ABSTRACT

We summarize the multiwavelength properties of X-ray sources detected in the 80 ks XMM-Newton observation of the Groth-Westphal strip, a contiguous strip of 28 Hubble Space Telescope Wide Field Planetary Camera 2 (WFPC2) images. Among the $\approx$150 X-ray sources detected in the XMM-Newton field of view, 23 are within the WFPC2 fields. Ten spectroscopic redshifts are available from the Deep Extragalactic Evolutionary Probe and Canada-France Redshift Survey projects. Four of these show broad Mg II emission and can be classified as type 1 active galactic nuclei (AGNs). Two of those without any broad lines, nevertheless, have [Ne v] emission, which is an unambiguous signature of AGN activity. One is a narrow-line Seyfert 1 and the other a type 2 AGN. As a follow-up, we have made near-infrared spectroscopic observations using the OHS/CISCO spectrometer for five of the X-ray sources for which we found no indication of AGN activity in the optical spectrum. We have detected H$\alpha$ + [N II] emission in four of them. A broad H$\beta$ component and/or a large [N II]/H$\alpha$ ratio is seen, suggestive of AGN activity. Nineteen sources have been detected in the K$_s$ band, and four of these are extremely red objects (EROs) ($I_{814}-K_s > 4$). The optical counterparts for the majority of the X-ray sources are bulge-dominated. The $I_{814}-K_s$ color of these bulge-dominated hosts are indeed consistent with evolving elliptical galaxies, while contaminations from star formation/AGNs seems to be present in their V$_{606}-I_{814}$ color. Assuming that the known local relations among the bulge luminosity, central velocity dispersion, and the mass of the central black hole still hold at $z \sim 1$, we compare the AGN luminosity with the Eddington luminosity of the central black hole mass. The AGN bolometric luminosity to Eddington luminosity ratio ranges from 0.3% to 10%.

Key words: galaxies: bulges — galaxies: Seyfert — quasars: general — X-rays: galaxies — X-rays: general

1. INTRODUCTION

Deep X-ray images of a patch of the sky show numerous X-ray sources, which mainly consist of a mixture of absorbed and unabsorbed active galactic nuclei (AGNs). It is now recognized that these AGNs make up the bulk of what has been called the “X-ray background.” While normal galaxies, whose X-ray emission is probably dominated by the integration of X-ray binaries, start to emerge (Miyaji & Griffiths 2002; Hornschemeier et al. 2003) at the faintest fluxes, the dominant X-ray source population in the deep Chandra and XMM-Newton surveys comes from AGN activity. Thus, multiwavelength studies of these X-ray sources are key to understanding the detailed history and physical conditions of the formation and the growth of the supermassive black holes (SMBHs), which are now known to reside in the centers of almost all galaxies with a bulge (Magorrian et al. 1998; Merritt & Ferrarese 2001).

The region known as the “Groth-Westphal strip” (GWS) consists of Hubble Space Telescope (HST) Wide Field Planetary Camera 2 (WFPC2) medium-deep images of a strip of 28 contiguous fields (Groth et al. 1994). It is a particularly useful field for extensive multiwavelength studies. Numerous on-going and future follow-up projects have been or are being conducted on and around this field. Existing morphological information from the original WFPC2 observations, combined with the Deep Extragalactic Evolutionary Probe (DEEP), Canada-France Redshift Survey (CFRS), and the ongoing DEEP2 redshift surveys, is providing us with the first clues to the nature of the X-ray source counterparts.

Because of the contamination from starlight in the host galaxy, optical searches for faint AGNs in deep survey fields such as GWS need elaborate efforts. Such attempts have been made by searching for an unresolved component at the centers of galaxies, searching for variable nuclei, and by selecting those with ultraviolet-excess cores (Sarajedini et al. 1999; Sarajedini, Gilland, & Kasm 2003; Beck-Winchatz & Anderson 1999). These surveys reveal up to 10% of galaxies as AGN candidates with nuclei extending as faint as $M_B \sim -15$. Optical searches, however, are less sensitive to AGNs obscured by dust around the active nucleus. On the other hand, X-ray surveys for AGNs are not hindered by the luminosity of the underlying host galaxy. In particular, X-ray surveys with hard band ($E > 2$ keV) sensitivity are also sensitive to the obscured AGNs.

1 See http://deep.ucolick.org.
2 See http://www.astro.utoronto.ca/~lilly/CFRS.
3 See http://deep.berkeley.edu.
In view of this, we have obtained an 80 ks exposure of the northeast part of the GWS with XMM-Newton. This field also has the advantage of a low column density of neutral gas in our galaxy, corresponding to \( N_H = 1.3 \times 10^{20} \text{ cm}^{-2} \) (Dickey & Lockman 1990). A quick look at the X-ray survey and the preliminary log \( N \) versus log \( S \) relations from these data have been presented at Miyaji & Griffiths (2001) and Miyaji et al. (2003). In this paper, we present the nature of the 23 X-ray sources in the GWS, where morphological properties from the WFPC2 images and some redshifts are available from the DEEP/CFRS redshift surveys. We further make supplemental near-infrared spectroscopic observation for some of these X-ray sources for which we did not observe AGN signatures in the optical spectra. \( K_s \)-band photometry of the X-ray sources are also presented.

The scope of this paper is as follows. In § 2, we describe the X-ray data and analysis, including source detection and spectral analysis. In § 3, we explain the source of the optical and near-infrared (NIR) data. The optical and NIR nature of the XMM-Newton sources and related statistics are presented. In § 4, we discuss the overall results on these X-ray sources, black hole mass, and the relationship with the bulge luminosity. We also comment on selected individual sources. A summary is given in § 5. Throughout this paper, we use \( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1} \), \( \Omega_m = 0.3 \), and \( \Omega_{\Lambda} = 0.7 \). Unless otherwise noted, \( L_X \) is the 2–10 keV rest-frame luminosity in units of ergs per second calculated using the cosmological parameters shown above.

