Abstract Major abscesses and diabetic foot infections (DFIs) are predominant subtypes of complicated skin and skin structure infections (cSSSIs), and are mainly caused by Staphylococcus aureus and β-hemolytic streptococci. This study evaluates the potential benefit of direct pathogen-specific real-time polymerase chain reaction (PCR) assays in the identification of causative organisms of cSSSIs. One-hundred and fifty major abscess and 128 DFI biopsy samples were collected and microbial DNA was extracted by using the Universal Microbe Detection kit for tissue samples. Pathogen-specific PCRs were developed for S. aureus and its virulence factor Panton–Valentine leukocidin (PVL), Streptococcus pyogenes, S. agalactiae, S. dysgalactiae, and the S. anginosus group. Identification by pathogen-specific PCRs was compared to routine culture and both methods were considered as the gold standard for determination of the sensitivity and specificity of each assay. Direct real-time PCR assays of biopsy samples resulted in a 34 % higher detection of S. aureus, 37 % higher detection of S. pyogenes, 18 % higher detection of S. agalactiae, 4 % higher detection of S. dysgalactiae subspecies equisimilis, and 7 % higher detection of the S. anginosus group, compared to routine bacterial culture. The presence of PVL was mainly confined to S. aureus isolated from major abscess but not DFI biopsy samples. In conclusion, our pathogen-specific real-time PCR assays had a higher yield than culture methods and could be an additional method for the detection of relevant causative pathogens in biopsies.

Introduction

Major abscesses and diabetic foot infections (DFIs) are the predominant subtypes of a spectrum of infections termed complicated skin and skin structure infections (cSSSIs). The Food and Drug Administration (FDA) defined cSSSIs as infections of the deeper soft tissues, involving surgical intervention or a significant underlying disease state that complicates the response to treatment. Superficial infections located in an anatomical site in which the chance of involvement of anaerobic or Gram-negative pathogens is high should also be considered as cSSSIs [1, 2]. cSSSIs are associated with significant morbidity and mortality, as well as prolonged and expensive hospitalizations [3]. The management of cSSSIs involves surgical debridement of the infection, combined with antibiotic therapy [4].

Gram-positive cocci, in particular Staphylococcus aureus and β-hemolytic streptococci, are the leading causative organisms of cSSSIs [2, 4]. In a recent multicenter randomized clinical trial, 65 % of the cultured isolates consisted of Gram-positive cocci (S. aureus 33 % and β-hemolytic streptococci 15 %), whereas Gram-negative bacilli (28 %) and anaerobes (7 %) were found to a lesser extent [5], but geographical differences exist in the type and amount of species isolated [6]. Correct and rapid identification of pathogens is
crucial for clinical decision-making and optimal antibiotic therapy. Up to now, routine bacteriological assessment of biopsies from cSSSIIs relies upon culture, which, in order to be successful, requires viable pathogens in tissue and the use of suitable culture conditions for growth. Difficult to culture pathogens, those present in low numbers or that died before/during sampling of the infected tissue make detection by culture complicated and time-consuming. This may result in low sensitivity and underestimated bacterial prevalence. Several molecular assays, such as pathogen-specific, broad-range, and multiplex polymerase chain reaction (PCR) assays, either directly on clinical samples or cultured isolates, have been developed in recent years to improve bacteriological detection [7, 8]. This study evaluates the potential benefit of direct, pathogen-specific real-time PCR assays on clinical samples in the identification of the causative organisms of cSSSIIs.

Biopsy samples of 150 major abscesses and 128 DFIs were collected during a multicenter clinical trial involving patients with cSSSIIs [5]. Detection of the pathogens S. aureus and Streptococcus species by real-time PCR directly on DNA isolated from these clinical cSSSI samples was compared to routine cultures.

