Abstract

Ultra-faint dwarf galaxies (UDFs) are the faintest known galaxies, and due to their incredibly low surface brightness, it is difficult to find them beyond the Local Group. We report a serendipitous discovery of a UFD, Fornax UFD1, in the outskirts of NGC 1316, a giant galaxy in the Fornax cluster. The new galaxy is located at a projected radius of 55 kpc in the south–east of NGC 1316. This UFD is found as a small group of resolved stars in the *Hubble Space Telescope* images of a halo field of NGC 1316, obtained as part of the Carnegie-Chicago Hubble Program. Resolved stars in this galaxy are consistent with being mostly metal-poor red giant branch (RGB) stars. Applying the tip of the RGB method to the mean magnitude of the two brightest RGB stars, we estimate the distance to this galaxy, 19.0 ± 1.3 Mpc. Fornax UFD1 is probably a member of the Fornax cluster. The color–magnitude diagram of these stars is matched by a 12 Gyr isochrone with low metallicity ([Fe/H] ≈ −2.4). Total magnitude and effective radius of Fornax UFD1 are $M_V \approx −7.6 \pm 0.2$ mag and $r_{\text{eff}} = 146 \pm 9$ pc, which are similar to those of Virgo UFD1 that was discovered recently in the intracluster field of Virgo by Jang & Lee. Fornax UFD1 is the most distant known UFD that is confirmed by resolved stars. This indicates that UFDs are ubiquitous and that more UFDs remain to be discovered in the Fornax cluster.

Key words: galaxies: abundances – galaxies: clusters: individual (Fornax UFD1) – galaxies: dwarf – galaxies: stellar content

1. Introduction

Ultra-faint dwarf galaxies (UDFs) are the faintest known galaxies (McConnachie 2012; Belokurov 2013; Martin et al. 2016). Some of them are even fainter than typical globular clusters, albeit they are much more extended than the latter. Dwarf galaxies fainter than $M_V = −8.0$ mag and larger than $r_{\text{eff}}$ (effective radius) = 20 pc are often called UDFs (Bechtol et al. 2015). They are optically feeble, but they are dominated by dark matter, having very high values of mass-to-light ratios (Simon & Geha 2007; McConnachie 2012). Thus, nearby UDFs may be ideal laboratories to explore the particle properties of dark matter (e.g., Calabrese & Spergel 2016). Stellar populations in UDFs are mostly old metal-poor stars, Brown et al. (2014) found, from deep photometry of six UDFs around the Milky Way Galaxy, that formation of the stars in these galaxies was finished by 11.6 Gyr ago ($z \approx 3$). They suggested that this early quenching of star formation might have been due to global processes such as the reionization of the universe. Thus, UDFs are considered to be fossils of the first galaxies (Bovill & Ricotti 2011a, 2011b; Jang & Lee 2014; Ricotti et al. 2016). Recently Ricotti et al. (2016) suggested, from high-resolution simulations of the first galaxies, that some UDFs may be the remnants of a few distinct star clusters that were dissolved and expanded to the size of UDFs.

UDFs may be the most abundant type of galaxies in the universe, but they are revealing today only a tiny tip of a giant iceberg to our current observational facilities (McConnachie 2012; Sand et al. 2012; Belokurov et al. 2014; Jang & Lee 2014; Laevens et al. 2014; Dark Energy Survey Collaboration et al. 2016). They were first discovered, as a small overdensity of resolved red giant stars, around the Milky Way Galaxy from the Sloan Digital Sky Survey data, and more of them were found later around M31 in the Local Group (Willman et al. 2005a, 2005b; McConnachie 2012; Sand et al. 2012; Belokurov et al. 2014; Laevens et al. 2014; Martin et al. 2016). With the recent advent of the Dark Energy Camera on CTIO 4 m telescope, as many as 17 new UDFs have been discovered around the Milky Way Galaxy and the Large Magellanic Cloud in 2015 (Bechtol et al. 2015; Drlica-Wagner et al. 2015; Kim et al. 2015; Koposov et al. 2015; Dark Energy Survey Collaboration et al. 2016). It is expected that more UDFs will be discovered in the Local Group soon from current and future wide-field surveys (e.g., LSST, PANStarrs, etc.). UDFs in the Local Group can play an important role to help resolve the well-known missing satellite dwarf problem (Moore et al. 1999) and understand the nature of the first galaxies. However, it is very difficult to find UDFs outside the Local Group with the current observational facilities. Therefore, little is known about the UDFs outside the Local Group.