2. X-RAY DATA AND ANALYSIS

The field has been observed with XMM-Newton as part of a Guaranteed Time program (principal investigator [PI]: R. E. G.). After cleaning for background flares, we have obtained a total of 69 and 81 ks of exposure for EPIC PN and MOS, respectively. The log of observation is shown in Table 1.

First, we have generated an X-ray image for each of the PN, MOS1, and MOS2 data from XMM-Newton revolutions 0113 and 0114. We have determined the positions of the counterpart X-ray sources by Gaussian fits for two broad-line AGNs detected in the Canada-France Redshift Survey (Lilly et al. 1995) and a few objects in the Medium Deep Survey (MDS) database (Ratnatunga, Griffiths, & Ostrander 1999) with trivial X-ray counterparts. Based on the positions of the optical counterparts, we have determined the linear transformation coefficients of the X-ray source positions. During this process, we did not use X-ray sources that fell in the gaps of the CCDs. Using the coefficients, we then aligned each cleaned EPIC event file.

Using the aligned events, we made summed images in three energy bands, corresponding to photon energies of 0.5–2, 2–4.5 and 4.5–10 keV. We also made a 2–10 keV image. In making the images, we have used PATTERN \( \leq 4 \) (12) for the PN (MOS) data and applied the standard screening criteria. In order to avoid the instrumental line emission feature that dominates the background in 7.33–9.05 keV, the channel energy range corresponding to this energy range has been excluded from the PN data. In addition, exposure maps have been created for each energy band using the task EEPMAP. The MOS exposure maps in each band have been multiplied by the ratio of the MOS and PN efficiencies in the given band, so that the source counts from the summed PN+2MOSs image divided by the summed exposure map gives count rates that can be converted to fluxes using the PN response. The slight shift due to the alignment process (at most 2") is negligible in the usage of the exposure map.

The final source detection has been made to the sum of all PN and MOS data for the three bands. These three images were simultaneously fed into the SAS software EBOXDETECT in the “local” mode. For each band, we have created the “background map” by cubic spline fitting the source excluded image (divided by the exposure map) using the sources detected in the first step. The next step is to use these “background” maps to rerun the EBOXDETECT in the “map” mode, i.e., search for the excess over the background map. The final step is to make a multisource maximum likelihood fit over the background map using the positions of the sources in the previous step as a starting model. This has been made using the SAS task EMLDETECT. The images in the soft (0.5–2 keV), medium (2–4.5 keV), and ultrahard (4.5–10 keV) bands have been simultaneously fit. The procedure also calculates the source detection likelihood for each band, as well as for the sum of these. We accepted sources with a likelihood parameter of

\[
ML = - \ln (1 - P) > 14,
\]

where \( P \) is the probability that the source exists. We also made a separate source detection to the 2–10 keV image to obtain fluxes of the sources in a more traditional energy band.

One of the caveats is that cubic spline fits generated using the SAS procedure ESPLANEMAP sometimes generate spurious wavy structures depending on the choice of the number of spline nodes (the ESPLANEMAP parameter NSPLINENODES). This is probably because some structures in the input image are not well represented by the spline function for the given number of nodes. In order to obtain the best background map, we have manually varied the number of spline nodes until a satisfactory background map is obtained. While this strategy involves a certain subjectiveness, we have checked the goodness of this strategy with extensive simulations. The basic results of this analysis are presented in Miyaji et al. (2003). While the source detection should be improved for further quantitative analysis (Baldi et al. 2002; Valchanchan, Pierre, & Gastaud 2001), our current source detection scheme provides a sufficiently complete list of X-ray sources for the purpose of this paper, which is focused on the multiwavelength properties of the X-ray sources within a limited area. These have been verified by visual comparisons of the images and the detected source lists. The detected source counts have been converted into “effective” count rates by dividing by the value of the exposure map smoothed with a \( \sigma = 12'' \) Gaussian.

In this paper, we concentrate on the sources that fall within the HST WFPC2 fields of view. Sixteen of the original 28 GWS fields overlap with the XMM field of view (FOV). Additionally, there is another WFPC2 field in this general field (PI: S. J. Lilly). We excluded from this paper a few X-ray sources located close to the edge of the WFPC2 field if their optical counterparts were not included in the MDS database. Table 2 lists the X-ray sources within the WFPC2 FOVs detected using...
the above procedure. In this table, the fluxes have been obtained from the count rate assuming a power-law or an absorbed power-law spectrum, depending on the hardness ratios from detected count rates in the 0.5–2 and 2–10 keV bands. If the hardness ratio corresponds to an effective photon index of $\Gamma > 1.8$, a power-law spectrum is used. For a harder spectrum, an absorbed spectrum with fixed $\Gamma = 1.8$ and varying intrinsic absorption column density ($N_H$) placed at $z = 1$ (a typical redshift of the sources) is used. As long as the value of $N_H$ is matched to the observed hardness ratio, the count rate to flux conversion factor is insensitive to the assumed redshift.

The columns of Table 2 are explained below:

Column (1): The internal XMM source identification (hereafter referred to as the X-number), which is used to identify the XMM-Newton sources throughout this paper (with or without the preceding “X”).

Column (2): The source name according to the IAU registry in the format XMMGWS JHHMMSS.s ± DDMMSS. This also gives the detected XMM source position. Note that the last digits are truncated.11

Column (3): Positional error (90% encircled) in arcseconds. See below.

Column (4): The detected counts in the total (0.5–10 keV) band.