Materials and methods

Definitions

cSSSIIs were characterized as infections of bacterial origin that required hospitalization, initial parenteral therapy for ≥48 h, and which met at least one of the following criteria: deep soft tissue involvement; significant surgical intervention, including drainage and/or debridement; and association with an underlying comorbid condition. Major abscesses were defined as collections of pus associated with extensive cellulitis, requiring surgical intervention followed by antibiotic therapy. DFIs were characterized as infections occurring below the ankle in patients with confirmed diabetes [5].

Collection of major abscess and DFI biopsy samples

From a population of 813 cSSSI patients included in a large randomized, multicenter clinical trial [5], performed from September 2006 to June 2008, 389 patients gave informed consent to participate in this substudy. Of these, the first visit, prestudy treatment biopsy samples were selected, resulting in the inclusion of 150 major abscesses and 128 DFI samples from 225 cSSSI patients. Samples were collected via biopsy of tissue or bone, curettage of the wound, or aspiration of purulent discharge. After collection, samples were directly stored in preservation medium (BBL Port-A-Cul Transport vial, Becton Dickinson, Franklin Lakes, NJ, USA) and transported within 72 h to the central laboratory (Eurofins Medinet SAS, Plaisir, France) [5]. On arrival, samples were split into two, one part for immediate culture and identification by using standard clinical laboratory procedures, and the other part was stored at −80 °C for subsequent DNA isolation and PCR analysis.

Bacterial DNA extraction from biopsy samples

Pathogen DNA was manually extracted by using the MolYsis Universal Microbial Detection kit for tissue samples (Molzym, Bremen, Germany), following the manufacturer’s instructions. Briefly, selective lysis of human cells is performed, followed by degradation of human DNA. After washing the pellet, a second round of DNA extraction is performed to release DNA from bacterial and fungal cells. This approach enables an increased sensitivity and specificity for pathogen DNA, since interfering non-target human DNA is no longer present [9]. Pathogen DNA extraction was carried out in a laminar flow cabinet to prevent contamination. Prior to further handling, the DNA samples were stored at −20 °C.

Real-time PCR primer and probe design

To detect S. agalactiae, in both subspecies of S. dysgalactiae and S. pyogenes, the recA gene was chosen as the target, based on the results from previous studies [10, 11]. Partial recA sequences of clinically relevant Streptococcus species were extracted from GenBank (accession numbers EU156792–EU156872), an alignment was generated in MEGA v6 [12], and primer and probe sets were developed to make sure that there was no overlap with other Streptococcus species. The specificity of the primers and probes were in silico tested by a BLAST search in GenBank.

A previously described multiplex real-time PCR assay was used to detect the S. aureus-specific fragment S442 and the Panton–Valentine leukocidin (PVL) gene [13].

The duplex real-time PCRs were performed in reaction volumes of 20 μL consisting of 10 μL 2× LC480 Probe Master Mix (Roche Diagnostics), 0.1 μL of each primer and 0.04 μL of both probes (100pmol/μL; Eurogentec, Brussels, Belgium), 1.72 μL ddH2O, and 8 μL sample DNA. The PCRs were performed with the following settings: initial denaturation step for 10 min at 95 °C, 50 cycles of 1 s at 95 °C, 12 s at 60 °C, followed by measuring the fluorescence signal, and a cooldown step for 30s at 40 °C.

For detection of members of the S. anginosus group (S. anginosus, S. constellatus, and S. intermedius, also termed the S. milleri group), a set of primers was developed based on an alignment made in MEGA v6 of the recN sequences EU917226–EU917315 [12, 14]. The PCRs were performed in 10 μL reaction volumes, containing 5 μL 2× LC480 Probe Master Mix (Roche Diagnostics, Almere, the Netherlands), 0.5 μL of each primer (10pmol/μL; Eurogentec), 0.5 μL
SYTO82 (40 μM; Molecular Probes, Eugene, OR, USA), 2.5 μL ddH2O, and 1 μL sample DNA. The following PCR program was used: initial denaturation for 10 min at 95 °C, 35 cycles of 5 s at 95 °C, 5 s at 60 °C, and 10 s at 72 °C, followed by a melting curve analysis at 65 °C to 95 °C. Fluorescence was measured after each extension step.

