ABSTRACT

The second survey of the molecular clouds in the Large Magellanic Cloud in $^{12}$CO ($J = 1 – 0$) was carried out by NANTEN. The sensitivity of this survey is twice as high as that of the previous NANTEN survey, leading to a detection of molecular clouds with $M_{CO} \approx 2 \times 10^{4} M_{\odot}$. We identified 272 molecular clouds, 230 of which are detected at three or more observed positions. We derived the physical properties, such as size, line width, and virial mass, of the 164 GMCs that have an extent more than the beam size of NANTEN in both the major and minor axes. The CO luminosity and virial mass of the clouds show a good correlation of $M_{vir} \propto L_{CO}^{1.4 \pm 0.1}$, with a Spearman rank correlation of 0.8, suggesting that the clouds are in nearly virial equilibrium. Assuming the clouds are in virial equilibrium, we derived an $X_{CO}$-factor of $\sim 7 \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$. The mass spectrum of the clouds is fitted well by a power law of $N_{cloud}(>M_{CO}) \propto M_{CO}^{-0.75 \pm 0.06}$ above the completeness limit of $5 \times 10^{4} M_{\odot}$. The slope of the mass spectrum becomes steeper if we fit only the massive clouds, e.g., $N_{cloud}(>M_{CO}) \propto M_{CO}^{-1.2 \pm 0.2}$ for $M_{CO} \geq 3 \times 10^{5} M_{\odot}$.

1. INTRODUCTION

Star formation requires a cool and high-density interstellar medium (ISM) in which most of the hydrogen is in molecular form; therefore, studies of distribution and properties of molecular clouds are very important for understanding the star formation process. Emission from the tracer CO molecule has been widely used to estimate the distribution and amount of H$_2$ in the Galaxy and other galaxies. Nevertheless, the CO lines in dwarf irregular galaxies are relatively weak (e.g., Ohta et al. 1993), making the surveys of molecular clouds toward dwarf galaxies difficult.

The Large Magellanic Cloud (LMC) is one of the nearest galaxies to our own. Owing to its unrivaled closeness to the solar system ($\varepsilon \approx 50$ kpc) and its favorable viewing angle, studies of this galaxy have provided valuable information for our understanding of various aspects of the universe and galaxies, including the evolution of stars and stellar clusters. The LMC also provides a unique opportunity for studying molecular clouds and star formation in galaxies whose environment is different from that in the Galaxy. In the LMC, the gas-to-dust ratio is much higher (e.g., Koornneef 1982), and the metal abundance is about $\sim 3 – 4$ times lower (Rolleston et al. 2002; Dufour 1984) than that of the Galaxy.

For these reasons, the LMC has been surveyed at a wide variety of wavelengths. H$\alpha$ maps of moderate ($\sim 15''$) to high ($\sim 1'$) angular resolution have been obtained with the Parkes 64 m telescope (McGee & Milton 1966; Rohlfs et al. 1984; Luka & Rohlfs 1992) and with the Australian Telescope Compact Array (e.g., Kim et al. 1998), respectively. These studies have shown that the H$\alpha$ distribution is dominated by many features, such as filaments, shells, and holes. The ionized-gas content has been investigated with the aid of H$\alpha$ photographs (e.g., Henize 1956; Davies et al. 1976; Meaburn 1980; Kenicutt & Hodge 1986) and the radio continuum (e.g., Haynes et al. 1991; Filipovic et al. 1996; Dickel et al. 2005). The H$\alpha$ and radio continuum images show a variety of interstellar shells, ranging from small supernova remnants to large supersonic shells more than a few hundred parsecs across. The stellar contents of the LMC have been widely studied by photometry of the stars from the near-infrared to the optical bands (e.g., Ita et al. 2004; Zaritsky et al. 2004; Blum et al. 2006, Kato et al. 2007). In particular, the stellar clusters and associations in the LMC have been surveyed and cataloged by many authors (e.g., Lucke & Hodge 1970; Hodge 1988). Bica et al. (1996) estimated the ages of 504 stellar clusters and 120 associations based on their color indices in the $UBV$ bands. Soft X-ray images of the LMC have also been obtained by $\textit{ROSAT}$ (Snowden & Petre 1994), revealing a variety of discrete sources, like supernova remnants, X-ray binaries, supersoft sources, and also diffuse sources associated with superbubbles and supersonic shells. Recent $\textit{Spitzer}$ observations cover $7' \times 7'$ of the LMC, revealing the distribution and properties of the dust, young stellar objects, and evolved stars (Meixner et al. 2006).

