I. INTRODUCTION

In community detection, the goal is to regroup nodes of an observed network into different groups (or communities) of nodes believed to be similar, and thus to find a meaningful partition of the network. The assumption that this is possible comes from the hypothesis that the structure of the graph reflects hidden attributes of the nodes, that can therefore be inferred. Though recent studies show that such an assumption does not hold in general for real networks [1], generative models with this property, such as the stochastic block model [2] (SBM), have proved the efficiency of community detection algorithms [3]. Different classes of community detection algorithm exist: among the popular approaches, algorithms relying on Bayesian inference fit the parameters of an assumed generative model to the observed network [3, 4], while spectral algorithms find communities of an assumed generative model to the observed network [5, 6].

The hypothesis most commonly made is that of assortative networks, which means that nodes with the same hidden attributes are more likely to be linked than nodes with different attributes. Under this hypothesis of assortative networks, a popular measure of the goodness of a partition is the modularity, and therefore various community detection algorithms rely on modularity maximization [7–10]. Recently the authors of [11] (called ZM hereafter) introduced such an algorithm that avoids the common pitfall of overfitting: indeed maximizing modularity predicts communities even in unstructured (i.e. random) networks. The only free parameters in the mod-bp algorithm are the number of groups \( q \) and a temperature-like parameter \( T \). Three ranges of temperatures are identified that correspond to phases in which the algorithm has qualitatively different behaviours: at high temperatures no division in groups is found, at intermediate temperatures meaningful groups are found and for low enough temperatures the algorithm does not converge. In this paper, we broaden the picture given in ZM by showing that there are in general more than three phases. We show that despite passing to the mod-bp algorithm the number \( q \) of groups, it can spontaneously return a partition with a smaller number of groups \( \hat{q} < q \). We introduce a new set of order parameters that allows to determine \( \hat{q} \), and observe both on synthetic and real networks the existence of phases with different values of \( \hat{q} \in \{1, q\} \), which were unknown before. We discuss how to interpret the results of mod-bp and how to make the optimal choice for the problem of detecting significant communities.

\[ Q(\{t\}) = \frac{1}{m} \left( \sum_{(ij) \in E} \delta_{t_i, t_j} - \sum_{(ij)} \frac{d_i d_j}{2m} \delta_{t_i, t_j} \right), \]  

where \( \delta \) is the Kronecker delta function. High values of modularity indicate that there are more edges between nodes of the same group than between nodes of differ-
ent groups: thus, the higher the modularity, the better the partition. The advantage of modularity is that it makes no assumption on the way the network was generated, but only that it has an assortative structure. This encourages its use on real networks, in which the true generative process is generally unknown, and has lead to several algorithms performing community detection by maximization of modularity [7–10].

One drawback of modularity is that finding the partition with highest modularity is a discrete combinatorial optimization problem [13], which becomes rapidly intractable as $N$ increases; so effective heuristics have to be developed. Another drawback is that modularity maximization is prone to overfitting: it is possible to find high-modularity partitions even in Erdős-Rényi random graphs [14] although by construction they do not contain an underlying group structure [15–17]. Finally, there exists a fundamental resolution limit [18], that prevents from recovering small-sized groups.

ZM introduces a new community-detection algorithm based on modularity maximization, tackling the two first mentioned drawbacks, and proposing a multi-resolution strategy to overcome the third. The algorithm, called mod-bp , is scalable, i.e. is of polynomial complexity with respect to $N$, and the authors show that it does not overfit, in the sense that it does not return high-modularity partitions for Erdős-Rényi networks.

This is achieved by treating modularity maximization as a statistical physics problem with an energy

$$E(\{t\}) = -mQ(\{t\}) \quad (2)$$

at a finite temperature $T = \frac{1}{\beta}$. In this way, every partition $\{t\}$ is given a probability taken from the Gibbs distribution