Column (5): The soft (0.5–2 keV) band flux, in units of $10^{-14}$ ergs s$^{-1}$ cm$^{-2}$.

Column (6): The hard (2–10 keV) band flux, in the same units.

Column (7): The source existence likelihood (see above) in the total band.

Column (8): The source existence likelihood in the soft band.

Column (9): The source existence likelihood in the hard band.

While we treated sources with $ML > 14$ for the total band as detected and included them in Table 2, in each of the soft and hard bands, the ML values are smaller. In the soft and hard bands, we list a nominal flux and 1 $\sigma$ error if $ML > 10$ and a 3 $\sigma$ upper limit for a lower significance.

Figure 1 shows the summed full-band (0.5–10 keV) XMM-Newton image smoothed with a $\sigma = 2''$ Gaussian for display. The HST WFPC2 FOVs are overlaid, and the positions of the sources in Table 2 are marked with crosses with the X-number designations.

There is a 200 ks Chandra ACIS-I observation (PI: K. Nandra) covering the northeastern part of the field and the data came to public archive immediately after the observation. We have also generated a source list from the Chandra data. We have aligned the Chandra events in the same way as the XMM-Newton data. Within 7/4 of the Chandra pointing center, the Chandra data provide much more accurate X-ray source positions and we used them for unambiguous identification of the X-ray source counterparts as shown below. In this paper, we choose not to discuss X-ray sources detected in the Chandra data but not detected in the XMM-Newton data, because they are fainter than those in this paper and the current optical data and redshift information are very limited.

The uncertainties of the source positions have been determined by the combination of the empirically determined systematic errors and the statistical errors. The former has been determined by the rms residuals of the alignment procedure described above. These are $\sigma_{\text{sys}} = 1''5$ for the XMM data and $0''7$ for the Chandra data along each of the $x$- and $y$-axes. For fainter sources and/or sources with large off-axis angles, the statistical error of the source position ($\sigma_{\text{stat}}$) becomes comparable to $\sigma_{\text{sys}}$. Since the $\sigma_{\text{stat}}$ is much smaller than $\sigma_{\text{sys}}$ for brighter sources, including those used for the

---

11 See http://cdsweb.u-strasbg.fr/iau-spec.html.
alignment process, $\sigma_{\text{stat}}$ and $\sigma_{\text{sys}}$ are independent of each other. Thus, we can estimate the 90% encircle radius ($r_{0.9}$) by

$$r_{0.9} = 2.15(\sigma_{\text{sys}}^2 + \sigma_{\text{stat}}^2)^{1/2},$$

(1)

where 2.15 is the conversion factor between 1 $\sigma$ and 90% encircle radius assuming a two-dimensional Gaussian probability distribution.

The XMM X-ray sources with improved positions from the Chandra data are summarized in Table 3.

### 2.1. X-Ray Spectral Properties

As a preview of the X-ray spectral properties of the detected sources, we plot a hardness ratio diagram in Figure 2. The hardness ratio between 2–4.5 and 4.5–10 keV is plotted against that between 0.5–2 and 2–4.5 keV. The typical 1 $\sigma$ errors of the hardness ratios are 0.05–0.2; errors exceeding 0.4 are shown. We overplot grids showing the loci of absorbed power-law spectra for varying values of the photon index $\Gamma$ and intrinsic absorption $N_H$ for $z = 0.7$ and $z = 2$, respectively, as described in the figure caption (Galactic $N_H = 1.3 \times 10^{20}$ cm$^{-2}$ has been included). Key optical/IR properties (§ 3) of the X-ray sources are indicated.

| XMM X-No. | R.A. (deg) | Decl. (deg) | $r_{90}$ (arcsec) |
|-----------|------------|-------------|-------------------|
| X-8       | 214.39514  | 52.46958    | 0.7               |
| X-20      | 214.42441  | 52.47316    | 0.7               |
| X-26      | 214.31275  | 52.38685    | 0.8               |
| X-44      | 214.37476  | 52.46324    | 0.7               |
| X-46      | 214.44027  | 52.46722    | 0.7               |
| X-52      | 214.44140  | 52.50901    | 0.7               |
| X-61      | 214.49547  | 52.52754    | 0.8               |
| X-69      | 214.45498  | 52.46987    | 0.8               |
| X-125     | 214.46674  | 52.52354    | 0.8               |
| X-130     | 214.47583  | 52.52329    | 0.8               |
| X-133     | 214.33364  | 52.41676    | 0.8               |
| X-146     | 214.43923  | 52.49754    | 0.8               |

For bright sources, ($XMM$ counts $\geq$ 500), X-ray pulse-height spectral analysis gives further constraints on the spectral parameters. For the spectral analysis, we have used the data from the first observation in Table 1 (Rev/OBSID = 0113/0127921001), which contain most of the good intervals.
FIG. 2.—X-ray color-color diagram of the X-ray sources in GWS. The inner symbol shows the spectral classification (see §3), one NLS1 has been included among AGN1’s) and the outer symbol shows the morphological classifications labeled. Error bars show 1 among AGN1’s) and the outer symbol shows the morphological classifications (off-nucleus) and X-83 (Galactic star) are excluded from the plot.

For sources with greater than 600 counts, we could reasonably constrain the parameters with a $\chi^2$ fit to the background-subtracted spectra rebinned to have at least 20 counts per bin. For fainter sources, we have used the XSPEC implementation of the C-statistics (Cash 1979) to the spectra with much finer binnings. Because the C-statistics cannot be applied to background-subtracted data, the background and (source+background) spectra have been jointly fit. The background has been approximated by one or two power laws and a broad Gaussian. This background model was then scaled by the source and background extraction areas and added to the source model. The result was then fitted to the source spectrum without background subtraction.