Studies of molecular gas in the LMC began with observations with either low angular resolution or a small spatial coverage. Cohen et al. (1988) obtained the first complete CO map of the LMC with the southern Center for Astrophysics 1.2 m telescope at Cerro Tololo Interamerican Observatory. However, the survey was limited by the low spatial resolution, $8.8''$, corresponding to 130 pc at the distance of the LMC. High-resolution CO observations of selected regions by the Swedish-ESO Submillimetre Telescope (SEST) 15 m telescope have been performed in the LMC (e.g., Israel et al. 1986, 2003; Johansson et al. 1994, 1998; Caldwell & Kutner 1996; Kutner et al. 1997). They have mapped some of the well-known H$\alpha$ regions, for example, 30 Doradus, N11, and the molecular cloud complex extending some 2 kpc south of the LMC (e.g., Israel et al. 1986, 2003; Johansson et al. 1994, 1998; Caldwell & Kutner 1996; Kutner et al. 1997). They have mapped some of the well-known H$\alpha$ regions, for example, 30 Doradus, N11, and the molecular cloud complex extending some 2 kpc south.
of 30 Doradus. Although these observations revealed detailed structure of the individual molecular clouds at a linear resolution of less than 10 pc, they are limited in spatial coverage, about 1 deg².

Fukui et al. (1999) carried out and completed a survey of the LMC in CO J = 1–0 with NANTEN, a 4 m radio telescope installed at the Las Campanas Observatory, Chile, to reveal a molecular gas distribution with resolution high enough to identify individual molecular clouds in the LMC. The 3 $\sigma$ noise level of the velocity-integrated intensity was $\sim 1.8$ K km s$^{-1}$. This corresponds to $N(\text{H}_2) \sim 1.3 \times 10^{21}$ cm$^{-2}$, by using a conversion factor of $X_{\text{CO}} = 7 \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$ (see § 4.2). The first results were presented in Fukui et al. (1999) with particular emphasis on the formation of populous clusters. The catalog of 107 molecular clouds and a comparison of these molecular clouds with the H i distribution was described by Mizuno et al. (2001b). A comparison with the young stellar clusters and H ii regions was the subject of Yamaguchi et al. (2001c). The comparisons of the molecular clouds with H i gas and infrared emission by the Infrared Astronomical Satellite (IRAS) were made by Sakon et al. (2006) and Hibi et al. (2006).

In order to have a more comprehensive understanding of the distribution and properties of the molecular clouds in the LMC, a survey in CO J = 1–0 with a sensitivity higher than that of the first survey has been carried out since 1999. Preliminary results focussing on the mass spectrum of this survey are presented by Fukui et al. (2001) and on the comparison of the molecular clouds with supergiant shells by Yamaguchi et al. (2001a, 2001b). Hughes et al. (2006) made a comparison of radio, far-infrared (FIR), H i, and CO in the LMC and revealed the correlation of the radio and FIR distributions.