$$P(\{t\}) = \frac{1}{Z} e^{-\beta E(\{t\})}, \quad (3)$$

where $Z$ is the partition function

$$Z = \sum_{\{t\}} e^{-\beta E(\{t\})}. \quad (4)$$

To solve the problem of sampling from the Gibbs distribution (3), ZM proposes a belief propagation (BP) algorithm [19 20], in which so-called messages $\psi_i \rightarrow k$ are sent between all pairs of nodes $\langle ik \rangle$, for $q$ different groups $t$. We refer the reader to ZM for a precise description of the algorithm. After convergence of the BP algorithm, marginals $\psi_i^t$ are obtained from the messages. $\psi_i^t$ represents the probability that node $i$ belongs to group $t$, and the most-likely group for node $i$ is therefore:

$$\hat{t}_i = \arg \max_t \psi_i^t. \quad (5)$$

Using this maximization, the maximum a posteriori modularity $Q_{\text{MAP}}$ corresponding to the assignment $\{t\}$ can be calculated as

$$Q_{\text{MAP}} = Q(\{\hat{t}\}). \quad (6)$$

As the algorithm samples from the distribution (3), one can also define an average modularity $Q_{\text{MARG}}$ that is calculated from the marginals instead of the most-likely partition, and which is proportional to the average energy of the model

$$Q_{\text{MARG}} = \frac{1}{m} \frac{\partial}{\partial \beta} \left( \sum_i \log Z_i - \sum_{\langle ij \rangle \in E} \log Z_{ij} + \frac{\beta}{4m} \sum_i \theta_i^2 \right),$$

where $Z_i$ and $Z_{ij}$ are the normalizations of the marginals and the two-point correlation functions respectively, and $\theta_i = \sum_{j=1}^N d_j \psi_i^j$.

While the problem of maximizing modularity is equivalent to finding the ground state of (2), sampling from (3) at a finite temperature corresponds to minimizing the corresponding free energy. This means taking into account not only the modularity, but also the entropy, counting the number of partitions with a given modularity. In this way, instead of focussing on a single partition, mod-bp at finite $T$ returns a partition that is a good consensus of the many existing high-modularity partitions, as advocated in [21].

II. PHASE TRANSITIONS

As in numerous statistical physics problems, (3) may lead to phase transitions at some given temperatures. Using modularity as an energy function is similar to study a Potts-like statistical mechanics problem [22], for which Ref. [23] has shown that a phase transition is always present. ZM reports that temperature ranges define three different regimes of the algorithm. At very low temperatures, the system is in a spin glass phase, in which the algorithm does not converge to a fixed point. At high temperature, the system is in a paramagnetic phase in which the fixed point is trivial and all nodes have an equal probability $1/q$ of belonging to any of the groups. In networks with statistically significant communities, there is an intermediate temperature range called recovery phase, in which the algorithm converges to a non-trivial fixed point, from which group assignments can be obtained using (5).

Here, we broaden this picture by showing that the recovery phase itself can be divided in up to $q - 1$ phases, with $2 \leq q \leq q$. At a temperature separating two phases, there is an order parameter that becomes vanishingly small, increasing $T$, and the number of iterations needed by the algorithm to reach the fixed point diverges.

A. Model-based critical temperatures

Modularity as a measure of goodness of a partition is particularly appealing for real networks, because it makes no assumption about an underlying model that generates the network. Though appealing, this absence of model is problematic when it comes to determining the
best temperature at which to run mod-bp (i.e. there is not Bayes optimal temperature). In ZM two generative models are analyzed, allowing to find two useful characteristic temperatures:

1. In the configuration model, a network is built by randomly creating links between nodes of known degree, until all nodes have the right number of neighbours. ZM shows that in this model, the phase transition between the spin-glass and the paramagnetic phase takes place at

$$T^* = \left( \log \left( \frac{q}{\sqrt{c - 1}} + 1 \right) \right)^{-1},$$

where $c$ is the average excess degree, calculated from the average degree $\langle d \rangle$ and the average squared degree $\langle d^2 \rangle$, and given by

$$c = \frac{\langle d^2 \rangle}{\langle d \rangle} - 1.$$

2. In the stochastic block model (SBM) [2], the nodes are grouped into $q^*$ equal-sized groups, and for each pair of nodes $\langle ij \rangle$, a link is created with probability $p_{rs}$ if $i$ belongs to group $r$ and $j$ belongs to group $s$. In the most simple case, we take $p_{rs} = p_{\text{out}}$ if $r \neq s$ and $p_{rs} = p_{\text{in}}$ if $r = s$. One often considers networks with sparse connectivity, i.e. the average number of links between a node $i$ from group $r$ and all the nodes from group $s$, $c_{rs}$, does not grow with the size of the network. ZM shows that mod-bp is as successful as a Bayes-optimal algorithm [24] and that the transition between the paramagnetic phase and the recovery phase takes place at

$$T_R(\epsilon) = \left( \log \left( \frac{q(1 + (q - 1)\epsilon)}{(c(1 - \epsilon) - (1 + (q - 1)\epsilon))} + 1 \right) \right)^{-1},$$

where $\epsilon = p_{\text{out}}/p_{\text{in}}$.