Surprisingly, Jang & Lee (2014) discovered one UFD, Virgo UFD1, in the intracluster field of the Virgo cluster, using deep images of the *Hubble Space Telescope (HST)* available in the MAST archive. Virgo UFD1 was found as a resolved stellar overdensity. Virgo UFD1 is the first UFD found beyond the Local Group. Total magnitude and effective radius of Virgo UFD1 are $M_V \approx −6.5 \pm 0.2$ mag and $r_{\text{eff}} = 81 \pm 7$ pc, and its central surface brightness is as low as $\mu_{V,0} = 26.37 \pm 0.05$ mag arcsec$^{-2}$. Metallicity of the stars in this
galaxy is estimated from their colors, to be, on average, very low, [Fe/H] = −2.4 ± 0.4. Virgo UFD1 is located at the distance of 16.4 ± 0.4 Mpc, being the most distant UFD at the time of discovery. Later, Crnojević et al. (2016) reported detection of one UFD in the remote halo of NGC 5128 (Cen A), a massive elliptical galaxy at the distance of 3.8 Mpc. They used the images obtained as part of the Panoramic Imaging Survey of Centaurus and Sculptor (PISCeS) at the Magellan 6.5 m telescope.

In this Letter, we report a serendipitous discovery of a UFD, Fornax UFD1, breaking the distance record of Virgo UFD1. It is located in the outskirts of NGC 1316, a giant galaxy in the Fornax cluster. Fornax UFD1 was detected as a small group of resolved stars in the HST/ACS images for a halo field of NGC 1316, obtained as part of the Carnegie-Chicago Hubble Program (CCHP; Beaton et al. 2016).

2. Data

The CCHP is an ongoing program to estimate the value of the Hubble constant \( H_0 \) with high precision using the Population II distance indicators, using RR Lyrae and the tip of the red giant branch (TRGB; Beaton et al. 2016). As part of the CCHP, deep F606W and F814W images of a halo field in the outskirt of NGC 1316 using HST/ACS were obtained. Total exposure times for F606W and F814W are 14,676 and 24,396 s, respectively. These data were used for estimation of the distance to NGC 1316 using the TRGB (Lee et al. 1993), and detailed analysis of the data is given in I. S. Jang et al. (2017, in preparation). We use photometry of the point sources derived from these images by Jang & Lee (2017). The magnitudes of the point sources in the images were derived using DAOPHOT (Stetson 1994). In this study, we adopted a distance to NGC 1316 based on the TRGB, given in I. S. Jang et al. (2017, in preparation): \( (m − M)_0 = 31.45 ± 0.05 \text{(ran)} ± 0.06 \text{(sys)} \) and \( d = 19.5 ± 0.5 \text{Mpc} \).

3. Results

3.1. Discovery of a New UFD

First, we searched for any dwarf galaxies with low surface brightness in the HST images of NGC 1316, which would appear to be similar to the morphology of Virgo UFD1 (see Figure 1 in Jang & Lee 2014). Since the Fornax cluster is only slightly more distant than the Virgo cluster, it is expected that some of the brightest stars in Fornax UFDs, if any, would be resolved in the deep HST images.

Through visual inspection of the images, we noticed the presence of a small group of faint resolved point sources embedded in diffuse stellar light in the southern part of the HST field (at the position of the small red circle in Figure 1(b)). A zoom-in image of the field centered on the new system in Figure 1(c) shows clearly a faint fuzzy system embedding a small number of resolved stars, the diameter of which is about 4". This new system looks much fainter and smaller than

\[ \text{Figure 1.} \text{ (a) Location of the HST field (square) in the inverted color image of the inner region of NGC 1316 provided in the ESO archive, embedded in the grayscale map of R-band image given by Richtler et al. (2012). North is up, and east to the left. A small galaxy in the north of NGC 1316 is NGC 1317, a dwarf galaxy. The position of the new UFD is denoted by a red circle.} \]

(b) A color image of the HST field. (c) A 15" × 15" section of the HST field centered on Fornax UFD1. Note that most resolved stars in the central region are red giants in this dwarf galaxy.