The primer and probe sequences of all assays are provided in Table 1.

### Real-time PCR assays and analysis

The analytic specificity was tested by applying the newly developed *Streptococcus* assays on a set of 62 clinically relevant *Streptococcus* reference strains. The sensitivity of the *Streptococcus* assays was performed by applying two-step dilution series of the relevant type strains, starting with an input ranging from 0.01 ng to 4.9 fg per reaction. The equivalent of genomic copies per reaction was calculated based on the genome sizes for each of the *Streptococcus* species [15, 16].

Table 1  Primer and probe sequences

| Specificity | Forward primer | Probe | Reverse primer |
|-------------|----------------|-------|----------------|

### Statistical analysis

McNemar’s test was performed to study differences between real-time PCR and culture-based assessment of pathogenic presence, for major abscesses and DFIs separately. The results for major abscesses and DFIs were combined for the determination of the sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). Both culture and real-time PCR were considered as the gold standard.

### Results

**Validation of species-specific *Streptococcus* real-time PCR assays and analysis**

The *S. agalactiae* real-time PCR assay was found to be positive for the included strains; however, atypical amplification curves were observed for two *S. anginosus* strains. The *S. pyogenes* assay, included in the duplex real-time PCR with *S. agalactiae*, was found to be exclusively positive for strains that belong to this species. The *S. dysgalactiae* duplex real-time PCR assay was positive for the included subspecies *dysgalactiae* and *equisimilis*. However, the assay for subspecies *equisimilis* showed an atypical amplification curve for one strain of *S. constellatus* and *S. cristatus*.

The lower limit of detection was found to be at the 9th dilution step for the targets *S. agalactiae*, both subspecies of *S. dysgalactiae* and *S. pyogenes*, equivalent of ~39 fg DNA per reaction, equal to ~17 genomic copies per reaction. For the intercalating dye-based assay for *S. anginosus*, *S. constellatus* and *S. intermedius* assay, the lower limit of detection was found to be at the 8th dilution step, equal to 78 fg or ~37 genomic copies per reaction.

### Real-time PCR versus culture-based assessment of *S. aureus* prevalence in major abscesses and DFIs

The first visit biopsy samples of 150 major abscesses and 128 DFIs were collected, and the identification of *S. aureus* was performed by real-time PCR and culture. Of the 150 major abscess samples, 81% were positive for *S. aureus* by real-time PCR, whereas 44% were culture-positive for *S. aureus*. None of the culture-positive samples were real-time PCR-negative (Table 2). Of the 128 DFI samples, 88% were positive for *S. aureus* by real-time PCR, whereas 57% were culture-positive for *S. aureus*. One culture-positive sample was found to be real-time PCR-negative (Table 2). Subsequent real-time PCR determination of the cultured strain from the culture-positive, real-time PCR-negative biopsy sample confirmed the presence of *S. aureus*. Statistical analysis using McNemar’s test showed a significant difference between *S. aureus* real-time PCR and culture-based assessment for
major abscesses (p<0.001) and DFIs (p<0.001). The sensitivity, specificity, PPV, and NPV for the S. aureus real-time PCR and culture are shown in Table 3.

Real-time PCR-based assessment of PVL versus S. aureus prevalence in major abscesses and DFIs

The presence of S. aureus virulence factor PVL was determined by real-time PCR and correlated to S. aureus real-time PCR-positive biopsies. Of interest, the majority of S. aureus real-time PCR-positive major abscess samples were also PVL real-time PCR-positive (89%). In contrast, a minority of S. aureus real-time PCR-positive DFI samples were PVL real-time PCR-positive (14%). In both groups of major abscesses and DFIs, two samples were PVL real-time PCR-positive but not S. aureus real-time PCR-positive (Table 4).