For real networks, the stochastic block model is usually a bad model, and the recommendation of ZM is to run the algorithm at $T^*$, which seems to always lie inside of the recovery phase. We can also note that the $\epsilon \to 0$ limit of [9].

$$T_0 = \left( \log \left( \frac{q}{c - 1} + 1 \right) \right)^{-1}$$

is a useful upper bound for $T$. Indeed, above this temperature, the algorithm converges to the paramagnetic solution even for networks composed of disconnected components, and is therefore useless.

**B. Degenerate groups**

In the paramagnetic phase, the marginal $\psi_i^t$ of every node $i$ of the network is equal to $\frac{1}{q}$ for all $t$, up to some minor fluctuations due to the numerical precision of the machine or incomplete convergence of the algorithm. Due to those fluctuations, calculating a retrieval configuration with [5] is in general still possible, and would lead to a very small but non-vanishing retrieval modularity $Q^\text{MAP}$.

However, the meaning of the paramagnetic phase is that all groups are strictly equivalent or degenerate, and therefore $Q^\text{MAP}$ should be exactly zero. In order to obtain this, the algorithm has to check for degenerate groups before assigning a group to each node, and assign the same “effective” group to nodes for which the maximization [5] leads to different, but actually degenerate groups.

To check if groups are degenerate, we can look at the following distance between two groups $k$ and $l$:

$$d_{kl} = \frac{1}{N} \sum_{i=1}^{N} (\psi_k^i - \psi_l^i)^2.$$

If $d_{kl}$ is smaller than a chosen threshold $d_{\text{min}}$, we can consider that group $k$ and group $l$ are degenerate and that they should not be distinguished.

An effective number of groups, $\hat{q}$, can then be defined as the number of distinguishable groups. We can define a mapping $\phi$ between the $q$ groups used by the algorithm and the $\hat{q}$ distinguishable groups: for each group $k$, $\phi(k)$ is an integer between 1 and $\hat{q}$ representing one of the effective groups, and

$$\forall (k, l),\; \phi(k) = \phi(l) \iff d_{kl} < d_{\text{min}}.$$

With this mapping, we replace the group assignment pro-
FIG. 2. Matrices of distances between groups for different temperatures. The dataset is “political books”, the algorithm is run

with $q = 6$ for $T = 0.26, 0.9, 1.0, 1.25, 2.1, 2.3$ (from left to right). We observe the formation of a growing cluster of groups that

are equivalent, allowing us to define a number of effective groups $\hat{q}$, that varies from 6 at low temperature (left) to 1 in the

paramagnetic phase (right). Note that the area of the squares is not related to the number of nodes contained in the groups.

cedure (5) by

$$i_t = \phi \left( \arg\max_t \psi_t^i \right).$$

(13)

With this assignment procedure, $Q_{MAP}^q$ is strictly zero in the

paramagnetic phase, because all nodes belong to the same group.

Fig. 1 shows that choosing a threshold $d_{\text{min}}$ is meaningful because $d_{kl}$ undergoes a phase transition at which it sharply drops of several orders of magnitude.

Interestingly, group degeneracy is not only observed in the paramagnetic phase, but also inside the retrieval phase. In that case, not all groups are degenerate, but only a subset of them. Fig. 2 shows this for the popular network “political books” [25], on which mod-bp was run at different temperatures.