In this paper, we present a catalog and properties of the molecular clouds from the complete data set of the second survey. Comparisons of the molecular clouds with the indication of the formation of clusters and massive stars detected in optical or radio are found elsewhere (Fukui 2005; Kawamura et al. 2007, 2008, hereafter Paper II). Fukui (2007) introduces a comparison of the molecular clouds with the H i gas distribution. Detailed studies of the H i and molecular gas distribution seeking molecular cloud formation will be presented in Y. Fukui et al. (2008, in preparation, hereafter Paper III). In this paper, the survey by NANTEN is described in § 2, and the spatial distribution and a catalog of molecular clouds are presented in § 3. We also discuss the correlations among cloud properties, such as $L_{\text{CO}}$, the virial mass of the molecular clouds, and the mass spectrum in § 3. A comparison of the cloud properties from the first survey and the discussion of the CO to N(\text{H}_2) conversion factor are presented in § 4. Section 5 summarizes the paper.

2. OBSERVATIONS

We carried out sensitive CO (J = 1–0) observations toward the LMC with NANTEN, a 4 m radio telescope of Nagoya University at Las Campanas Observatory, Chile. The half-power beamwidth was 2.6$^\circ$ at 115 GHz. The telescope had a 4 K, cooled Nb superconductor-insulator-superconductor mixer receiver, which provided a system noise temperature of $\sim 170$–270 K, including the atmosphere toward the zenith.

The spectrometers were two acousto-optical spectrometers (AOs) with 2048 channels; one had a velocity coverage and a resolution of 100 and 0.1 km s$^{-1}$, respectively. The other had a velocity coverage and a resolution of 650 and 0.65 km s$^{-1}$, respectively. The pointing accuracy was better than 20$^\prime$, as checked by optical observations of stars with a CCD camera attached to the telescope, as well as by radio observations of Jupiter, Venus, and the edge of the Sun. Further details about the telescope and related instruments are given by Ogawa et al. (1990) and by Fukui & Sakakibara (1992). The spectral intensities were calibrated by employing the standard room-temperature chopper-wheel technique (Kutner & Ulich 1981). An absolute intensity calibration was made by observing Orion-KL [R.A.(B1950.0) = 5$^h$32$^m$47.0$^s$, decl.(B1950.0) = $-5^\circ$24$^\prime$21$^\prime\prime$] by assuming its absolute temperature $T_R$ to be 65 K. We also observed the strongest peak position of the LMC, N159 [R.A.(B1950.0) = 5$^h$40$^m$1.5$^s$, decl.(B1950.0) = $-69^\circ$47$^\prime$27$^\prime\prime$] every 2 hr to confirm the stability of the system.

The observed region covers $\sim 30$ deg$^2$ where the molecular clouds were detected by the first survey. Figure 1 shows the observed region from 1998 April to 2003 August, superposed on the integrated-intensity map of the CO from the first survey (Fukui et al. 1999; Mizuno et al. 2001b). In total, about 26,900 positions were observed in equatorial coordinates (B1950.0) in position switching. The observed grid spacing was 2$^\prime$ (corresponding to $\sim 30$ pc at a distance of the LMC, 50 kpc) with a 2.6$^\prime$ beam ($\sim 40$ pc). Out of the $\sim 26,900$ positions, 6229 were observed with the narrowband spectrometer for $\sim 100$ days from 1998 April to November, while the rest were observed with the wideband spectrometer for $\sim 300$ days after 1999 March. In this paper, all the spectra observed by the narrowband spectrometer are smoothed to 0.65 km s$^{-1}$ resolution for the reduction to have a uniform velocity resolution throughout the map. The rms noise fluctuations were $\sim 0.07$ K at a velocity resolution of 0.65 km s$^{-1}$ with $\sim 3$ minutes integration for an on position. The typical 3 $\sigma$ noise level of the velocity-integrated intensity was $\sim 1.2$ K km s$^{-1}$. This corresponds to $N(\text{H}_2) \sim 8 \times 10^{20}$ cm$^{-2}$, by using a conversion factor of $X_{\text{CO}} = 7 \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$ (see § 4.2).

