within the restrictions regarding the validity of the two-band approximation. For example, the fact that in Fig. 43(c) we see the polarization becoming constant at \( q \gg k_F \) is an artifact of the two-band approximation. In reality, we should bear in mind that the full dispersion is hyperbolic, and hence becomes linear at high densities. We then expect to recover the linear-in-\( q \) dependence of \( \Pi^{(1)}(q, 0) \) seen in Fig. 3(c) for the monolayer.

For this reason, proper caution is needed when considering the extrapolation of these results to highly doped bilayers, where the consideration of the four-band hyperbolic dispersion (9.4) is inevitably required. In terms of electronic densities, this corresponds to values above \( \sim 10^{12} \) cm\(^{-2}\), for which the two-band model is no longer warranted. The full dynamical response using the spectrum in eq. (9.4) has been recently derived in closed analytical form by Borghi et al., 2009b. Notwithstanding the lengthy and cumbersome nature of these analytical results, they afford a more accurate perspective on the screening response of doped bilayer graphene, its collective modes, and the crossover between the regimes of a massive-chiral system at low densities, to a system of weakly coupled monolayers at higher densities. Borghi et al., 2009b’s approach is ultimately limited by systems of such high densities that \( \mu \approx t \), in which case the full tight-binding dispersion (9.3) is needed, but is beyond closed analytical approaches.

B. Quasiparticles

In the two band model, the structure of perturbation theory for Coulomb interactions is set only by self-energy renormalizations in the effective mass of the electrons, \( m \), and in the quasiparticle residue, \( Z \).

From the Hamiltonian (9.7), the renormalized Green’s function is

\[
\hat{G}(k, \omega) = \frac{1}{\omega - \sum_{\alpha = \pm} k^2 / (2m) \sigma_\alpha - \hat{\Sigma}(k, \omega)}, \quad (9.16)
\]

\( \hat{\Sigma}(k, \omega) \) is the quasiparticle self-energy correction, which is described in the \((\hat{a}_{k, \sigma}, \hat{b}_{k, \sigma})\) basis by a matrix in the
FIG. 44 (Color online) Mass renormalization for α = 0.5 in the bilayer, calculated with a static Thomas-Fermi screened Coulomb interaction \( V(q) = e^2/(\epsilon_0(q + q_{TF})) \), as a function of the electronic density. Blue circles: \( \lambda = 1 \); red squares: \( \lambda = 0.01 \); green triangles: \( \lambda = 10^{-4} \). (From Borghi et al., 2009a). The inset shows \( \log_{10}(m^*/m) \) as a function of \( \log_{10}(n) \) for two of the \( \lambda \) values; the mass saturates at a finite value for \( n \to 0 \).

form

\[
\hat{\Sigma} = \begin{pmatrix} \Sigma_0 & \Sigma_+ \\ \Sigma_- & \Sigma_0 \end{pmatrix},
\]

(9.17)

or, equivalently, \( \hat{\Sigma} = \Sigma_0 \sigma_0 + \Sigma_+ \sigma_+ + \Sigma_- \sigma_- \), where \( \sigma_\pm = (\sigma_x \pm i \sigma_y)/2 \). By symmetry, \( \Sigma_\pm = \Sigma^* \). In a more conventional form,

\[
\hat{G}(k, \omega) = \frac{Z}{\omega - Z \sum_{\alpha=\pm} [k^2_\alpha/(2m) + \Sigma_{\alpha} \sigma_{\alpha}],
\]

(9.18)

where \( Z^{-1} = 1 - \partial \Sigma_0 / \partial \omega \) corresponds to the quasiparticle residue, and

\[
m^* = \frac{1 - \partial \Sigma_0 / \partial \omega}{1 + 2m \partial \Sigma_+ / \partial k^+_\alpha}
\]

(9.19)

is the mass renormalization.

We saw in the previous section that, unlike the monolayer, Coulomb interactions in the bilayer are screened. The self-energy is given in terms of the bare Green’s function and the RPA effective interaction by

\[
\hat{\Sigma}^{(1)}(q, \omega) = i \int \frac{d^2k d\varepsilon}{(2\pi)^3} V^{RPA}(k, \varepsilon) \hat{G}^{(0)}(k + q, \varepsilon + \omega),
\]