III. EXISTING DOMAINS OF PHASES

Thanks to the group assignment procedure in Eq. (13), up to $q + 1$ phases can exist for any network on which mod-bp is run with $q$ groups: one for each $\hat{q} \in \{1, q\}$, plus a spin glass phase. Fig. 2 shows this for the network “political books”. On this network, several phases coexist at low temperature, whereas for higher temperatures, the phases exist in well separated temperature intervals. In the latter case, we can define a ‘critical’ temperature $T_k$, separating the phase with $\hat{q} = k$ from the one with $\hat{q} = k + 1$. As can be seen on Fig. 3, the number of iterations needed for mod-bp to converge greatly increases around these critical temperatures. As noted before, $T_0$ is a good reference temperature, and normalizing all temperatures by $T_0$ is a good way to compare critical temperatures $T_k$ for the same network with different $q$ values, and also for comparing different networks.

A. Location of critical points $T_k$

In some cases, a subset of $n$ critical temperatures $T_k$ can be degenerate, in which case there is a phase transition between a phase with $\hat{q} = k$ and a phase with $\hat{q} = k + n$. For instance, this is the case in networks

FIG. 3. (Color online) Modularities and numbers of effective groups $\hat{q}$ obtained by sweeping a temperature range from 0 to 1.2 $T_0$ on the dataset “political books” with $q = 6$. The vertical lines indicate the positions of $T^*$ (left) and $T_0$ (right). Above $T^*$, the changes in $\hat{q}$ define quite homogeneous phases, separated by sharp transitions, where the number of iterations necessary to reach convergence increases greatly. Below $T/T_0 \approx 0.4$, the phase is not homogeneous: depending on the starting conditions, $\hat{q}$ can be 4, 5 or 6. Note that $Q_{MAP}^q$ increases only minimally when $\hat{q}$ exceeds 3, which agrees with the fact that $q^* = 3$. 
generated by the stochastic block model with the same in-connectivity $p_{nn}$ inside each of the $q^*$ groups (Fig. 4 above). This agrees with the description of the three phases given in ZM.

In contrast, in networks generated by the SBM with $p_{rr} \neq p_{tt}$ if $r \neq t$, the degeneracy is lifted (Fig. 3 below). The figure also shows that, starting above $T_0$ (i.e. in the paramagnetic phase) and lowering the temperature, the groups are inferred in order of their strength.

To show this, we use the recall score for different groups, which allows to see if one of the inferred groups corresponds well to a given real group. To quantify the similarity between a real group $G$ and an inferred group $\hat{G}_i$, that are not necessarily of the same size, we can use the Jaccard score $[1]$, which is defined by:

$$J(G, \hat{G}_i) = \frac{|G \cap \hat{G}_i|}{|G \cup \hat{G}_i|}. \quad (14)$$

The recall score is the maximum of the Jaccard score:

$$R(G) = \max_i J(G, \hat{G}_i). \quad (15)$$

A recall score close to 1 means that one of the inferred groups $\hat{G}_i$ is almost identical to group $G$. Fig. 4 (below) therefore shows that around $T/T_0 = 0.7$, the group with the biggest in-connectivity is nearly exactly recovered by one of the groups returned by the algorithm, whereas the two groups with lower in-connectivity are not. Only by further lowering temperature, when $\hat{q} = 3$, all the groups are correctly inferred.

### B. Running mod-bp with $q \neq q^*$

On networks generated with the SBM, the real number of groups $q^*$ is known, and it is thus interesting to look at what happens when mod-bp is run with $q \neq q^*$. The behaviour for $q = q^*$ is described in ZM and in Fig. 4. If $q < q^*$, mod-bp cannot return the right number of groups, and will merge some of the real groups together so as to obtain $q$ groups. The more interesting case is when $q$ is bigger than $q^*$.

First of all, the range of temperatures of the spin glass phase grows as $q$ increases. If $\epsilon$ is only slightly above the detectability threshold $\epsilon^* [24, 26]$, increasing $q$ can lead to a situation where there is no recovery phase, between the paramagnetic phase and the spin-glass phase.

However, we will focus on the case when $\epsilon$ is small enough for intermediate phases to be present. As described previously, the phase transitions are degenerate if $p_{nn}$ is the same for all groups. Therefore, we generally observe only one intermediate phase, with $\hat{q} = q^*$. However, this is not always the case and mod-bp can return partitions with different $\hat{q}$ values, depending on the initialization, similarly to what is observed on the real network in Fig. 3. Two phenomena can be observed, separately or simultaneously.