Real-time PCR versus culture-based assessment of S. pyogenes prevalence in major abscesses and DFIs

Of the 150 major abscess samples, 85% were positive for S. pyogenes by real-time PCR, whereas 15% were culture-positive for S. pyogenes. None of the culture-positive samples were real-time PCR-negative (Table 2). Of the 128 DFI samples, 15% were positive for S. pyogenes by real-time PCR, whereas 1% were culture-positive for S. pyogenes. The only culture-positive sample was also real-time PCR-positive (Table 2). Statistical analysis showed a significant difference between S. pyogenes real-time PCR and culture-based assessment for major abscesses (p<0.001) and DFIs (p<0.001). The sensitivity, specificity, PPV, and NPV for the S. pyogenes real-time PCR and culture are shown in Table 3.

Real-time PCR versus culture-based assessment of S. agalactiae prevalence in major abscesses and DFIs

Of the 150 major abscess samples, 31% were positive for S. agalactiae by real-time PCR, whereas 5% were culture-positive for S. agalactiae. Three culture-positive samples were real-time PCR-negative (Table 2). Of the 128 DFI samples, 30% were positive for S. agalactiae by real-time PCR, whereas 22% were culture-positive for S. agalactiae. Ten culture-positive samples were real-time PCR-negative (Table 2). Subsequent real-time PCR determination of the cultured samples showed

Table 2  Real-time polymerase chain reaction (real-time PCR) versus culture-based assessment of Gram-positive coccal prevalence in major abscesses and diabetic foot infections

|                   | Major abscesses |                      | Diabetic foot infections |                      |

strains from the 13 culture-positive, real-time PCR-negative biopsy samples confirmed the presence of *S. agalactiae* of four strains. The other nine strains were negative for *S. agalactiae* real-time PCR. Statistical analysis showed a significant difference between *S. agalactiae* real-time PCR and culture-based assessment for major abscesses (*p* < 0.001) but not DFIs (*p* > 0.05). The sensitivity, specificity, PPV, and NPV for the *S. agalactiae* real-time PCR and culture are shown in Table 3.

Real-time PCR versus culture-based assessment of *S. dysgalactiae* prevalence in major abscesses and DFIs

Of the 150 major abscess samples, 2 % were positive for *S. dysgalactiae* subspecies *equisimilis* by real-time PCR, whereas 3 % were culture-positive for *S. dysgalactiae* subspecies *equisimilis*. One of the culture-positive samples was real-time PCR-negative (Table 2). Of the 128 DFI samples, 22 % were positive for *S. dysgalactiae* subspecies *equisimilis* by real-time PCR, whereas 13 % were culture-positive for *S. dysgalactiae* subspecies *equisimilis*. One DFI sample was found to be culture-positive but real-time PCR-negative (Table 2). Subsequent real-time PCR determination of the cultured strains from the two culture-positive, real-time PCR-negative biopsy samples confirmed the presence of *S. dysgalactiae* subspecies *equisimilis* of one strain. The other strain was negative for *S. dysgalactiae* subspecies *equisimilis* real-time PCR. Statistical analysis showed a significant difference between *S. dysgalactiae* subspecies *equisimilis* real-time PCR and culture-based assessment for DFIs (*p* < 0.01) but not major abscesses (*p* > 0.05). The sensitivity, specificity, PPV, and NPV for the *S. dysgalactiae* subspecies *equisimilis* real-time PCR and culture are shown in Table 3.

None of the 150 major abscess samples were real-time PCR or culture positive for *S. dysgalactiae* subspecies *dysgalactiae*. Of the 128 DFI samples, only one sample was positive for *S. dysgalactiae* subspecies *dysgalactiae* by real-time PCR but culture-negative, and, also, one sample was culture-positive for *S. dysgalactiae* subspecies *dysgalactiae* but real-time PCR-negative. Subsequent real-time PCR determination of the cultured strain from the culture-positive, real-time PCR-negative biopsy sample was negative for *S. dysgalactiae* subspecies *dysgalactiae* but positive for *S. dysgalactiae* subspecies *equisimilis*.

