(Dated: October 30, 2018)

Analytic results for the asymptotic decay of the electron density matrix in insulators have been obtained in all three dimensions \((D = 1 \rightarrow 3)\) for a tight-binding model defined on a simple cubic lattice. The anisotropic decay length is shown to be dependent on the energy parameters of the model. The existence of the power-law prefactor, \(\propto r^{-1/2}\), is demonstrated.

In a phenomenological classical approach to atomic dynamics, a very local picture of interatomic interactions is often highly appropriate. The simplest example is the use of Keating “springs” to describe small atomic oscillations in solids [3]. In quantum mechanics (QM), the situation is superficially quite different. If \(\psi_i\) are single-particle wave functions (for example, the Kohn-Sham orbitals of density-functional theory), then the electronic contributions to the total energy, forces or the dynamical matrix can all be obtained from the single-particle density matrix (DM): \(\rho(r, r') = \sum_{i\sigma\sigma'} \psi_{i\sigma}^*(r) \psi_{i\sigma'}(r')\). For a condensed-matter system, virtually all of the Hamiltonian eigenstates \(\psi_i\) are extended and oscillatory throughout the volume of the system, except some of the states near the band edges in the case of disordered systems. To the extent that \(\rho(r, r')\) is built from objects that are extended in real space, it is a nontrivial feature of the quantum mechanics of extended systems that in fact the DM can be localized, even exponentially so in insulators [3, 4].

The possibility of a local formulation of QM goes back at least to Wannier [5], whose “Wannier functions” decay in real space. Kohn [6] extended this work, and emphasized the principle of “nearsightedness”, that is the dependence of local properties, such as forces, on the local environment. The possibility of real-space local formulations of QM has inspired vigorous activity on efficient “order-N” methods for electronic structure [3].

In early pioneering work, Kohn [7] showed that the DM and Wannier functions for a 1D centrosymmetric two-band model decay exponentially in insulators: \(\rho(r, 0) \propto \exp(-\lambda |r|)\), where \(\lambda \propto E_{\text{gap}}^{1/2}\), although Ismail-Beigi and Arias [8] find instead that \(\lambda \propto E_{\text{gap}}\) as \(E_{\text{gap}} \rightarrow 0\). Des Cloizeaux proved that the DM decays exponentially quite generally in insulators [9]. Recently, He and Vanderbilt [10] demonstrated that in 1D there is in fact a power-law prefactor \(\propto r^{-1/2}\), and that the characteristic inverse decay length, \(\lambda\), of both the DM and Wannier functions is universal, although the prefactor is different in each case.

In this Letter, we report analytic results for the spatial decay of the DM for a two-band tight-binding (TB) Hamiltonian for all three dimensions, \(D = 1 \rightarrow 3\). The Hamiltonian we use is similar in spirit to that of Harrison’s bond orbital model [11] and is the minimal model which contains the basic features of an insulator. Both the power-law prefactor and the exponential spatial decay of the DM are found in the asymptotic regime. Thus, we reproduce the results of Refs. [7, 10], and extend them to 2D and 3D. We derive the dependence of the inverse decay length, \(\lambda\), in terms of the fundamental energy parameters of the model. We further show how, in certain cases, the exponential localization arises from the truncation of the sum defining \(\rho\). Precise numerical results support the analytic asymptotic behaviour in all three dimensions.

Our model is of centrosymmetric nearest-neighbor TB form on a simple cubic (s.c.) lattice described by the Hamiltonian:

\[
\hat{H} = \sum_{i\mu} \varepsilon_{\mu}[i\mu][i\mu] + \sum_{i\mu,j(\mu')} t_{\mu\mu'}[i\mu][j\mu'].
\] (1)

Here, each site \(i\) is characterized by two bare orthogonal electronic states, \([i\mu]\) (\(\mu = 1, 2\)) with bare energies \(\varepsilon_{\mu}\) \((\Delta \varepsilon = \varepsilon_1 - \varepsilon_2 > 0\) for definiteness), which together form the orthonormal bare basis set. These may be interpreted as bonding and antibonding states centered at each lattice site. The hopping integrals, \(t_{\mu\mu'}\), between similar states (the same \(\mu\)) on different nearest-neighbour sites \(j\) (to \(i\)) transform the on-site energy levels into bands, while the hopping integrals, \(t_{\mu\mu'}\), between different states (\(\mu \neq \mu'\)) on different sites are responsible for inter-band hybridization. For this model, the eigenstates \([k, \gamma]\) \((k\) is the wavevector and \(\gamma = 1, 2\) indexes the bands) and dispersion are analytically available and the spectrum exhibits the main features of a semiconductor/insulator (i.e. two bands separated by a gap for a certain range of parameters).