The first phenomenon is the one with $\hat{q} = q^* + 1$, where $q^*$ of the groups correspond very well to the real groups, and the last group contains only a very small fraction of nodes. Depending on the initialization, this last group can even contain no node at all, in which case it can be simply discarded. This phenomenon is likely to come from the stochasticity of the SBM and is observed also for large networks with $10^5$ nodes. The modularity of those partitions is equal to, or slightly higher than those found in the $\hat{q} = q^*$ phase of mod-bp run with $q = q^*$, which explains why they are found. On the other hand, we have never observed more than one of these additional, and almost empty, groups, such that $\hat{q}$ is always at most equal to $q^* + 1$. 

![Degeneracy of $T_{hs}$ on networks generated by the SBM with $N = 5000$, $q^* = 3$ and $c_{\text{out}} = 2$. mod-bp was run with $q = 3$. Top: group 1 has higher in-connectivity than the two others: $c_{11} = 30$ whereas $c_{22} = c_{33} = 15$. $T_1$ and $T_2$ are distinct, and from the recall scores we see that only group 1 is detected between $T_1$ and $T_2$, whereas groups 2 and 3 have an equally low recall score, as in the partition given by the algorithm, they are merged to a single group. Below $T_2$, $\hat{q} = 3$ and the algorithm separates groups 2 and 3. Bottom: all 3 groups have the same in-connectivity $c_{\text{in}} = 30$. There is no $\hat{q} = 2$ phase because $T_1$ and $T_2$ are degenerate. For both experiments, the spin-glass phase is not reached.](image-url)
The other phenomenon is that of distinct groups merging together in the retrieval partition, leading to $q < q^*$. Such partitions have lower modularity than partitions with $q = q^*$ (found at same temperature from a different initialization), showing that the algorithm is unable to correctly maximize the modularity starting from any initialization. This is likely due to the existence of “hard but detectable” phases [21], in which frozen variables cause algorithms to be stuck in suboptimal solutions. A simple way out from this problem is to run the algorithm several times with different initial conditions, selecting finally the configuration of higher modularity found.

These two effects might coexist, and produce retrieval partitions in which two of the real groups are merged into a single one, and an additional group containing very few or even no nodes at all is also present. In this case $q = q^*$, but the retrieval partition is not the right one. So the existence of of an almost empty group should be considered as a warning on the reliability of the mod-bp result.

C. Results on real networks

For community detection on real networks, $q^*$ is in general unknown and there is no available ground truth. From Fig. 4 and the previous section, we know that mod-bp can converge to partitions with different $q$ at the same temperature, depending on the initialization. This motivates us to run mod-bp several times for each temperature, which allows us to quantify the probability a given $q$ is found at any given temperature $T$. Fig. 6 shows the coexistence of phases in the “political books” [25] and “political blogs” [27] datasets for different values of $q$. The analysis made in these figures is similar to the one proposed in [28] for multiresolution community detection.

These figures suggest that, at a given normalized temperature $T/T_0$, the results returned by mod-bp only marginally depend on the chosen $q$ as long as $q > q^*$. Moreover we observe that, within a phase with a given number $q$ of groups found, the partition $\{t\}$ only marginally depends on the temperature $T$. Averaging over the several partitions found at different temperatures and with different initial condition, we show in Fig. 6 and 7 that $Q_{\text{MAP}}$ depends essentially on $q$, and only minimally on $q$. As in ZM, we consider that the largest $q$ leading to a significant increase of $Q_{\text{MAP}}$ w.r.t. $q - 1$ is a plausible estimate of $q^*$, which agrees well with the commonly accepted “ground truths” of $q^* = 3$ for “political books” and $q^* = 2$ for “political blogs”.