The source spectrum is fitted with a power law, Galactic absorption (fixed at $N_H = 1.3 \times 10^{20}$ cm$^{-2}$), and an intrinsic absorption at the source redshift. For the sources without known redshifts, we have assumed a redshift for determining the value of $N_H$. The results have been summarized in Table 4. See comments to this table for details.

### 3. OPTICAL IDENTIFICATIONS AND NIR OBSERVATIONS

This field has been targeted by a number of past and future survey projects in many wavelength, starting with the 28 contiguous HST WFPC2 observations (Groth et al. 1994). The main source of the optical data summarized in this paper comes from the HST MDS (Ratnatunga et al. 1999) database and the DEEP survey. We have also made supplemental NIR spectroscopic observations for several of the X-ray sources. Infrared ($K_s$) photometry of these sources from the EMIR-COSMOS project (Cristóbal-Hornillos et al. 2003) are also included. The basic results are summarized in Table 5.

#### 3.1. Optical Morphology

Figure 3 shows the HST WFPC2 F814W images (with the exception of X-8, X-20, and X-44, where the F606W images are shown) with $r_{0.9}$ error circles for XMM and Chandra (where applicable) source positions. Because each WFPC2 image may have absolute astrometric error of $\sim$1", in a few cases, the X-ray sources in one WFPC2 FOV show systematic offsets from their counterparts. In those cases, we have shifted the WFPC2 image by matching the positions of one of the X-ray sources with its unambiguous counterpart in making

### TABLE 4

| X-No.  | $z^a$ | $\Gamma$ | $N_H^{10^{20} cm^{-2}}$ | $S_{14}^{\text{ergs s}^{-1} \text{cm}^{-2}}$ | $\log L_x^{\text{ergs s}^{-1}}$ | $\chi^2/\text{dof}$ | Prob. (%) |
|--------|-------|---------|-------------------------|---------------------------------|---------------------------------|----------------|-----------|
| X-8    | 1.223 | 2.2 2(0.2, 2.5) | $<1.3$ | 1.6 | 44.2 | 22/38 |
| X-9    | 0.5*  | 2.5 2(2.3, 2.9) | $<0.07$ | 1.0 | ... | 20/47 |
| X-10   | 0.801 | 2.2 2(2.0, 2.8) | $<0.3$ | 1.4 | 43.7 | 7/29 |
| X-11   | 1*    | 1.7 1(4.2, 2.2) | 1.6 0(7.2, 2.5) | 3.5 | ... | 16/31 |
| X-20   | 1.148 | 2.0 1(6.2, 2.7) | 1.8 0(7.3, 3.3) | 1.9 | 44.2 | 9/19 |
| X-22   | 0.983 | 1.4 1(2.1, 2.7) | $<0.5$ | 2.7 | 44.2 | 11/20 |
| X-28   | 0.76p | 1.2 1(0.8, 1.7) | 3.0 1(7.3, 5.3) | 4.1 | 43.8 | 62 |

a Objects without spectroscopic redshifts are marked with an asterisk and the assumed redshift for $N_H$ calculation is shown. Photometric redshifts are marked with "p".

b Source flux in the 2–10 keV band at the observer’s frame, corrected for Galactic absorption.

c The base 10 logarithm of the source luminosity in the 2–10 keV band at the source rest frame corrected for Galactic and intrinsic absorption.

d For the $\chi^2$ fitting results, $\chi^2$ and the degrees of freedom are shown. For fits using C-statistics, we give the percentage of simulated spectra drawn from a Gaussian distribution centered on the best fit with sigma from the covariance matrix which gives C-values smaller than the observed. (Using the xspec command “goodness” with the “sim” option.)
overlays. In Figure 3, the overlays for X-8, X-20, and X-44 have been tuned using X-8, those for X-61, X-125, and X-130 using X-61, those for X-52, X-146, and X-118 using X-69. In any case, a translational shift without a rotation gives a satisfactory correction, where all the unambiguous counterparts (including *Chandra* sources without XMM detections) are within the *Chandra* error circles. Note that the drawn error circles ($r_{0.5}$) may be an overestimate in these cases.

All of the X-ray source counterparts have an entry in the MDS database, where the results of the disk-bulge decomposition are provided. The entries from the MDS database, including the MDS-ID, magnitudes in F814W and F606W (or $V_{606}$) filters, and the bulge-to-total brightness ratios (B/T) (or other morphological classifications) have been shown in Table 5 in columns (2), (3), (4), and (5), respectively. The first and second entries in column (5) (separated by a comma) are for the F606W and F814W bands, respectively. If an entry in column (5) shows a number between 0 and 1, it means that the host galaxy has been deconvolved with an exponential disk + bulge model and the bulge-to-total light ratio is shown. Other possible entries in this column are “B” (pure bulge), “D” (pure disk), “S” (unresolved point source), and “G” (galaxy; emission is extended, but unable to discriminate between the exponential disk and bulge models).

3.2. Optical Spectroscopic Classification

Optical spectra are available for eight of our X-ray sources through the DEEP survey and two from the CFRS. Key AGN classification emission lines are shown in column (12) of Table 5. Broad permitted lines are indicated in boldface.

In summary, four X-ray sources show broad Mg II emission lines, and we classify these as type 1 Seyfert/QSOs. They are identified with “AGN1” in column (12) of Table 5. Other objects with optical spectra show only narrow permitted and/or forbidden lines. Two of these show [Ne v] emission, which is an unambiguous indicator of AGN activity. One of these (X-10) is a narrow-line Seyfert 1 galaxy (“NLS1” in col. [11]) as discussed in § 4.3. We tentatively classify the other object (X-146) as a type 2 AGN and classify it as “AGN2-Opt.”