Real-time PCR versus culture-based assessment of *S. anginosus* group prevalence in major abscesses and DFIs

*S. anginosus*, *S. constellatus*, and *S. intermedius* together constitute the *S. anginosus* group. Of the 150 major abscess samples, 19 % were positive for members of the *S. anginosus* group. The other nine strains were negative for *S. anginosus* group real-time PCR. Statistical analysis showed a significant difference between *S. anginosus* group real-time PCR and culture-based assessment for major abscesses (*p* < 0.001) but not DFIs (*p* > 0.05). The sensitivity, specificity, PPV, and NPV for the *S. anginosus* group real-time PCR and culture are shown in Table 3.
group by real-time PCR, whereas 15% were culture-positive for members of the S. anginosus group. Seven culture-positive samples were real-time PCR-negative (Table 2). Of the 128 DFI samples, 15% were positive for members of the S. anginosus group by real-time PCR, whereas 6% were culture-positive for members of the S. anginosus group. One culture-positive sample was real-time PCR-negative (Table 2). Subsequent real-time PCR determination of the cultured strains from the eight culture-positive, real-time PCR-negative biopsy samples confirmed identification of the S. anginosus group of six strains. Of the two other strains, one was negative for S. anginosus group real-time PCR and the other strain was not viable. Statistical analysis showed a significant difference between S. anginosus group real-time PCR and culture-based assessment for DFIs (p < 0.01) but not major abscesses (p > 0.05). The sensitivity, specificity, PPV, and NPV for the S. anginosus group real-time PCR and culture are shown in Table 3.

Discussion

This study is the first to demonstrate that the use of direct real-time PCR versus culture-based assessment for the determination of pathogens in clinical biopsy samples of patients with major abscesses and DFIs resulted in an increased detection of all studied cSSSI pathogens: S. aureus, S. pyogenes, S. agalactiae, S. dysgalactiae, and S. anginosus group.

The current routine practice for the detection and identification of bacterial pathogens in cSSSI is culture of biopsy samples collected from the site of infection. Development of direct real-time PCR assays on bacterial DNA isolated from biopsy samples resulted in a higher detection of 34% for S. aureus, 37% for S. pyogenes, 18% for S. agalactiae, 4% for S. dysgalactiae subspecies equisimilis, and 7% for the S. anginosus group compared to standard cultures. No differences were observed for S. dysgalactiae subspecies dysgalactiae, which could be due to its low prevalence in human infections [17]. Significant differences were found between real-time PCR and culture assessment for S. aureus (major abscesses and DFIs), S. pyogenes (major abscesses and DFIs), S. agalactiae (major abscesses), S. dysgalactiae subspecies equisimilis (DFIs), and S. anginosus group (DFIs). Possible explanations for the real-time PCR-positive, culture-negative biopsy samples are: culture is less sensitive than real-time PCR for the detection of organisms, real-time PCR detects nonviable organisms in contrast to culture, splitting of the biopsy sample into two parts for culture and real-time PCR, contamination of the real-time PCR reagents, cross-reactivity of the real-time PCR assay with DNA from other organisms or human origin not controlled for during the development of the assay inducing false-positives.

In contrast, our real-time PCR assays did not identify some pathogens that were grown in culture. Possible explanations for the culture-positive, real-time PCR-negative biopsy samples are: real-time PCR is less sensitive than culture for the detection of organisms, incorrect determination during culture, low prevalence of bacterial DNA in the biopsy sample, splitting of the biopsy sample into two parts for culture and real-time PCR, low DNA yield or poor quality DNA after extraction or the presence of factors that inhibit the real-time PCR assay, poor target specificity, and/or competition between primers and probes within the developed real-time PCR not controlled for during the development of the assay.

