MSSM Constraints from Higgs Boson Searches

André Sopczak
Lancaster University

Abstract
The LEP era has brought immense progress in searches for Higgs bosons over the last 12 years which will guide searches at future colliders. The evolution of the Higgs boson mass limits is reviewed with the focus on results from general parameter scans in the Minimal Supersymmetric extension of the Standard Model (MSSM) in contrast to the so-called benchmark limits. The hint for a Standard Model (SM) Higgs boson of 115.6 GeV can also be interpreted as a preference for a Higgs boson of that mass in the MSSM. Further small data excesses allow the hypothesis that the neutral Higgs bosons of the MSSM all have masses between 90 and 116 GeV.

Presented at the Seventh Topical Seminar on the Legacy of LEP and SLC, Siena, Italy, October 2001
The LEP era has brought immense progress in searches for Higgs bosons over the last 12 years which will guide searches at future colliders. The evolution of the Higgs boson mass limits is reviewed with the focus on results from general parameter scans in the Minimal Supersymmetric extension of the Standard Model (MSSM) in contrast to the so-called benchmark limits. The hint for a Standard Model (SM) Higgs boson of 115.6 GeV can also be interpreted as a preference for a Higgs boson of that mass in the MSSM. Further small data excesses allow the hypothesis that the neutral Higgs bosons of the MSSM all have masses between 90 and 116 GeV.

1. Introduction

The search for Higgs bosons has been one of the most important lines of research during the LEP era. Final LEP-1 results from data taken at the Z-resonance [1] and preliminary LEP-2 results for complete data up to 209 GeV center-of-mass energy [2] were recently reviewed. The MSSM is well motivated and the most discussed extension of the SM. It predicts three neutral (h, H, and A) and two charged Higgs bosons. At the beginning of LEP operation in 1989, no radiative corrections to the neutral Higgs boson masses were calculated and \( m_h < m_Z \) was predicted. First- and second-order corrections increased the upper mass bound to about 130 GeV. The neutral Higgs boson masses and production cross sections strongly depend on various model parameters. At LEP two ways were chosen to present the mass limits: benchmark limits for a certain set of MSSM parameters and mass limits based on MSSM parameter scans. Details of the benchmark and scan parameters are given for example in Refs. [3,4].

2. Largely reduced h mass limit

The importance of a MSSM parameter scan to set mass limits was already realized at LEP-1. The region marked by the thick black line in Fig. 1 shows that the h mass limit is reduced from 41 to 25 GeV in a parameter scan compared to benchmark results [5,6].

3. Removal of A mass limit

An early LEP-2 study showed that a benchmark limit of 52 GeV on the A mass [7] disappeared completely in a MSSM parameter scan (Fig. 2).
4. Similar limits from different experiments

The results from very different parameter scan methods of different LEP experiments agree well as shown in Figs. 3 and 4 for 189 GeV data. The shaded region in Fig. 3 is excluded by charge- and color-breaking (CCB) criteria [9].

Figure 3. 189 GeV \((m_h, m_A)\) result.

Limits from charmless \(b\)-decays, the electroweak parameter \(\Delta \rho\) and direct searches for Supersymmetric particles do not change the \(h\) and \(A\) mass limits [10]. The parameter scan reduced the benchmark limits by up to 7 GeV [11,10]. The constraints on \(\tan \beta\) are given in Figs. 5 and 6.

Figure 4. 189 GeV \((m_h, m_A)\) result. The dotted line indicates the corresponding benchmark limit.

Figure 5. 189 GeV \((m_A, \tan \beta)\) result.

Figure 6. 189 GeV \((m_h, \tan \beta)\) result.
5. Small reduction of limits

With increasing center-of-mass energy, benchmark and parameter scan limits agree within 1 GeV for 202 GeV data \[12\]. The mass and $\tan \beta$ limits are given in Figs. 7, 8 and 9.

Figure 8. 202 GeV $(m_A, \tan \beta)$ result.

![Figure 9](image3.png)

Figure 9. 202 GeV $(m_h, \tan \beta)$ result.

6. Combined LEP parameter scan limits

The mass limits from benchmark and parameter scan agree within about 2 GeV in the combination of the 202 GeV data from all LEP experiments \[13,14\]. The scan limits are given in Figs. 10, 11 and 12.

![Figure 10](image4.png)

Figure 10. 202 GeV $(m_h, m_A)$ result.
7. Latest results

The latest benchmark and scan results including 209 GeV data agree within 2 GeV \cite{15,16} and give mass limits on h and A of 89 GeV (Figs. 13, 14 and 15). The importance of a MSSM parameter scan is underlined in Fig. 16 which shows that large parameter regions exist where a Higgs boson could decay invisibly into a pair of neutralinos. Thus, only in conjunction with a dedicated search \cite{16} the h and A mass limits are set.
8. Three Higgs boson hypothesis

For 202 GeV data, taken in 1999, and first 2000 data, h and A mass limits were 2 GeV below expectation \cite{17}. This tendency is enhanced by including complete 209 GeV data, in which case the limits are 3.1 to 3.6 GeV below the expectations of about 95 GeV \cite{3}. A possible explanation is that the HZ excess at about 115 GeV is due to the heavier scalar H and that, in addition, the production of hA with masses between 90 and 100 GeV occurs \cite{17}. Figure 17 (from \cite{3}) shows a data excess above $2\sigma$ for $m_h + m_A = 187$ GeV in the $bb\bar{b}b$ channel. The same data excess is also expressed by the confidence level $CL_h$ for a signal observation as shown in Fig. 18 (from \cite{3}).