28 kpc
5" 454 pc
any other typical dwarf galaxies in the Fornax cluster (Ferguson 1989; Mieske et al. 2007; Muñoz et al. 2015). This system turns out to be, indeed, a new UFD, named as Fornax UFD1, as shown below. Fornax UFD1 is located 10.1 (\( \sim 55 \) kpc) south–east of the NGC 1316 center in the sky.

3.2. Color–Magnitude Diagrams (CMDs) of the Resolved Stars in Fornax UFD1

Figure 2(a) displays the CMDs of the resolved point sources in a circular region with \( r < 2'' \) where \( r \) is the projected radial distance from the center of Fornax UFD1. We plotted also the CMD of the control field in the annular region at \( 5'' < r < 15'' \), in Figure 2(b). The area of this control field is 50 times bigger than that of the Fornax UFD1 field. The CMD of the point sources in the control field shows a broad red giant branch (RGB), and these point sources are mostly RGB stars in the halo of NGC 1316 (I. S. Jang et al. 2017, in preparation). We used statistical subtraction to remove the contribution of the foreground and background sources from the CMD in (a), using the CMD of the control field. For this process we used bins with 0.3 mag in both magnitude and color, which is similar to the mean errors of the RGB stars. Figures 2(c) and (d) show two realizations of the control field subtraction. Both CMDs look very similar in general. In the lower panels of Figure 2, we plotted similar CMDs but for Virgo UFD1 (Jang & Lee 2014) for comparison.

There are 12 resolved stars brighter than \( I = 28.5 \) mag in the net CMDs (Figures 2(c) and (d)). The number of field contaminants with \( I < 28.5 \) mag in the area covered by the UFD field is estimated to be 4.8 \( \pm \) 0.3, while there are 15 stars in the area of UFD. Thus, the net number of the member stars in the area of the UFD is estimated to be 10 \( \pm \) 4, which is consistent with the number derived after CMD decontamination. Eight of the 12 stars have a narrow range of colors with \( V - I < 1.4 \), showing a vertical sequence, while three of them show much redder colors than the others. Therefore, these eight stars are considered to show the RGB of Fornax UFD1, while three redder stars are probably foreground or background sources.

Because of the small sample of the RGB stars in the CMD, it is not easy to derive an accurate distance to Fornax UFD1. We estimate approximately the distance to this UFD, assuming that the mean magnitude of the two brightest blue RGB stars in the
Fornax UFD1 is marked by a vertical line in magnitude and color of these two stars are I CMD corresponds to the magnitude of the TRGB. The mean magnitude and color of these two stars are $I = 27.38 \pm 0.14$ mag and $(V - I) = 1.19 \pm 0.03$. This magnitude value is 0.24 mag fainter than the value of Virgo UFD1, $I = 27.14 \pm 0.04$ mag (Jang & Lee 2014; see the lower panels in Figure 2). Applying the TRGB calibration in Jang & Lee (2017) to this TRGB magnitude, we derive a value for the distance to Fornax UFD1, $d = 19.0 \pm 1.3$ Mpc ($(m - M)_0 = 31.37 \pm 0.15$). This value is consistent with the distance to NGC 1316. This shows that Fornax UFD1 is likely to belong to Fornax.