We have written the density operator for the Hamiltonian given by Eq. (1), first, in the eigenvector basis, \([k, \gamma]\), then expanded the eigenstates in the site basis \([i\mu]\) and evaluated the density matrix elements, \(\rho_{\mu\mu', i\mu'}\).
in the site basis. For fixed site indices \( i \) and \( j \), the DM contains four elements, which, in the case of a semiconductor at zero temperature, obey the following relations: \( \sum_{\mu} \rho_{\mu ij} = \delta_{ij} \) and \( \rho_{\mu_1 j_1} = \rho_{\mu_2 j_2} \). Below we investigate the decay properties only for the off-diagonal elements, \( \rho_{\mu_1 j_2} \) (the analysis and results for the diagonal elements \( \rho_{\mu_1 j_1} \) are very similar to those for \( \rho_{\mu_1 j_2} \) presented below). The expression for \( \rho_{\mu_1 j_2} \equiv \rho(r_{ij}) \) can be conveniently represented via an integral in reciprocal space over the first Brillouin zone:

\[
\rho(r_{ij}) = \frac{-1}{2(2\pi)^D} \int \cdots \int d\mathbf{k} e^{i\mathbf{k} \cdot \mathbf{r}_{ij}} S_{\mathbf{k}} (A_{\mathbf{k}}^2 + S_{\mathbf{k}}^2)^{-1/2},
\]

where \( \mathbf{r}_{ij} = \nu_{ij} = \mathbf{r}_j - \mathbf{r}_i \) is the connection vector (with the unit-cell parameter \( a \) taken hereafter to be unity, and \( \nu_{ij} \) (e.g. \( \alpha = x, y, z \) in 3D) being an integer). \( S_{\mathbf{k}} = (1/2) \sum_{\lambda(i)} \exp(i\mathbf{k} \cdot \mathbf{r}_{ij}) \) is the structure factor and \( A_{\mathbf{k}} = (\Delta \epsilon + 2(t_{12} - t_{22}^2)S_{\mathbf{k}})/4t_{12} \) is the only energy parameter of the model which, for the symmetric case \( t_{11} = t_{22} \equiv t \), analyzed below for simplicity, is \( k \)-independent i.e. \( A_{\mathbf{k}} \equiv A = \Delta \epsilon / 4t_{12} \). In the model without interband hybridization \( (t_{12} = 0 \) or \( A \to \infty \)), the DM given by Eq. (2) is obviously \( \rho_{ij} = 0 \). In order to study the spatial decay of the density matrix, we should take the integral in Eq. (2) and investigate its dependence on the lattice indices \( \nu_{ij} \). This can be done analytically in the asymptotic regime for all or some \( \nu_{ij} \gg 1 \), if the energy parameter of the model obeys the inequality, \( A > D \), which is the case for weak interband hybridization in semiconductors.

Eq. (2) has been derived without making use of the particular symmetry type of the underlying lattice, and is valid for any primitive lattice (one atom per unit cell). The structure factor, \( S_{\mathbf{k}} \), reflects the differences between various lattices. The DM given by Eq. (2) can be easily calculated numerically for any reasonable choice of parameters, and the results of such calculations support the main conclusions derived below analytically for the s.c. lattice, subject to some additional restrictions (symmetric case, \( t_{11} = t_{22} \), and weak hybridization, \( A > D \)).