(9.20)

where \( V^{RPA}(q, \omega) = V(q)/\epsilon_{RPA}(q, \omega) \) is dressed by the RPA dielectric function. Even if the ratio between the Coulomb and kinetic energies diverges in the low density limit (as in a 2DEG) the validity of RPA can be, in principle, justified in the large \( N \) limit. If only static screening is taken into account (Hartree-Fock-Thomas-Fermi theory), the self-energy is frequency independent and, to leading order, the quasiparticle residue \( Z \) does not renormalize. Calculations based on the static screening picture for the two-band model (Borghi et al., 2009a), and also for the four-band model (Kusminskiy et al., 2009), have found mass renormalization in the bilayer. The mass decreases \( (m^*/m < 1) \), and the renormalization grows stronger as the screening is suppressed. In Fig. 44 we show this renormalization within the two-band model, where the parameter \( \lambda \) interpolates between the Thomas-Fermi screened potential \( (\lambda = 1) \) and the unscreened Coulomb potential \( (\lambda \approx 0) \). As a consequence of the reduced mass, the charge compressibility is also expected to decrease (Borghi et al., 2010; Kusminskiy et al., 2008).

More recent calculations that account for the full dynamical screening have found quite different results. When the dynamical RPA polarization bubble, Eq (9.14), is taken into account, the self-energy exhibits a strong \( \ln^2 \) leading divergence, \( \text{Re} \Sigma^{(1)}(k, \omega) = 2k^2_\alpha/(N\kappa^2)\ln^2(\Lambda/k) \), and \( \text{Re} \Sigma^{(0)}(k, \omega) = -4\omega/(N\pi^2)\ln^2[\Lambda/(\sqrt{m}\omega)] \), at small energies and momenta (Barlas and Yang, 2009). The ultraviolet momentum scale \( \Lambda \sim q_{TF} \) is related to the effective “Bohr radius”, \( a_0 = \epsilon_0/\langle m^2 \rangle \), and we set \( \Lambda = 1/a_0 \). At leading \( (\ln^2) \) order, the two terms in the self-energy compensate each other exactly in Eq. (9.19) and the mass does not renormalize, \( m^*/m \to 1 \) at \( k \to 0 \), while the quasiparticle spectral weight vanishes as \( Z \sim \ln^{-2}(\Lambda/k) \). The RG analysis of the dynamically screened interaction at large \( N \) was carried out by Nandkishore and Levitov, 2010c, where subleading (single log) contributions were collected. These were found to cause a (weak) increase of the effective mass \( m^*/m \approx 1 + [0.56/(N\pi \ln 4)] \ln \Lambda \), and consequently an increase of the compressibility.

Once again, the validity of a two band model rests on the assumption that all relevant energy scales are small compared to \( t_\perp \approx 0.4\text{eV} \). However the Coulomb energy \( \Delta E \) on the scale of \( a_0 = \epsilon_0/\langle m^2 \rangle \) is substantial for not too strong dielectric screening, \( \Delta E = \epsilon^2/(\epsilon_0 a_0) \approx 1.47/\epsilon_0^2 \text{eV} \) (Nandkishore and Levitov, 2010a,c). Hence, Coulomb interactions can promote electronic transitions among the four bands, while the two-band model is only justified in the limit \( \Delta E < t_\perp \). To what extent the two band model provides a valid description of the quasiparticles in the presence of Coulomb interactions is a matter of ongoing discussion.

C. Many-body instabilities

The finite DOS in the bilayer enhances the possibility of many body instabilities in comparison with the single layer case. For instance, the spin polarization tensor in the bilayer is defined in leading order by Eq. (5.4), with the matrix element \( \hat{A}^\dagger(k) = 1 + s \sum_{\alpha=\pm} (k^2_\alpha/k^2) \sigma_{\alpha} \). In matrix form,

\[
\Pi^{(1)}_{++} = \begin{pmatrix} \Pi^{(1)}_{++} & \Pi^{(1)}_{+b} \\ \Pi^{(1)}_{b+} & \Pi^{(1)}_{bb} \end{pmatrix},
\]

(9.21)
which leads to one ferromagnetic, and one antiferromagnetic eigenstate, \( \Pi^{AF}_{F/A} = \Pi_{aa} \pm \Pi_{ab} \), by symmetry under exchange of the \( a \) and \( b \) labels. In bilayers the AF state has a leading logarithmic divergence with the cut-off, \( \Lambda \), at zero frequency and magnetic field, (Nilsson et al., 2006)

\[
\Pi^{(1)}_{AF}(q, 0) = \frac{m}{\pi} \ln \left( \frac{2\Lambda}{|q|} \right),
\]

suggesting (within RPA) a tendency towards an AF instability for any value of the Hubbard interaction \( U \). In addition, at finite \( U \), a first order ferromagnetic transition can be driven by the Stoner criterion, leading to a ferromagneto-electric state where the layers have different magnetization and polarized charge (Castro et al., 2008b).