In Fig. 7 we also show the distribution of overlaps between randomly chosen partitions with the same $q$. The overlap between two partitions $\{t\}$ and $\{s\}$ is a number between zero and one and is defined as

$$O(\{t\}, \{s\}) = \max_{\sigma} \left( \frac{1}{N} \sum_{i=1}^{N} \delta_{t_i, \sigma(s_i)} \right),$$

where the maximum over all permutations $\sigma$ of $\{1, \ldots, q\}$ allows to lift the permutation symmetry of the group numbering choice. The closer the overlap between two partitions is to one, the more similar they are. Fig. 7 thus shows that partitions with the same $q$ are very similar to one another, independently of the two parameters.
is that the \( \hat{q} \) have essentially the same modularity. So the conclusion is roughly 380+280+40 nodes. All these configurations may be worried about the double peak structure of the \( \hat{q} = 3 \) case and wondering whether the two peaks do actually correspond to different communities structures. We have looked at the groups partitions returned by the algorithm and found the following. There is always a well conserved group of 520 to 530 nodes, while the remaining roughly 700 nodes can be clustered in different ways: for \( \hat{q} = 3 \), there are 2 different partitions with roughly 600+100 and 500+200 nodes; for \( \hat{q} = 4 \), the partition is roughly 380+280+40 nodes. All these configurations have essentially the same modularity. So the conclusion is that the \( \hat{q} = 2 \) partition (320+700 nodes) is significant, while further splitting of the cluster of 700 nodes is not very meaningful.

**IV. DISCUSSION**

Apart from the advantage of not requiring the knowledge of the generative model, a further advantage of mod-bp is that it has only two adjustable parameters, \( T \) and \( q \). However, for a given network, it is not clear how to choose them in order to obtain the optimal partition. The recommendation of ZM is to run mod-bp at \( T^* (q) \), defined in Eq. (7), for increasing values of \( q \), until it does not lead anymore to a significant increase in modularity. Based on the experiments on synthetic and real networks presented in this work, we conclude that an important additional step in this procedure is to calculate the effective number of groups \( \hat{q} \) of each partition returned by the algorithm, which can be different from \( q \). Furthermore, this phenomenon leads to a new rule for assigning a group to each node, given that some groups might be merged, which also affects the modularity.

Another possible way to proceed is to run mod-bp with a large value of \( q \), and sweep the temperature scale from \( T_0(q) \) downwards. As \( T \) is lowered, the network is clustered into an increasing number of effective groups \( \hat{q} \), and the found partitions have increasing modularities. Again, the procedure can be stopped once the modularity does not increase anymore in a significant way as \( \hat{q} \) is increased.

For real networks, where the generating process is in general not known and not as straightforward as in the SBM, the number of groups to cluster the nodes is in part let as a choice to the user. In this case, running mod-bp with a quite large value of \( q \) and using \( T \) as the parameter to search for the optimal partition seem both desirable and efficient. To make the optimal choice, in addition to the value of the modularity of a partition with \( \hat{q} \) groups, the range of temperatures where this \( \hat{q} \) phase exists might indicate how relevant it is (as shown in Fig. 5). In particular, if a \( \hat{q} \) phase only exists on a narrow range of temperatures, then it is likely to be less important, because less stable with respect to changes in the model parameter (\( T \) in the present case).

Furthermore, as seen on graphs generated by the SBM, it may occur that some group contains a very small number of nodes. In this case, merging them with bigger groups will only slightly change the modularity and result into a more meaningful and stable partition.
V. CONCLUSION

In this paper, we have studied the mod-bp algorithm proposed in Ref. [11], focusing on the influence of the choice of the two adjustable parameters $q$ and $T$, on both real and synthetic networks. We have given a more precise picture of the algorithm behaviour by identifying new order parameters that allow to define several different phases inside the recovery phase. In each of these phases, mod-bp clusters the nodes into a different number of groups $\hat{q}$. These phases can either be well separated on the temperature scale and be accompanied by a divergence in the number of iterations of the algorithm, or coexist on in the low temperature regime. The partitions with the same number $\hat{q}$ of groups typically have high overlaps among them and very similar modularities. We have proposed a normalized temperature scale $(T/T_0)$ on which mod-bp has a very similar behavior for different values of $q$. These findings provide a broader description of the mod-bp algorithm behaviour, showing its robustness and effectiveness. Hopefully they can be very useful when mod-bp is run on real networks where the ground through is unknown.

Real network may have hierarchical structures [25–31] and the deeper understanding of the different recovery phases achieved in this work may help in using the temperature as a simple parameter to study by mod-bp different levels of the hierarchical clustering. The different levels of clustering hierarchy may correspond to recovery phases with different values of $\hat{q}$, obtained decreasing the temperature.