To proceed with the evaluation of the DM given by Eq. (2), first we expand in a series the denominator of the integrand (\( S_{\mathbf{k}} / A < 1 \), if \( A > D \)), separate the variables and then evaluate all \( D \) integrals making use of the orthogonality of the \( \cos(k_{\alpha} \nu_{ij}) \)-functions involved. This results in the following general exact form for the DM for all three dimensions:

\[
\rho_{\nu_{ij}} = \frac{(-1)^{\sigma}}{(4A)^{2\pi + 1}} \sum_{k=0}^{\infty} (-1)^{k} \left[ \left(\frac{2k^{\prime}!}{(4A)^{k^{\prime}}(k^{\prime})!}\right)^{2}(2k^{\prime} + 1)\Sigma_{D} \right],
\]

if \( \sigma \equiv \sum_{\alpha}^{D} \nu_{\alpha} \) is odd, and zero otherwise. Here \( k^{\prime} = k + \nu_{ij} \equiv k + (\sigma - 1)/2, \Sigma_{1} = 1/[k!(k + \nu_{ij})] \) and \( \Sigma_{2,3} \) are hypergeometric finite sums, the one for \( 2D \), \( \Sigma_{2} = \sum_{m=0}^{\infty} 1/[m!(k - m)!/m + \nu_{ij})] \) being expressible in closed form [12], but that for \( 3D \), \( \Sigma_{3} = \sum_{m=0}^{\infty} (m + \nu_{ij})/[m!(k - m)!/m + \nu_{ij}) \) cannot be so written, in principle [13]. The orthogonality of the \( \cos(k_{\alpha} \nu_{ij}) \)-functions, being a consequence of the Fermi level lying in the gap (only in this case are the upper limits of the integrals in Eq. (2) equal to \( \pi \)), is an important feature in deriving Eq. (3). The original series is truncated for small indices which results in the appearance of the exponential factor, \( (4A)^{-2\pi - 1} \), before the sum in Eq. (3). This factor then appreciably contributes to the energy \( (A) \)-dependent part of the decay length of the DM (although see Fig. (3) where this is not the case).

Further analysis is based on the use of Stirling’s approximation for \( \nu_{ij} \gg 1 \) which allows us to evaluate asymptotically both the internal finite sum \( \Sigma_{2} \) in the \( 3D \) case and the external infinite sums over \( k \) in all dimensions. For example, if all \( \nu_{ij} \gg 1 \), then keeping the leading term in the asymptotic expansions, we can write the
The dependence on distance of $\ln |\rho_{\nu_\alpha}|$ (a-c) and of $\lambda = -\ln |\rho_{\nu_\alpha}|/\sigma$ (d-f) in the 3D case. In (a) and (d), the DM has been calculated on the lattice sites situated around the main diagonal [111] for solid angles defined by the polar angle $\phi \in [20^\circ, 70^\circ]$ and azimuthal angle $\theta \in [20^\circ, 70^\circ]$; in (b) and (e), $\nu_x = 0$ and $\nu_x$ and $\nu_y$ vary around the plane diagonal and are characterized by the polar angle $\phi \in [20^\circ, 70^\circ]$ (around the [110] direction); and in (c) and (f), $\nu_x = \nu_y = 0$ and $\nu_x$ varies (in the [100] direction). All the symbols have the same meaning as in Figs. 1 except in (e), where the solid circles represent the contribution to $\lambda$ due to the exponential term in Eq. (5), the squares and triangles are due to $J_{\nu_x}$ and $J_{\nu_x+\nu_y}$, respectively, while the diamonds signify the prefactor in Eq. (6).

The dependence of the inverse decay length $\lambda$ (a) and the effective inverse decay length $\tilde{\lambda}$ (b) on the energy-dependent parameter $A$ of the model in 3D. The data in (a) given by the thick solid and long dashed lines were obtained by linear regression from the slope of $\ln |\rho|$ evaluated numerically using Eqs. (4) and (5) for the [111] direction, respectively. The thin solid line in (a) represents Eq. (4) (the difference between the thin and thick solid lines is due to the prefactor in Eq. (6)), while the short dashed line shows the $\ln(2A)$-contribution to $\lambda$. The solid line in (b) represents the analytical result according to Eqs. (7)-(8), while the long dashed line is obtained by exact numerical evaluation of Eq. (4) or Eq. (5). The short dashed line in (b) shows the $\ln(2A)$-contribution, while the dot-dashed line gives the $1/A^2$-contribution. The DM in (b) has been calculated on the particular representative node characterized by $\nu_x = \nu_y = \nu_z = 0$.

