Abstract

Lipomas are said to be the most common soft tissue benign mesenchymal neoplasm of fat cells with an incidence of 15-20%. They have a higher incidence of occurrence in the posterior neck region. There occurrence in the oral cavity is rare, amounting to 0.5-5% of all the benign tumors [2]. Clinical presentation of intraoral lipoma is usually a well-circumscribed, painless, slowly enlarging submucosal mass and may be superficially or deeply seated [3,4].

Superficial lipomas can be differentiated by the presence of yellowish tinge on its mucosal surface. The etiology and pathogenesis of lipomas are still in debate, with various authors suggesting mechanical, endocrine, and inflammatory causes [4]. Clinical diagnosis for lipomas is usually apparent, and the use of imaging studies aid in diagnosis. The base of the lesion can vary as being pedunculated or sessile [4]. The most frequent sites of presentation are lips, tongue, palate, buccal mucosa, gingivo-buccal sulcus and the floor of the mouth [5,6]. A review of the English literature has shown that a maximum size of 5cm has been reported for intraoral lipomas.

Case report

A 52-year old male patient reported to Department of Oral and Maxillofacial Surgery, KMCT Dental College and Hospitals, complaining of a slow growing mass inside the left side of mouth since 2 years. It started as a single soft swelling of size 0.5cm which originated on the left buccal mucosa near to the retromolar region. It attained a size of 1.5cm in the first few months, and then remained static for a long period. Six months prior to the excision, the swelling size again started increasing to the present size. Occasional traumatization of the lesion occurred while chewing. There was no history of any co-morbidities or regular medications. Personal history revealed that he is an alcoholic and cigarette smoker.

On intraoral examination, there was a large ovoid pedunculated swelling of size 6cm x 4cm x 3cm on the left buccal mucosa, originating near the retromolar region (Figure 1). Surface bosselation with areas of fibrosis was present, which may be attributed to the self-inflicted trauma during mastication. On palpation, it was soft in consistency and showed compressibility. Keeping the social status of the patient in consideration, we decided to go for a high resolution ultrasonographic examination, and magnetic resonance imaging, if indicated. Color Doppler ultrasonographic examination revealed that the lesion was well defined, heterogeneously hyperechoic with no obvious vascularity and no signs of intramuscular infiltrations, eliminating the need for a biopsy. Histological examination following lipoma excision is imperative to detect or exclude liposarcomatous degeneration. Complete removal of the lesion should be done so as to avoid recurrence.

Keywords: Lipoma; Intraoral lipoma; Rare benign intraoral neoplasm
for expensive magnetic resonance imaging (Figure 2). Fine needle aspiration cytology was done and on histopathological examination it showed more number of fat cells than the normal mucosa. With a hypothetical diagnosis of lipoma patient was suggested surgery under general anesthesia.

The patient underwent pre-operative routine examinations, which showed an increased blood glucose level and blood pressure, and was advised with multispecialty consultations, which diagnosed him with type 2 diabetes mellitus and hypertension. Necessary medications were given, and once his co-morbidities were under control, we proceeded with the surgery.

Under hypotensive general anesthesia, surgical site was infiltrated with vasoconstrictor. A suture was passed through the lesion for orientation and to aid in retraction. A number 15 scalpel blade was used to place an incision around the pedunculated base of the lesion, followed by blunt dissection. The whole lesion was excised in-toto (Figure 3). The base of the lesion was made clear of all tissues until the muscle layer was left (Figure 4). After attaining hemostasis, closure was attained using resorbable sutures. Post-operative period was uneventful and the patient was discharged on the third day. Histopathological examination of the gross specimen confirmed the lesion as intraoral lipoma (Figure 5). Post-operative reviews showed good healing of the surgical site.

Discussion

Lipomas are benign soft tissue neoplasms of mature adipose tissues. Etiology of lipomas has been elusive with various authors suggesting various factors, the “hypertrophy theory”
Oral dermoid and epidermoid cysts [18]. Even though computed tomography and magnetic resonance imaging are the preferred investigative modality, histopathological confirmation still remains the gold standard in the diagnosis of lipomas. High resolution ultrasonographic studies can also be used for this purpose, as done in this case. They also yield accurate results, which is comparable to other investigative modalities. In all the situations, the final diagnosis will be based upon the histopathological report.

Based on the histological features, lipomas are classified into classic lipoma, fibro lipoma, angiolipoma, spindle cell lipoma, and pleomorphic, myxoid, sialolipoma, and intramuscular lipomas. But in general, lipomas appear to be composed of adult fat cells, which are again subdivided into lobules by fibrous connective tissue septa [2]. Most frequent histological subtype in the oral cavity is simple lipoma, followed by fibro-lipoma. Lipomas usually demonstrate chromosomal aberrations such as translocations between 12q13-15, interstitial deletions of 13q and rearrangements of 8q11-13 locus [4]. Complete surgical excision, irrespective of the histological variant, is the mainstay treatment. Less incidence of recurrences has been reported, except for the infiltrating variety of lipoma. Infiltrating or intramuscular lipoma originates between skeletal muscle bundles and infiltrates through the intramuscular septa. Due to the close relationship between the adipose tissue and the muscular layer, they show predilection for tongue.

Medical management of lipomas is also gaining popularity. This technique includes intralosomal injection of steroids, leading to local fat atrophy, thus, shrinking the tumour size. It is only recommended for lipomas with diameter less than 1 inch. Repeated injection of 1:1 mixture of lidocaine and triamcinolone acetonide, once a month, into the central region of tumour is also recommended [18].

Conclusion

Oral lipomas are rare benign mesenchymal tumors. They are asymptomatic till they get larger in dimensions. Histological examination following lipoma excision is imperative to detect or exclude liposarcomatous degeneration. It is always not necessary to go for higher imaging modalities like MRI for the diagnosis of lipomas. Unless indicated, high resolution USG can act as an alternative cost-effective method for diagnostic imaging in cases of lipoma. This article goes on to show that even though the lesion is large, the management of a lipoma by complete removal of the lesion to avoid any recurrence, remains same, irrespective of the size.