The other four objects do not show signs of AGN activity in their optical spectra in that they show neither broad permitted lines nor high excitation lines. These are classified as “LEX” (low-excitation emission line objects) in column (12).

3.3. Subaru CISCO/OHS NIR Spectroscopy

We have made NIR spectroscopic observations for a subset of the X-ray sources with no optical spectroscopic indication of AGN activity. These include objects with optical spectra that show only low-excitation lines, as well as those without optical activity.

Fig. 3.—Postage-stamp images from the HST WFPC2 images of the XMM-Newton sources in Table 2 are shown. Each image has a dimension of $12'' \times 12''$. North is up, and east is left. Large dashed circles and small solid circles are the 90% error circles of XMM-Newton and Chandra sources (if they exist), respectively.
spectra. Observations were made using the CISCO spectrometer with the OH suppressor (CISCO/OHS) (Motohara et al. 2002; Iwamuro et al. 2001) attached to the Nasmyth focus of the 8.2 m Subaru Telescope on 2003 March 22–24. The JH-grism with a 0.5 slit width was used. The spectral resolution of this configuration is $\lambda/\Delta \lambda = 400$.

The primary purpose of the NIR spectroscopy was to detect the redshifted H$\alpha$ $\lambda 6563 + [N \, II] \lambda \lambda 6548, 6583$ complex and investigate the AGN nature of these X-ray sources. The ratio of the strengths of the [N II] doublet and H$\alpha$ is a good discriminator between the AGN and starburst origins of the ionizing radiation. Typical Seyfert 2 galaxies have $\log ([N \, II]/H\alpha) > -0.25$ (Veilleux & Osterbrock 1987).

We also intended to search for broad components in H$\alpha$. Since a dust cloud is more transparent to redder light, moderately obscured AGN activities are much more visible in the longer wavelength lines such as H$\alpha$ rather than shorter wavelength lines, such as H$\beta$ or Mg $\text{II}$. In fact, there have been a number of reported cases where X-ray source counterparts show broad H$\alpha$ lines, even though they only show narrow lines in the shorter wavelength optical spectra (Akiyama, Ueda, & Ohta 2002; Schmidt et al. 1998).

We did not include those with $z < 0.7$ (X-46 and X-61) in our NIR spectroscopy targets, because the H$\alpha + [N \, II]$ line complex does not fall within the wavelength range observable by CISCO/OHS JH-grism. In addition, in order to make spectroscopic observation feasible within a reasonable exposure time, we limited our spectroscopic observation to those with an estimated H-band magnitude of $H < 21$ (Iwamuro et al. 2001), where H-band magnitudes were estimated by $H \approx I_{B}^{13} - 1.4$ (Barger et al. 2001). Five from the 23 XMM-Newton sources were observed during our observing run.

The resulting spectra, reduced following the procedure by Iwamuro et al. (2001), are shown in Figure 4. Preliminary flux calibrations have been made using a nearby standard star observed immediately after the target.

We have detected the H$\alpha + [N \, II]$ complex in four of the five observed X-ray sources. In all four cases, the spectra suggest a possible broad H$\alpha$ component (FWHM $\sim 2000$ km s$^{-1}$) and/or strong [N II] lines. This is indicated in column (13) of Table 5, and the sources are classified as “AGN-IR” in column (11).

Because of the weak signal-to-noise ratio and difficulty in determining the background, careful analysis is required to make any quantitative conclusions. This will be the topic of a separate paper that will describe the details of the observations, data reduction, and quantitative analyses for the Subaru CISCO-OHS spectra of the sources shown in this paper and a few additional sources observed during the observation run.

3.4. Infrared ($K_s$) Photometry

The $K_s$ photometry was provided by the EMIR-COSMOS project (Guzmán 2003; Balcells 2003). The GWS was imaged with the near-infrared camera INGRID on the William Herschel Telescope in the Spanish Observatorio del Roque de los Muchachos during two runs in 2000 April and 2001 June. These data are fully described by Cristobal-Hornillos et al. (2003). Atmospheric conditions were photometric, with seeing ranging from 0\".06 to 0\".075 FWHM in 2000 April, and 0\".06 to 1\".3 FWHM in 2001 June. Source extraction and photometry of $K_s$-band data was done using SExtractor (Bertin & Arnouts 1996). Zero-point uncertainty is 0.03 mag. SExtractor BEST magnitudes are provided with errors including photon noise. The resulting $K_s$ magnitudes are listed under column (7) of Table 5.

3.5. Redshifts and X-Ray Luminosities

Redshifts, redshift quality flag, and the reference source of the redshift are shown in columns (8), (9), and (10) of Table 5. The meanings of the redshift quality flags are $(-1)$ photometric redshift only, (0) no redshift information, (1–5) as defined by the DEEP project (Lowenthal et al. 1997) or the CFRS (Lilly et al. 1995) confidence class if the redshift source is CFRS. The redshift of X-22 has been solely determined by the H$\alpha + [N \, II]$ complex from the Subaru OHS data. Since this feature is unambiguous, it has been assigned the quality flag of 3.

For those with redshift information, we have calculated the X-ray luminosity of the source and listed the results in column (13). The luminosities have been calculated from the $2–10$ keV rest-frame fluxes given in Table 2 and the $K$-corrections have been made using the spectral assumptions described in § 2. The luminosities have been corrected for possible intrinsic absorption using the same spectral assumption. Because of the difference in methods and exact time selections, the luminosities listed here can be slightly different from those in the full spectral analysis listed in Table 4.
4. RESULTS AND DISCUSSION

4.1. X-Ray Source Population

The 23 sources detected in our 80 ks XMM-Newton observation of the GWS are representative of the X-ray sources that contribute most to the “cosmic X-ray background,” and many of them represent the regime that marks the peak of accretion onto SMBHs in centers of galaxies.