Other possibilities include the emergence of CDW instabilities induced by the short range part of the Coulomb interaction, (Dahal et al., 2010) or else, an excitonic instability at strong local electronic repulsion (Dillenschneider and Han, 2008). With long range Coulomb interactions, the inverse electronic compressibility \( \kappa^{-1} \) becomes negative at small densities (Kusminskiy et al., 2008), indicating a tendency to Wigner crystallization (Dahal et al., 2006), which is compensated by the positive compressibility of the lattice.

Bilayers share similar features with one-dimensional (1D) electron systems, such as the point like Fermi surfaces and the parabolic spectrum. In particular, in biased bilayers, the 1D interface between biased regions confines chiral modes that propagate as in a strongly interacting Luttinger liquid (Killi et al., 2010). This affords the possibility of studying such interacting models experimentally in appropriately prepared samples of bilayer graphene.

For short-ranged interactions in 2D, the structure of the diagrams in bilayers and in 1D electron liquids is quite similar, although the diagrams compensate each other in a rather different way. The dimensionless coupling which determines the strength of the interactions is \( Ua/m \), where \( U \) is the strength of the local interactions, and \( a \) is the lattice constant. Perturbative renormalization group calculations in the bilayer have identified distinct leading instabilities of the electron gas. For different choices of possible interactions, two different low-temperature broken symmetry phases have been found: in one case, a ferroelectric gapped phase (Zhang et al., 2010) induced by the coupling between the different layers; in the other, a nematic phase (Vafek, 2010; Vafek and Yang, 2010), where each Fermi point splits into two Dirac points.

The possibility of an excitonic instability has been also predicted by Nandkishore and Levitov, 2010a, who found that the dynamically screened Coulomb interaction gives rise to a ferroelectric state that polarizes the two layers. In the ferroelectric state, the kinetic energy inflicts an energy cost \( \delta E_{\text{Kinetic}} \propto \Delta^2 \ln(\Delta_E/\Delta) \), where \( \Delta \) is the energy gap. Finite separation between the layers generates an additional electrostatic energy cost to polarize the charge between the layers, which dominates the kinetic energy at the Hartree level, \( \delta E_{\text{Hartree}} \propto \Delta^2 \ln^2(\Delta_E/\Delta) \) (McCann et al., 2007). The excitonic instability is induced by the exchange term, which is parametrically larger than the Hartree term by the factor \( (a_0/d) \), where \( d \) is the interlayer distance (Nandkishore and Levitov, 2010b). The existence of a ferroelectric state has nevertheless been disputed by independent RG calculations, that also accounted for the dynamically screened Coulomb interactions, and infrared trigonal warping effects (Lemonik et al., 2010). The spontaneous symmetry breaking found in this work leads to a Lifshitz transition consistent with the nematic state found by Vafek and Yang, 2010, rather than the opening of a gap.

In the Quantum Hall (QH) state, two terminal measurements of the conductivity in clean suspended samples have found an insulating state at the \( \nu = 0 \) filling factor (Feldman et al., 2009), rather than the metallic QH state previously found in supported samples (Novoselov et al., 2006). Further theoretical works predicted the possibility of a zero field excitonic QH state, which spontaneously breaks time reversal symmetry, and can evolve into a ferromagnetic QH state at finite magnetic field (Nandkishore and Levitov, 2010b). In biased bilayers, a chiral anomaly has been predicted in the QHE, splitting the degeneracy of valley quantum numbers (Nakamura et al., 2009). Another predicted effect resulting from interactions in the QH state is the formation of charge \( 2e \) skyrmions at even filling factors (Abanin et al., 2009).

X. CONCLUSIONS

As we have seen, the understanding of the many-body problem in graphene has evolved quite rapidly in only a few years. The case of monolayer graphene in the weak coupling regime (which means, graphene embedded in an environment with large dielectric constant) is quite clear, namely, although Lorentz invariance is explicitly broken because of the Coulomb interactions, the effective low energy theory is still Lorentz invariant with well defined quasiparticles. Nevertheless, these quasiparticles have a renormalized speed of light that grows logarithmically in the infrared, while their spectral weight decreases slowly in the same limit. This situation can be contrasted with the conventional Fermi liquid picture where all the physical constants (the so-called Landau parameters) and spectral weight are finite in the infrared (that is, at the Fermi surface). Hence, these logarithmic renormalizations are weak enough, even in the presence of strong Coulomb interactions, and a Dirac liquid picture is preserved.