The hypothesis of the production of three MSSM Higgs bosons is supported by the data excess seen in Fig. 14 (from \cite{3}) at 100 GeV which could result from hZ production in addition to HZ production. For the reported MSSM parameters \cite{17} $\cos^2(\beta - \alpha) \approx 0.9$; therefore $\sin^2(\beta - \alpha) = \xi^2 \approx 0.1$. The $\xi^2$ limit in the 100 GeV mass region shows a deviation of about $2\sigma$ between the expected and observed limit, as seen in Fig. 24 (from \cite{18}). Figure 22 shows that this new support is only observed in the complete LEP data.

Figure 15. 209 GeV ($m_h, \tan\beta$) result.

Figure 16. 209 GeV ($m_h, \tan\beta$) result from searches for invisibly decaying Higgs bosons.

Figure 17. Limits on the hA cross section as a function of $m_h + m_A$ at 95% CL ($m_h \approx m_A$) for the MSSM processes $e^+e^- \to hA \to bb\bar{b}b$. This corresponds also to limits on $\cos^2(\beta - \alpha)$ in the general extension of the SM with two Higgs boson doublets. The data of the four LEP experiments collected at energies from 88 to 209 GeV are combined. The solid curve is the observed result and the dashed curve shows the expected median. Shaded areas indicate the $1\sigma$ and $2\sigma$ probability bands.
The confidence level $1 - CL_b$ as a function of $m_h + m_A$ for the case $m_h \approx m_A$ (where only the $e^+e^- \rightarrow hA$ process contributes since $\sin^2(\beta - \alpha) \approx 0$). The straight line at 0.5 and the shaded 1\(\sigma\) and 2\(\sigma\) probability bands represent the expected background-only result. The solid curve is the observed result and the dashed curve shows the expected median for a signal.

Figure 18.

Distribution of the reconstructed SM Higgs boson mass in searches conducted at energies between 200 and 210 GeV. The figure displays the data (dots with error bars), the predicted SM background and the prediction for a Higgs boson of 115 GeV mass. The number of data events selected with mass larger than 109 GeV is 4, while 1.25 are expected from SM background processes and 1.89 from a 115 GeV signal. Between 96 and 105 GeV 10 data events are observed, while 3.6 background events are expected.

Figure 19.

The 95% CL upper bound on $\xi^2$ as a function of $m_H$, where $\xi = g_{HZZ}/g_{SM}^{HZZ}$ is the HZZ coupling relative to the SM coupling. About 2\(\sigma\) deviations from the expectation are observed at $m_H = 98$ GeV and $m_H = 115$ GeV. In the MSSM, hZ production at the lower mass and HZ production at the higher mass are possible.

Figure 20.

The excluded ($\xi^2, m_H$) region including 209 GeV data is compared with the results from combined LEP-1 data [14], taken around 91 GeV center-of-mass energy, and previous LEP-2 limits [14] up to 183, 189, 196 and 202 GeV. The $\xi^2$ limit below 100 GeV does not become significantly stronger when the 209 GeV data, taken in 2000, are included.

Figure 21.
9. Conclusions

The LEP-1 and LEP-2 data are consistent with a background-only hypothesis and give stringent mass limits on the neutral Higgs bosons h and A of the MSSM. During the LEP era, MSSM parameter scans reduced – or for early LEP-2 data even removed completely – the benchmark mass limits. The importance of parameter scans is stressed by large parameter regions where the Higgs boson decays invisibly, which is not considered in benchmark results. At the highest center-of-mass energies, benchmark limits are only slightly reduced by a general parameter scan when the results from invisible Higgs boson searches are included. Table 1 compares benchmark and scan mass limits in the MSSM.

The combined LEP data show a preference for the SM Higgs boson of 115.6 GeV, which can also be interpreted as a preference for a Higgs boson of that mass in the MSSM. Further small data excesses for Higgs boson pair-production and bremsstrahlung between 90 and 100 GeV allow the hypothesis that h, A and H of the MSSM all have masses below 116 GeV. Previously reported MSSM parameter combinations from a general parameter scan for this scenario are supported by the complete data set.

Acknowledgments

I would like to thank the organizers of the conference for their kind hospitality.

Table 1

| √s (GeV) | Data | m_h^b | m_A^b | m_h^s | m_A^s |