Following expression for the DM in all three dimensions:

$$\rho_{\nu_\alpha} \simeq (-1)^D (2\pi)^{-D/2} \left( \prod_{\alpha} \nu_{\alpha} \right)^{-1/2} \exp \left[ -\sigma \lambda \right], \tag{4}$$

where the inverse decay length, $\lambda(A, \nu_\alpha)$, is given by

$$\lambda(A, \nu_\alpha) = \ln(2A) + \frac{\sigma_{-1}}{4A^2} + \frac{\sigma_{\ln}}{\sigma} - \ln(\sigma), \tag{5}$$

with $\sigma_{-1} \equiv \sum_{\alpha}^D \nu_{\alpha}^{-1}$ and $\sigma_{\ln} \equiv \sum_{\alpha}^D \nu_{\alpha} \ln \nu_{\alpha}$. As follows from Eqs. (4)-(5) and Figs. 1(a,c) and 2(a,d), the DM in this model of an insulator: (i) exponentially decays with the distance-related parameter $\sigma$; (ii) has a power-law prefactor which is proportional to $\nu^{-D/2}$; (iii) is anisotropic; and (iv) the inverse decay length of the DM depends on the energy parameters of the model. The behaviour with effective distance of $\ln |\rho_{\nu_\alpha}|$ and the effective inverse decay length, $\lambda = -\ln |\rho_{\nu_\alpha}|/\sigma$, are shown in Figs. 1(a,c) for the 2D case and in Figs. 2(a,d) for the 3D case, respectively. The different points correspond to $\lambda$ all the lattice nodes within a relatively wide solid (polar in 2D) angle around the main diagonal. Examination of the results shows that the slowest decay of the DM occurs along the main diagonal, i.e. the [111] direction in the 3D case. The analytical expression (6) allows the different contributions to the effective decay length to be estimated. It is clearly seen in Figs. 2(c) and 2(d) that the major $A$-dependent contribution comes from the $\ln(2A)$-term in Eq. (5), while the role of the second term, $\sim 1/A^2$, in Eq. (5) is not important at all, especially in comparison with the significant $A$-independent contribution from the last two terms in Eq. (5) (see Fig. 2(b)).

In the case when one of the indices, e.g. $\nu_x \gg 1$, but the other ones are small and finite ($D \geq 2$),

$$\rho_{\nu_\alpha} \simeq \frac{(-1)^D}{\sqrt{2\pi \nu_a}} \exp \left[ -\nu_a \ln(2A) \right] \prod_{\alpha \neq a} J_{\nu_\alpha} \left( \frac{\nu_{\alpha}}{A} \right), \tag{6}$$

where $J$ stands for the Bessel function, the asymptotic form for which, with large argument $\nu_a$, must be used in Eq. (6). Bearing in mind that $J_{\nu_a}(\nu_x/A) \propto (\nu_x/A)^{-1/2}$ for $\nu_x \gg 1$, it is easy to see that the power-law prefactor, $\propto \nu^{-D/2}$, is restored in Eq. (5). The results for this particular case are presented in Figs. 3(b,d) and 3(c,f). Again, the contribution of the term $\ln(2A)$ in the inverse decay length is dominant, and the inverse decay length is now larger than for decay along the main diagonal (cf. e.g. Figs. 2(a,d) and 2(c,c)).

Finally, if $\nu_x, \nu_y \gg 1$ and $\nu_z$ is finite (in 3D),

$$\rho_{\nu_\alpha} \simeq \frac{(-1)^D}{\sqrt{2\pi \nu_a}} \exp \left[ -\nu_a \left( 1 + \frac{\nu_a}{2\nu_a} \ln(\nu_a/\nu_y) \right) \right].$$
\[ J_{\nu_{\pm}} \left[ \frac{\nu_{\pm}}{A} \right] J_{\nu_{\pm}} \left[ \frac{\nu_{\pm}^2}{\sqrt{\nu_{\pm}^2 - A^2}} \right] , \]

where \( \nu_{\pm} = \nu_x \pm i \nu_y \) and, for both Bessel functions, known asymptotic expressions (for the argument in \( J_{\nu_{\pm}} \) and for the argument and index in \( J_{\nu_{\pm}} \)) must be used \cite{12}. These asymptotics for both Bessel functions restore the \( \nu^{-3/2} \) prefactor for the DM in the same manner as for Eq. (6). The energy \((A)\)-dependent contribution to \( \lambda \) (see Fig. 2(c)), in this case, comes mainly from the asymptotic expression for \( J_{\nu_{\pm}} \) which is of exponential type if \( \nu_{\pm}/(A \sqrt{\nu_{\pm}}) < 1 \) (and of cos-type otherwise) \cite{12}.