3. RESULTS

3.1. Overall Distribution

Out of the $\sim 26,900$ observed positions, significant $^{12}$CO (J = 1–0) emission, with an integrated intensity greater than
1.2 K km s\(^{-1}\) (the ~3 \(\sigma\) noise level), was detected at about 1300 positions, which corresponds to ~5% of the total observed positions. The total velocity-integrated intensity distribution of the molecular gas is shown in Figure 2a.

The mass of the molecular gas in total is \(\sim 5 \times 10^7 M_\odot\), if we use a CO luminosity to hydrogen column density conversion factor, the \(X_{\text{CO}}\)-factor, of \(\sim 7 \times 10^{-20} \text{ cm}^{-2} \text{ (K km s}^{-1})^{-1}\) (see § 4). The CO distribution of the LMC is found to be clumpy with several large molecular cloud complexes, unlike the H \(\text{\textsc{i}}\) gas distribution, which is composed of many filamentary and shell-like structures (e.g., Kim et al. 1999). These clumps of the molecular gas tend to be detected toward the intensity peak of the H \(\text{\textsc{i}}\) gas as shown in Blitz et al. (2007), Fukui (2007), and Paper III. The cloud complex south of 30 Doradus at \(\alpha(J2000) \sim 5^h40^m\) and \(\delta(J2000) \sim -71^\circ\) to \(-69^\circ\) is remarkable, stretching in a nearly straight line from north to south, as already noted by the previous CO observations (Cohen et al. 1988; Fukui et al. 1999; Mizuno et al. 2001b). The current survey shows that the clouds in this molecular cloud complex, “the molecular ridge” are actually connected to one another by a low-density molecular gas, while the first survey traced only the densest regions and identified the molecular ridge as consisting of two or three discrete entities. The arecì"elike distribution of molecular clouds along the southeastern optical edge of the galaxy (the “CO Arc” in Fukui et al. 1999 and Fukui 2002) is also clearly seen. The current sensitive survey confirms that this CO Arc indeed clearly represents an arecì"elike edge of the molecular gas distribution in this eastern boundary of the LMC.

Other CO clouds are distributed over the observed area with moderate concentration toward several prominent H \(\text{\textsc{ii}}\) regions [e.g., N 44 at \(\alpha(J2000.0) \sim 5^h22^m\) and \(\delta(J2000.0) \sim -68^\circ\), N11 at \(\alpha(J2000.0) \sim 4^h55^m\) and \(\delta(J2000.0) \sim -66^\circ\) and the “bar” (e.g., clouds around \(\alpha \sim 5^h20^m\) and \(\delta \sim -70^\circ\)). The small molecular clouds are more clearly observable in the current survey, especially, toward a supergiant shell, LMC 4, at \(\alpha(J2000.0) \sim 5^h20^m-5^h40^m\) and \(\delta(J2000.0) \sim -68^\circ\) to \(-66^\circ\) (see also Yamaguchi et al. 2001a). A detailed comparison of the molecular gas with the indicators of star formation, such as H\(\alpha\) or radio continuum, will be discussed elsewhere (Paper II).

Figure 3 is a histogram of the integrated intensity, I, 1., of each observed position with I.I. > 0.4 K km s\(^{-1}\) (~3 \(\sigma\) noise level). About 980 observed positions have \(N(H_2) > 10^{21} \text{ cm}^{-2}\), while only four positions have \(N(H_2) > 10^{22} \text{ cm}^{-2}\).

Figure 4a shows the radial distribution of CO emission; the surface density, \(\Sigma\), is derived by integrating the CO luminosity within annuli spaced by 4\' and then dividing by the area of the annuli. The center used is \(\alpha(J2000.0) = 5^h17.6^m, \delta(J2000.0) = -69^\circ2^\prime\), which was determined from the kinematics of the H \(\text{\textsc{i}}\) observations by Kim et al. (1998). To see the angular distribution of the CO emission, the distribution of the surface density, \(\Sigma\), derived by integrating the CO luminosity over a sector with a 10\' width and then dividing by an observed area of the sector is shown in Figure 4b. The CO luminosity to mass conversion is carried out by assuming a conversion factor, \(X_{\text{CO}}\), of \(7 \times 10^{20} \text{ cm}^{-2} \text{ (K km s}^{-1})^{-1}\) (see § 4.2) for both.