Other studies evaluating the potential of direct real-time PCR in the detection of the organisms studied here frequently found comparable or increased detection rates compared to culture methods. The detection of (methicillin-resistant) S. aureus by real-time PCR was similar to culture in samples from skin and soft tissue infections and osteoarticular infections [18, 19], and increased in a screening for MRSA colonization [20]. In addition, the detection of S. pyogenes by real-time PCR was similar to culture in throat swabs from suspected pharyngitis [21, 22]. Furthermore, similar and increased detection rates of S. agalactiae were found in screening samples of vaginal and neonatal colonization [23–25], and increased detection was observed by real-time PCR for S. agalactiae in cerebrospinal fluid and blood from patients suspected of meningitis and sepsis [26]. Overall, combined detection by either culture and/or real-time PCR resulted in 85% of samples positive for S. aureus, 68% positive for S. pyogenes, 36% positive for S. agalactiae, 12% positive for S. dysgalactiae subspecies equisimilis, 0.7% positive for S. dysgalactiae subspecies dysgalactiae, and 20% positive for S. anginosus group. This again underlines the importance of Gram-positive cocci in cSSSI. Interestingly, there are differences in the species present in major abscesses and DFIs. S. pyogenes was mainly detected in biopsies from major abscesses, whereas S. dysgalactiae subspecies equisimilis was mainly found in biopsies from diabetic foot infections. Other identified pathogens were similarly present in both major abscesses and DFIs. In addition, a clear distinction was observed between major abscesses and DFIs for PVL-positive S. aureus. 73% of the major abscesses, but only 14% of the DFIs, were positive for PVL. PVL is a bi-component pore-forming toxin, encoded by the lukS-PV and lukF-PV genes, and is associated with lysis of leukocytes [27]. A recent meta-analysis confirmed the association between PVL and S. aureus skin and skin structure infections, which was not present for S. aureus invasive infections, such as pneumonia, musculoskeletal infections, and bacteremia [28].

In an attempt to evaluate the reliability of the real-time PCR and culture, we have calculated the sensitivity, specificity, PPV, and NPV. Both techniques were separately considered.
as the gold standard, as it is unknown which technique represents the “true” presence of pathogens in the biopsy samples.

In conclusion, current routine bacteriological assessment of biopsies by culture is time-consuming, requires viable pathogens, culture conditions suitable for growth, and results in lower detection sensitivity and may underestimate bacterial prevalence. However, given the fast and superior detection of cSSSI pathogens by real-time PCR, our study indicates that molecular analysis can be an additional method for the detection of bacteria in clinical samples.

Acknowledgments We are grateful to all the patients, investigators, and study centers who participated in the RELIEF clinical trial. Special thanks go to: Johanna Beekman (Bayer Healthcare, Berlin, Germany) for the collection, preparation, and storage of patient biopsy samples, and Corné Klaassen (Canisius-Wilhelmina Hospital, Nijmegen, the Netherlands) for his help with the laboratory methods of this study.

Funding This work was supported by an unrestricted grant from Bayer Healthcare. This study is part of the “Limburg Clinical Research Program (LCRP) U Hasselt-ZOL-Jessa”, supported by the foundation Limburg Sterk Merk, province of Limburg, Flemish government, Hasselt University, Ziekenhuis Oost-Limburg, and Jessa Hospital.

Conflict of interest MHT Stappers reports an unrestricted grant from Limburg Clinical Research Program (LCRP) U Hasselt-ZOL-Jessa; IC Gyssens reports an unrestricted grant from Bayer Healthcare; P Reimnitz was an employee of Bayer Pharma AG during the conduct of the study; JW Mouton reports grants from Astra-Zeneca, Basilea, Merck, Cubist, Polyphor, Roche, Pfizer, and Jansen-Cilag; JF Meis reports grants from Astellas, Basilea, Merck, and MSD, and personal fees from Merck and Gilead; IC Gyssens reports grants from Pfizer outside the submitted work.