A dominant population in this field consists of AGNs with \( \log L_X \sim 44 \) at \( z \sim 1 \). Only a few of them show signs of AGN activity in their optical spectra. Subaru OHS NIR spectroscopy of four of the X-ray sources with no previous optical signature of AGNs revealed H\(\alpha\) + [N II] emission lines showing hints of broad H\(\alpha\) and/or stronger narrow [N II] lines indicative of AGN activity.

The host galaxies of the X-ray sources tend to be bulge-dominated and four are extremely red objects (EROs, or very red objects [VROs]) \((I_{814} - K_s \geq 4)\). In addition, one object (X-130) has an upper limit \( I_{814} - K_s < 4.8\), which is consistent with being a ERO. Figure 5 shows \( V_{606} - I_{814} \) and \( I_{814} - K_s \) colors of the X-ray sources in our sample as a function of redshift. We have excluded X-33 (no \( K_s \) and \( V_{606} \) photometry available), X-46 (X-ray source is off-nucleus; see below), and X-83 (Galactic star) from the plot. Those without redshift information are plotted left of \( z = 0 \). For reference, we plot K- and evolution-corrected galaxy colors for elliptical (labeled as E1 in Fig. 5), Sa, and Sc galaxies from Poggianti (1997). Model E1 corresponds to Poggianti’s model “E,” which has a star formation rate with \( e \)-folding time of 1 Gyr. We have neglected the difference of cosmological parameters used by us and Poggianti (1997), which corresponds to a \( \sim 10\% \) difference in the age of the universe. In plotting these color tracks, we have converted the \( I \) and \( V \) magnitudes to \( I_{814} \) and \( V_{606} \) using the formulae given by Cowie, Songaila, & Barger (1999). We also plot the colors of an elliptical galaxy model, which we have calculated from the mean radio-quiet QSO spectrum by Elvis et al. (1994).

Figure 5 shows that the \( I_{814} - K_s \) color of the X-ray sources with bulge-dominated hosts indeed traces that of elliptical galaxies and, in particular, those of EROs with redshifts are roughly consistent with the passively evolving elliptical model (E2). The \( V_{606} - I_{814} \) color, which is more sensitive to the contaminations from star formation and AGN activities, shows a scatter toward bluer colors from the elliptical regime. The reddest one (X-20), with \( I_{814} - K_s = 5.0 \) may be contributed by a dust-enshrouded AGN or a starburst. Pointlike sources tend to be distributed toward bluer (QSO) colors, although the scatter is large. The scatter may be contributed to by unresolved host galaxies, intrinsic scatter in QSO colors and/or reddening by intrinsic dust absorption.

4.2. Bulge Mass and X-Ray Luminosity

The HST imaging of this field has allowed us to find a significant population of X-ray sources at \( z \sim 1 \) whose counterparts have a resolved bulge component, either as part of a disk+bulge structure or a pure bulge. In view of the relationship found between bulge mass and the central blackhole mass in nearby galaxies (Magorrian et al. 1998; Merritt & Ferrarese 2001), it is interesting to make a first-order estimation of blackhole mass (\( M_{\bullet} \)) from the bulge component of the host galaxy and compare it with the X-ray luminosity. In the rough estimation below, we take the approach of Aller & Richstone (2002) by first converting the bulge luminosity to the central velocity dispersion (\( \sigma \)) of the bulge stellar component using an empirical relation. Then, we use the tight \( \sigma-M_\bullet \) (Merritt & Ferrarese 2001; Tremaine et al. 2002) correlation to obtain the estimated blackhole mass. We use the F814W \( K \)-correction for the E galaxy in Figure 18d of Fukugita, Shimasaku, & Ichikawa (1995) to calculated the F814W absolute magnitude (\( M_{F814W} \)). We also assume an early-type galaxy color of \( M_{F814W} - M_{F814E} = 2.1 \).

(Fukugita et al. 1995; Gonzalez et al. 2000). We then use the relations,

\[ -M_{F814} + 5 \log h_0 = 20.5 + 7.7(\log \sigma - 2.3), \]

\[ M_\bullet/M_\odot = 1.48 \times 10^8(\sigma/200)^{4.65} \]

(Gonzalez et al. 2000; Merritt & Ferrarese 2001) to obtain the estimated blackhole mass. Because the F814W band
The luminosity of the AGN component, and $L_{\text{bol}}$ (data points are shown with X-number labels. Three lines correspond to the central blackhole mass ($M_{\bullet}$) for these X-ray sources, where $M_{\text{bol}}/L_{\text{bol}}$ corresponds to the version to $M_{\text{bol}}$ is the bolometric luminosity of the AGN component, and $L_{\text{bol}}$ is the Eddington luminosity corresponding to $M_{\bullet}$.

Figure 6 shows the estimated $M_{\bullet}$ versus $L_X$ (absorption-corrected, see § 3.5) for 10 X-ray sources in the sample that have a resolved bulge component in the $HST$ WFPC2 F814W image (MDS).

It is interesting to estimate the Eddington ratio $L_{\text{bol}}/L_{\text{edd}}$ for these X-ray sources, where $L_{\text{bol}}$ is the bolometric luminosity of the AGN and $L_{\text{edd}}$ is the Eddington luminosity corresponding to the blackhole mass. Writing $L_{\text{bol}} = bL_X$, where $b \sim 25$ (Elvis et al. 1994), we overplot three lines showing $(L_{\text{bol}}/L_{\text{edd}})(25/b) = 10^{-1}, 10^{-2},$ and $10^{-3}$ in Figure 6. Figure 6 shows that the estimated blackhole masses for the 10 AGNs range from $10^7$ to $10^{10} M_\odot$ and the Eddington ratios from 0.3% to 10%.