In Figure 2, we overlaid 12 Gyr isochrones for $[\alpha/Fe] = 0.2$ (Fabrizio et al. 2015) and $[Fe/H] = -2.4$ to $-0.4$ in the Dartmouth model (Dotter et al. 2008), which were shifted according to the distance and foreground reddening for Fornax UFD1. Although the number of stars is small, the RGB of UFD1 is, on average, bluer and narrower compared with the RGB of NGC 1316 in the control field. This shows that the mean metallicity of this new UFD is much lower than that of the NGC 1316 halo. The CMD of these RGB stars is matched roughly by the RGB part of the isochrones for low metallicity. It is noted that the RGB of Fornax UFD1 is even bluer than the RGB of the lowest metallicity with $[Fe/H] \approx -2.4$. We estimate roughly the mean metallicity of the RGB stars to be $[Fe/H] \approx -2.4 \pm 0.4$.

### 3.3. Basic Parameters of Fornax UFD1

We constructed radial profiles of surface brightness and cumulative integrated magnitude of Fornax UFD1 using IRAF/ELLIPSE, as plotted in Figures 3(a) and (b). We masked out cosmic rays and background galaxies in the original image and ran the ELLIPSE task adopting a smoothing option of $3 \times 3$ pixel binning. The radial profiles of surface brightness in Figure 3 show a flat core in the inner region at $r < 1''$ and decline rapidly in the outer region, showing that this UFD is a dynamically relaxed system like typical old star clusters. The radial profiles of surface brightness for $r < 4''$ are fitted well by a Sérsic law (Sérsic 1963) with an index $n = 0.54 \pm 0.06$ for V-band and $n = 0.49 \pm 0.07$ for I-band. The effective radius measured at the V-band of this galaxy is $r_{eff} = 1.6 \pm 0.1''$ (146 \pm 9 pc). This value is much larger than that of the typical globular clusters, $r_{eff} \approx 3$ pc. Its central surface brightness for V and I bands corrected for foreground extinction are derived to be $\mu_{V,0} = 25.46 \pm 0.06$ mag arcsec$^{-2}$ and $\mu_{I,0} = 24.66 \pm 0.05$ mag arcsec$^{-2}$, respectively. We derived the radial number density profile of the RGB stars with $I < 28.5$ mag and $0 < (V - I) < 2.0$, choosing an annular

![Figure 3](image_url)

**Figure 3.** Radial profiles of the V-band (open circles) and I-band (open triangles) surface brightness (a) and cumulative integrated magnitudes (b) of Fornax UFD1. The arrows denote the location of the control region. The bands represent the errors. Filled squares with gray bands denote the radial number density profile of the resolved red giant stars ($27 < I < 28.5$ mag and $0 < (V - I) < 2.0$). Dashed lines in (a) represent a Sérsic fit for each band. The V-band effective radius of Fornax UFD1 is marked by a vertical line in (b).

region at $r \approx 20''$ to subtract the field contribution. This profile at $r < 5''$ is similar to the surface brightness profiles, as shown in Figure 3.

The integrated color of Fornax UFD1 for the aperture of $r_{\text{eff}}$ is estimated to be $(V - I) \approx 0.98 \pm 0.05$ ($\langle V - I \rangle_0 \approx 0.95 \pm 0.05$). The integrated color of Fornax UFD1 is consistent with those of early-type dwarf galaxies in Fornax (Mieske et al. 2007), and that of Virgo UFD1 (Jang & Lee 2014).

The radial profiles of $V$- and $I$-band integrated magnitude of this galaxy become approximately constant at $r = 5''$. The integrated magnitude for $r = 5''$ is estimated to be $V = 23.8 \pm 0.2$ mag and $I = 22.5 \pm 0.2$ mag. These values can be considered to be the total magnitudes of Fornax UFD1. Corresponding absolute magnitudes of this galaxy are derived to be $M_V = -7.6 \pm 0.2$ mag and $M_I = -8.9 \pm 0.2$ mag. These results show that this new system is indeed a genuine UFD. We list basic parameters of Fornax UFD1 in Table 1.

4. Discussion

4.1. Comparison with Previous Surveys of Fornax Dwarf Galaxies

Ferguson (1989) published the Fornax Cluster Catalog based on the wide-field photographic survey of Fornax galaxies. Following this, several studies used CCD images to find new fainter galaxies in Fornax and investigate their properties (Kambas et al. 2000; Hilker et al. 2003; Mieske et al. 2007; Muñoz et al. 2015). Kambas et al. (2000) imaged a long strip region from NGC 1399 to NGC 1291 (an area of 13.8 deg$^2$) in Fornax, finding a large number of low surface brightness dwarf galaxies with $M_B < -12.0$ mag. These are unresolved faint galaxies.