In the strong coupling regime (that is, graphene in vacuum), many-body instabilities are possible albeit depending on a delicate balance of energy scales. This occurs because the renormalizations of quasiparticle properties also depend on details of the cut-off procedure in
the ultraviolet (as it is shown by the $f$-sum rule). While mean-field theories have predicted instabilities towards phases with broken chiral symmetry and superconducting quasi-long range order (because of the 2D nature of the material), and earlier Monte Carlo studies on a hyper-cubic lattice suggest the presence of instabilities (Drut and Lähde, 2009a,b,c), simulations of interacting electrons on the honeycomb lattice have still to be performed in order to address these issues, since the strong coupling regime cannot be reached by perturbative methods. This remains, at this point in time, as an important open problem in many-body graphene physics.

The Coulomb impurity problem in graphene shares many of the issues of the many-body problem but can be studied in much more detail because the 2D hydrogen problem in graphene was solved exactly. In the weak coupling regime (the so-called under-critical regime), the Coulomb interaction between a localized charge and the electrons leads to only mild changes in the physical properties due to the explicitly broken particle-hole symmetry. In the strong coupling (or super-critical) regime, the situation is rather different because of the phenomenon of fall to the center, that is, the electron states become unstable, with the generation of resonances near the Dirac point. Just like the many-body problem, the critical local charge depends on the dielectric environment, and in vacuum this amazing effect should be observed by local probes even for a single proton sitting on the graphene surface. So far, there is no experimental evidence of such effect, given that it is difficult to study adatoms in suspended samples with local probes, such as scanning tunneling microscopes. In supported samples, because of dielectric screening that brings the system to weak coupling, and of the disorder in the substrate, the study of this problem can be much more elusive.

In analogy to the 2DEG problem, the effect of disorder is rather strong in graphene which again is the effect of dimensionality. The low dimensionality implies strong quantum fluctuations that can easily couple to spatial variations of random scalar (chemical potential) and gauge (hopping) fields. Strong localization is the ultimate fate of any disordered two dimensional system but because the localization length grows very slowly in the infrared limit, the finite size of the samples, or the finite temperature of the system, ends up cutting off the tendency towards Anderson localization and, in practical terms, graphene behaves in a metallic way.

The problem of magnetism of adatoms in graphene is rather different from the one found in metallic hosts. Due to the strong energy dependence of the density of states (that vanishes at the Dirac point), the Anderson impurity problem has features that are unique. Firstly, in analogy with the strong coupling regime in the many-body and Coulomb impurity problems, the results are sensitive to the ultraviolet regularization. In fact, this is a generic feature of the Dirac spectrum, namely, strong coupling leads to spectral weight transfer from high energies to low energies, that is, to the Dirac point (as discussed in the context of the $f$-sum rule). Moreover, the damping by Dirac electrons leads to an anomalously large (and strongly energy dependent) broadening of the adatom energy level. This leads to an unusual situation as compared to the Anderson impurity problem in a metal, namely, that even when the chemical potential is above (below) the energy of the doubly (singly) occupied state, a magnetic moment can emerge. Hence, adatoms that may not be magnetic in a metal (hydrogen or fluorine, for instance), might become magnetic in graphene.

On the other hand, the Kondo effect that usually suppresses the appearance of magnetic moments in metals because of magnetic “screening” (the ultimate consequence of the so-called “Kondo cloud”), is strongly suppressed in graphene. This suppression has its roots in the low density of states and the sublattice structure. In fact, there is a strong dependence of the hybridization with the position on the lattice (whether it breaks or not the sublattice symmetry). Furthermore, the Kondo effect is very dependent on the chemical potential (that can be easily tuned in graphene by gating). This state of affairs reinforces the conclusion that magnetic states of adatoms could be more the norm than the exception in graphene, in a big contrast with the situation in ordinary metals. Experimentally, there are very few studies of the magnetism of adatoms in graphene. The main problem here is that most of the experiments done so far are in electronic transport. Just like the Kondo problem in metals and semiconductors, the observation of magnetic effects in transport is rather subtle, and requires careful analysis. At this point in time, this is a rather open field in graphene physics.