These results have interesting implications on how AGNs evolve and the current stage of evolution for the AGNs represented here ($z \sim 1, \log L_X \sim 44$). This is indeed a characteristic redshift and luminosity marking the peak of the accretion history of the universe. The result that these AGNs are typically radiating at a few percent may have important implications on the accretion history and formation of SMBHs. If this is a typical Eddington ratio throughout the AGN phase of these objects, the growth of the black-hole occurs on a timescale of roughly $t_{\text{s}}/(L_{\text{bol}}/L_{\text{edd}})$ which is roughly a few times $10^9$ yr, where $t_{\text{s}} \sim 5 \times 10^7 [\epsilon/(1-\epsilon)][(0.1/1 - 0.1)]^{-1}$ yr is the Salpeter timescale, that is the timescale at which the mass of an object accreting at the Eddington Luminosity grows by a factor of $\epsilon$ (for a radiative efficiency $\epsilon \sim 0.1$ of a standard accretion disk model). This scenario has difficulty in that the timescale of a few $10^9$ yr may be too long, while the number density of AGNs at $\log L_X \sim 44$ decreases beyond $z \sim 1$ (Ueda et al. 2003). Alternatively, it is possible that these AGNs have gone through a brief luminous phase in the past with near-Eddington accretion rates. These may have been observed as more luminous QSOs ($\log L_X \gtrsim 45$) at $z > 2$. Yet another more exotic possibility is that they are just accreting with a low radiative efficiency ($\epsilon \ll 0.1$), allowing much less time for the SMBH to grow.

We note, however, that there are a number of caveats in interpreting these results and drawing conclusions relating the X-ray AGN evolution and growth of the SMBH. First, the current MDS database shows the analysis for stellar (pointlike) images or galaxies (pure bulge, pure disk, or bulge+disk decomposition), but only limited analysis (Sarajedini et al. 1999) has been completed for decomposing pointlike (stellar) nuclei from the host galaxy (stellar+bulge+disk, stellar+bulge or stellar+disk). Thus, we select against those with strong AGN components (or with large $(L_{\text{bol}}/L_{\text{edd}})$, which are likely to be as “stellar” in the MDS database or the bulge luminosity in the database may be contaminated by the central AGN component. This situation should be improved in the future, where the $HST$ images are analyzed with pointlike nucleus+host galaxy decomposition. Extending this study to other deep fields with X-ray and $HST$ (WFPC2, as well as ACS) data, including the Extended Chandra Deep Field South and the COSMOS field, will be a next logical step. Second, a much more fundamental limitation is that we have assumed the local relations in equation (2) are still valid at $z \sim 1$. This assumption is not guaranteed to be valid.

4.3. Comments on Selected Individual Objects

X-8: This is a typical type 1 QSO at $z = 1.22$ with a broad Mg u line.

X-10: The DEEP optical spectrum shows many narrow emission lines including high-excitation lines like [Ne v] $\lambda\lambda$3346, 3426, which are unambiguous indicators of AGN activity. Permitted lines (Mg ii, H$\beta$) are also narrow. Since H$\beta$/[O iii] $\lambda\lambda$5007 $\gtrsim 0.7 > 1/3$, these lines are not dominated by a Seyfert 2. It is either a Seyfert 2 whose emission lines are heavily contaminated by starburst activity or a NLS1 (Osterbrock & Pogge 1985), where H$\beta$ is contributed to from the (narrow end of the) broad-line region. Because our X-ray spectral analysis shows no X-ray absorption ($N_{\text{HI}} < 10^{14.5}$ cm$^{-2}$; see Table 4), the NLS1 interpretation is more plausible.

X-11: The optical counterpart has a very bright stellar (pointlike) morphology, and there is no optical spectrum available for this source to discriminate between a galactic star and a QSO. However, its X-ray spectrum is inconsistent with a thermal plasma, having a significant residual in the soft part. In addition, its X-ray to optical flux ratio $\log (f_X/f_\text{opt}) \approx -0.7$ ($f_X$ is measured in 2–10 keV) is well within the AGN regime (roughly between $-1$ and 1; see, e.g., Hornschemeier et al. 2001). Thus, it is most likely to be a QSO.

X-20: Thanks to the Chandra position, we can identify the X-ray source with the brightest bulge-dominated galaxy at $z = 1.148$, among four candidates apparently interacting with one another indicated by tidal bridges (see Fig. 3). It is an interesting case where galaxy interactions are possibly feeding the AGN activity at this early stage of the universe. It has a QSO luminosity ($\log L_X = 44.2$), but the optical image is dominated by bulge component of the host galaxy. The X-ray spectrum shows a broad Mg u line. The X-ray spectrum shows an absorption of $\log N_{\text{HI}} \sim 22.3$. This is an example of an optical type 1, X-ray type 2 AGN. This is also an ERO
X-22: No previous optical/IR spectroscopic observations existed for this source. Our Subaru OHSS/CISCO observation detected H\(\alpha\) and [N II] \(\lambda\lambda 6548, 6583\) emission lines, giving \(z = 0.983\). Based on the sign of broad H\(\alpha\) and strong N II, high-luminosity \(\log L_{\text{X}} \sim 44.2\). While we mark it as an AGN-IR, it may well be a type 1 AGN.

X-28: This source is the most conspicuous hard X-ray source in the field with an intrinsic absorption of \(\log N_{\text{HI}} \sim 22.5\) (cm\(^{-2}\)). It is a bulge-dominated galaxy with no optical/IR spectroscopy and a photometric redshift of \(z = 0.76\) (Im et al. 2002) based on its \(V-I\) color alone. This is most likely a Seyfert 2 based on the X-ray properties.