Later deeper surveys of the central region in Fornax found a number of fainter dwarf galaxies. The detection limits of the dwarf spheroidal galaxies (dSphs) in the survey of Hilker et al. (2003) and Mieske et al. (2007) are $V \approx 23$ mag ($M_V \approx -8.5$ mag) and $\mu_I(0) \approx 27$ mag arcsec$^{-2}$. Mieske et al. (2007) determined distances to early-type dwarf galaxies in Fornax using the surface brightness fluctuation method and confirmed that 30 of the dEs with $-16.6 < M_V < -10.1$ mag are the members of Fornax. Fornax UFD1 is about one magnitude fainter that the detection limits of Hilker et al. (2003) and Mieske et al. (2007).

Recently, Muñoz et al. (2015) covered the central region of Fornax with Dark Energy Camera on CTIO 4 m as part of the program for the Next Generation Fornax Survey (NGFS), discovering 158 new dwarf galaxies with $M_I < -8.0$ mag. The effective radii and effective surface brightness of these galaxies are $r_{\text{eff}} = 0.1-2.8$ kpc and $\mu_I = 22.0-28.0$ mag arcsec$^{-2}$. Thus, the parameters of Fornax UFD1 are similar to the faint limit in their sample. However, none of the stars in Fornax UFD1-like dwarf galaxies can be resolved at the pixel scale of the Dark Energy Camera images.

4.2. Comparison with Other Galaxies

We compare scaling relations of Fornax UFD1 with those of other early-type stellar systems in Figures 4(a) and (b) (see Figure 4 for details of the kinds of other early-type stellar systems). We use the data for effective radii, total magnitudes, and central surface brightness of other stellar systems compiled in Jang & Lee (2014, see the references therein). We updated the data, adding data for new UFD galaxies: the new UFDs in the Local Group from the Dark Energy Survey (Bechtol et al. 2015; Drlica-Wagner et al. 2015; Kim et al. 2015; Kim & Jerjen 2015; Koposov et al. 2015; Laevens et al. 2015), a new UFD in the Centaurus A group (Crnojević et al. 2016) and Virgo UFD1 (Jang & Lee 2014). We also added the data for the new Fornax dwarf galaxies (Muñoz et al. 2015).

In the figure, it is found that Fornax UFD1 is located in the region of the Local Group UFDs and that the properties of
Fornax UFD1 are very close to those of Virgo UFD1 (Jang & Lee 2014). These results show that Fornax UFD1 is indeed a genuine UFD. The central surface brightness of Fornax UFD1 as well as Virgo UFD1 corresponds to the upper range for the Local Group UFDs. This implies that UFDs are ubiquitous and that there may be many more UFDs with lower surface brightness and fainter magnitudes in Fornax and Virgo.

5. Summary

Taking advantage of high-resolution deep images of a halo field in NGC 1316 obtained as part of the CCHP, we discovered a new UFD in Fornax, Fornax UFD1. The CMD of the resolved stars in this UFD shows that it is indeed a genuine UFD with low metallicity ([Fe/H] ≈ −2.4) and that it is likely to belong to the Fornax cluster. The size, luminosity, and surface brightness of Fornax UFD1 are similar to those of Virgo UFD1. Fornax UFD1 is the most distant one among the known UFDs that have been confirmed by resolved stars. Fornax UFD1 and Virgo UFD1 are, respectively, only the first known UFD in each of Fornax and Virgo, and it is expected that many more will be discovered in the future. We just opened an window to the realm of the UFDs beyond the Local Group.

The authors are grateful to anonymous referee for useful comments. Tom Richtler is thanked for providing deep CTIO 4 m images of NGC 1316. M.G.L and I.S.J are supported by the National Research Foundation of Korea (NRF) grant funded by the Korean Government (MSIP; No. 2012R1A4A1028713).

Facility: HST (ACS, WFC3/IR).