A superconducting state in graphene would have dramatic consequences given its low dimensionality and unusual electronic spectrum. While true long range order would not be possible because of its 2D nature, quasi-long range order would have unusual consequences. For one, because of the sublattice structure, there is room for exotic pairing states with even more exotic vortex excitations. The phase space for pairing is rather large due to the spin, sublattice, and valley degeneracies. However, the low density of states plays a deleterious role here. One way out of this conundrum would be the enhancement of the density of states by either gating or doping with adatoms. These two techniques have their own limitations. Gating is limited by the distance from the gate to the graphene sample, and by the dielectric breakdown of the spacer that separates the two. Doping inevitably introduces disorder, or can modify the electronic structure of the $\pi$ band too much leading to extrinsic effects. There are, however, serious hopes that come from the fact that intercalated graphite can be made to superconduct. An obvious idea would be intercalation of Ca or Yb in the graphene bilayer. So far, intercalation experiments in bilayers have not been performed, and very little is known about how to intercalate atoms or molecules in such systems. Again, this is very much an open field of research.
In addition to the dielectric environment, which has a strong influence on many-body effects in bulk graphene, finite size effects are also of great importance. It has been understood very early on that zig-zag edges are strongly interacting because of the high density of states they create at the Dirac point. Systems with high density of states are prone to many-body states due to kinetic and Coulomb energies, bringing a huge degeneracy into play. Once again, the added complication that the 2D nature of graphene brings is magnified because the electronic wavefunctions associated with impurity states do not decay exponentially, as they would in a semiconductor with a finite gap, or would be extended, as in a normal metal, but they are quasi-localized (that is, decay like power law). This implies that evanescent waves play an important role in determining the physical properties. Experiments in mesoscopic graphene samples show very clearly these effects through strong oscillations of the electronic conductance and the presence of Coulomb blockade peaks. From theoretical perspective, such problems are probably the hardest to solve because they involve the direct interplay between Anderson localization and interactions. Thus deeper understanding of mesoscopic graphene systems is still necessary, and this topic would merit a review of its own.

Magnetic fields also lead to spatial localization due to the presence of Landau levels with a length scale given by the cyclotron length. Hence, this problem shares many of the difficulties of the previous problems with the added complication that the 2D nature of graphene brings a huge degeneracy into play. Once again, the detailed balance between kinetic and Coulomb energies, and the details in the ultraviolet, determine the fate of the many-body ground state. The fractional quantum Hall effect was only observed recently in suspended two-probe experiments (Du et al., 2009), and very little is known about the sequence of FQHE fractions and their nature. It is believed that magnetic fields can generate a plethora of new many-body states, with symmetries that are rather different from the ones found in the 2DEG. But, compared to the 2DEG problem, this field is still in its infancy.

While we have demonstrated the complexity of the many-body problem in monolayer graphene, we have not even touched beyond the surface of the many-body problem in bilayer graphene. There is no doubt, at least from the theoretical perspective, that the many-body problem in the bilayer is much richer than in the monolayer. For one, the bilayer has a finite density of states at neutrality, making it similar to the 2DEG problem. However, unlike the 2DEG, the graphene bilayer is a Lorentz invariant system with a finite “rest mass” (that is, it has a hyperbolic dispersion relation) albeit with an accidental degeneracy that makes it a semi-metal (two of the four bands touch at the Dirac point). This accidental degeneracy can be lifted very easily by hopping or interactions, leading to a huge number of possible many-body states with different quantum numbers. Given this richness one can venture saying that bilayer graphene is the ultimate target of many-body theorists in this field. However, it is technically a major challenge given the high dimensionality of the problem, with its 2\textsuperscript{4}-dimensional spinorial structure (spin, valley, sublattice, and plane). Moreover, from the experimental perspective many details and conditions are still quite uncontrolled, which has led to a few contradictory results, and has so far yielded more questions than answers. In fact, both theoretically and experimentally, the graphene bilayer remains very much an open problem. If we now extrapolate from the monolayer to the bilayer, we see that there are problems that have not even been addressed theoretically and experimentally, like the Anderson impurity problem, or the Kondo effect in bilayers, the problem of magnetism, and superconductivity, just to mention some. These are topics for the future, for future generations of physicists to address and marvel.

Acknowledgments

We are indebted to our collaborators, friends and colleagues for their many invaluable contributions, discussions, comments, and suggestions. In particular we want to explicitly thank E. Andrei, Y. Barlas, S. Das Sarma, V. Fal’ko, M. M. Fogler, E. Fradkin, A. Geim, M. Goerbig, J. Gonzalez, I. Herbut, M. I. Katsnelson, P. Kim, A. Lanzara, J. Lopes dos Santos, A. MacDonald, E. Mucciolo, J. Nilsson, K. Novoselov, N. Peres, S. Sachdev, O. Sushkov, O. Vafek, S. Viola, M. A. H. Vozmediano, and A. Yacoby.