X-46: The position of the source has been determined with Chandra and the relative alignment of the WFPC2 image and X-ray sources has been achieved the three other Chandra sources in the field. The X-ray source counterpart is identified with a hot spot just off the patchy irregular star-forming galaxy DEEP GSS 074\_2638 (MDS u2ay1:0019) at \(z = 0.432\). If we assume that the X-ray source is at the same redshift as this irregular galaxy, the luminosity would be \(L_{\text{X}} \approx 42.8\). This is too luminous for an ultraluminous X-ray source (ULX). We also note that there is a nearby edge-on disk galaxy (DEEP GSS 074\_2237, \(z = 0.156\)). The X-ray source is \(4''\) away (projected distance of 10 kpc) from its nucleus and located toward the direction perpendicular to the disk. Therefore, the X-ray source could be a ULX associated with the halo of the galaxy. However, even if the X-ray source was at the redshift of this disk galaxy, its luminosity would still be \(L_{\text{X}} = 41.8\), again well above the ULX regime. One possibility is that this irregular galaxy is undergoing a merging process and the X-ray source is at the nucleus of one of the merging galaxies, or it may simply be a background QSO.

X-52: The DEEP spectrum show no broad lines and the location of Mg II shows only absorption. Other features include [O II] \(\lambda\lambda 3727\) and [Ne III] \(\lambda\lambda 3869\). The presence of [Ne v] \(\lambda\lambda 3426\) is suggested but uncertain. We observed this object with Subaru OHS and found a moderately broad H\(\alpha\) (FWHM \(\sim 2000\) km s\(^{-1}\)) and a strong [N II] doublet (Fig. 4). The fact that there is no broad Mg II line but a moderately broad H\(\alpha\) suggests that the AGN is obscured by a dust cloud. This is consistent with the hard color of this object, with the second largest HR (2–4.5 keV/0.5–2 keV) in the sample (see Fig. 2). This is an ERO \((K_{s-14} - K_s = 4.4)\).

X-66: We find no indication of an AGN in the DEEP spectrum. Like X-52, our Subaru OHS observation revealed possible AGN activity through the detection of a moderately broad H\(\alpha\) (FWHM \(\sim 2000\) km s\(^{-1}\)) line and a strong [N II] doublet. This is an obscured AGN similar to X-52 and has a hardest HR (2–4.5 keV/0.5–2 keV). There is also a hint of [Ne III] \(\lambda\lambda 3869\), a line which is often stronger in AGNs than star-forming galaxies.

X-69: A spectroscopic redshift of \(z = 0.995\) has been determined by our Subaru observation in close agreement with the photometric redshift determined by Brummer (1999) of \(z_{\text{ph}} = 0.935\). The Subaru OHS spectrum seems to indicate either strong [N II] \(\lambda\lambda 6583\) or broad H\(\alpha\) suggestive of AGN activity. This is an ERO \((K_{s-14} - K_s = 4.1)\).

X-83: Because of the low X-ray to optical flux ratio \((\log f_{\text{X}}/f_{\text{opt}}) \sim -3\) for this bright optical object (F606W = 14.8), this is certainly a Galactic star.

X-125: Although the MDS database shows that it is a point source, its color is consistent with an elliptical galaxy at the photometric redshift of \(z_{\text{ph}} = 1.55\) (Brunner 1999). The optical counterpart is probably dominated by the host galaxy.

X-146: This object is detected only in the hard (2–8 keV) X-ray band. The DEEP optical spectrum clearly shows [Ne v] \(\lambda\lambda 3426\) emission and strong [Ne III] \(\lambda\lambda 3869\). This is a typical Seyfert 2 galaxy with absorbed X-ray spectrum.

5. SUMMARY

1. We summarize the properties of X-ray sources in the GWS detected with XMM-Newton and discuss their morphology and optical and NIR spectra.

2. Ten out of the 23 X-ray sources have spectroscopic information available in the optical band through the DEEP and CFRS projects. Four of them have broad emission lines and thus can be classified as type 1 AGNs/QSOs. Two others have high excitation lines indicative of a narrow-line region of AGNs. Others do not reveal AGN signatures in their optical spectra.

3. We have obtained NIR spectra for five of the sources that did not reveal AGN signatures in their optical spectra using the CISCO/OHS spectrograph on the Subaru Telescope. In four of the five, we detect broad H\(\alpha\) and/or strong [N II] lines suggestive of AGN activity.

4. The X-ray hardness ratios and spectroscopic analysis show that a major part of the observed X-ray sources consists of a mixture of absorbed and unabsorbed AGNs. One of these AGNs (X-20) has an absorbed X-ray spectrum with a broad Mg II emission line and is another example of an optical type 1/X-ray type 2 AGN.

5. The \(I_{606} - I_{814}\) and \(I_{814} - K_s\) colors of the X-ray sources with bulge-dominated hosts well trace those of evolving elliptical galaxies. Sources with stellar morphologies show bluer colors with some scatter and are consistent with an AGN (QSO) with a host galaxy contamination and/or dust absorption.

6. Ten X-ray sources with redshift information have a resolved bulge. Based on a number of assumptions concerning the bulge luminosity–blackhole mass relation, we estimate that these AGNs have luminosities ranging from 0.3% to 10% of the Eddington luminosity, suggesting that these massive blackholes have previously gone through massive accretion (perhaps as luminous QSOs) or that their lifetimes are relatively long (\(\geq 10^9\) yr).

The authors are indebted to the efforts of the DEEP team for their observations, analysis, and archiving. This work has been supported by NASA grant NAG5-10875 to T. M. (Long-Term Space Astrophysics) and NASA grant NAG5-3651 to R. E. G. (XMM-Newton Mission Scientist support).