Another important point to discuss is the dependence of the typical inverse decay length, \( \lambda \), on the energy parameters of the model. The only energy-dependent parameter in this model is the parameter \( A \) which is simply related to the spectral characteristics of the model, \( A = \Delta_x/4t_{12} = D\Delta E_{\text{opt}}/(\beta \Delta E_b) \), where \( \Delta E_{\text{opt}} = 4Dt \) is the band width, \( \Delta E_{\text{opt}} = \Delta_x \) is the optical (direct) band gap and the ratio of hopping integrals, \( \beta = t_{12}/t \), which can be connected to the thermal gap, \( \Delta E_b = (\Delta E_{\text{opt}} + (\beta \Delta E_b)^2)^{1/2} - \Delta E_b \). The spectral parameters \((\Delta E_{b, \text{opt}} = \Delta E_{\text{opt}})\) are not independent values because the hopping integrals \( t_{\mu\mu'} \) in the Hamiltonian \cite{11} can depend on the orbital energies \( \epsilon_\mu \) and obtaining such a dependence, e.g. \( t_{12}(\Delta \epsilon) \), requires more accurate analysis which is not necessary for our approach (that is why we plot \( \lambda \) vs \( A \) but not the direct gap width \( \Delta x \) in Fig. 3). However, the limiting case, \( \Delta \epsilon \rightarrow 0 \), can be investigated, at least numerically (analytical results are valid only for \( A > D \)) under the reasonable assumption that \( t_{12} \neq 0 \) as \( \Delta \epsilon \rightarrow 0 \), and the results are presented in Fig. 3(a), confirming the linear scaling of the inverse decay length, \( \lambda \propto A \Delta \epsilon \) for \( A \rightarrow 0 \) \cite{10}.

This model can be analysed analytically only for a s.c. lattice and thus, strictly speaking, we stick to the atomic orbital representation. However, numerics show that the results (exponential decay of the density matrix and variation of the decay length with parameters of the Hamiltonian) are qualitatively the same for different underlying lattices. This is not surprising because the asymptotic behaviour at large distances hardly depends on the local structural details (the local features of the lattice can influence the value of \( \lambda \) by a factor of \( \sim 2 \); see Figs. 3(b)). Thus, we believe that our results, at least qualitatively, are general. Indeed, the inverse decay length decreases with decreasing \( A \) (see Fig. 3), thus reflecting the known delocalization tendency of the DM with increasing metallicity (in the bonding/antibonding representation \cite{11} \( A \approx V_2/V_1 \), being the ratio of the bonding-antibonding splitting energy and the metallic bandwidth energy). Moreover, the analytical expressions for the decay length give correct order-of-magnitude estimates of \( \lambda \) for Si and C \cite{14}.

To conclude, we have derived analytic asymptotic expressions for the spatial decay of the density matrix decay in insulators. The results have been obtained for a tight-binding Hamiltonian defined on the s.c. lattice having two orthogonal bare states on each node. Two additional assumptions, namely symmetric lattice (equal in-band transfer integrals) and relatively weak intraband hybridization, allow us to derive exact asymptotic results for the density matrix in all three dimensions. The main features of the analytic solution are: exponential spatial decay of the density matrix, anisotropy of the decay length, the dependence of the decay length on the energy parameters of the model, and the existence of a power-law prefactor \( \propto r^{-D/2} \). All the analytic asymptotic results have been supported by precise numerical solutions of the problem.

We are grateful to Peter Paule for giving us access to the finite hypergeometric summation codes. We thank L. He and D. Vanderbilt for helpful comments on the manuscript. DAD acknowledges support from the NSF under grants DMR 0081006 and DMR 0074624.