Figure 4 indicates that the radial profile of the molecular gas decreases moderately along the galactocentric distance, as is also seen in nearby spiral galaxies (e.g., Wong & Blitz 2002), although the profile does not really fit to a power law as they do for the spiral...
galaxies (Wong & Blitz 2000). It is interesting to note the sharp enhancement of the surface density around 2 kpc. This enhancement is due to the molecular cloud complexes, the molecular ridge, N11, and N44. This enhancement is also seen in the angular distribution, especially at about 120° due to the molecular ridge. Compared with the nearby galaxies of Wong & Blitz (2002), the local enhancement of the molecular gas is more conspicuous in the LMC.

Figures 5a–5l are a series of channel maps that show the velocity distribution; they present channel maps with velocities at (a) 200–210, (b) 210–220, (c) 220–230, (d) 230–240, (e) 240–250, (f) 250–260, (g) 260–270, (h) 270–280, (i) 280–290, (j) 290–300, (k) 300–310, and (l) 310–320 km s\(^{-1}\).

In the velocity range 200–240 km s\(^{-1}\), the CO Arc in the southeastern boundary of the LMC and the molecular ridge from the south of 30 Doradus are prominent. The two molecular cloud complexes associated with active star-forming regions N11 and N44 are also prominent in the velocity range between 270–290 km s\(^{-1}\). A systematic velocity gradient from the southeast to the northwest has been known from the first survey (Mizuno et al. 2001b). Our sensitive survey shows a clear feature in the northeast at high velocities, corresponding to LMC 4, in addition to the overall velocity gradient already observed in the first survey. Detailed comparisons of the velocity and spatial distributions of the H\(_i\) and CO emission will be presented in Paper III.

3.2. Identification of CO Molecular Clouds

To study the properties of the molecular gas in the LMC, individual cloud was identified by the cloud-finding algorithm, FITSTOPROPS (Rosolowsky & Leroy 2006). First, the intensity data cube is converted to a signal-to-noise–ratio (S/N) data cube by dividing through by the noise at each position to search for significant emission by clipping the maps at a constant S/N; a constant S/N is used instead of a constant flux-density threshold, although the sensitivity variation across the map is not large (Fig. 6). Then, pairs of adjacent velocity channels with normalized flux greater than 3 were searched for. For each pair, these velocity channels and all contiguous data pixels with normalized flux greater than 2 were assigned to a candidate molecular cloud. This process was continued until all the pairs of adjacent channels with normalized flux greater than 3 have been identified as candidate clouds.

We identified 272 clouds, of which 230 were detected at more than two observed positions. In this paper, we shall call these 230 clouds with more than two observed positions “the giant molecular clouds [GMCs].” The position and intensity-weighted mean velocity of the 230 GMCs and the rest (“the small clouds,” in the following) are listed in Tables 1 and 2, respectively. The sensitivity of a data set influences the cloud properties derived from that data as emphasized by Rosolowsky & Leroy (2006). In order to reduce the observational bias and to be able to compare data sets with different S/N levels, the boundary of a cloud is extrapolated to a boundary isosurface of \(T_{\text{edge}} = 0\) K (see also Blitz & Thaddeus 1980; Scoville et al. 1987). The major and minor axes, size \(R\), position angle (P.A.), and virial mass \(M_{\text{vir}}\) are derived for 164 GMCs (hereafter Group A GMCs) out of 230; the rest (hereafter Group B) have a minor axis less than the...
NANTEN beam, so that the size is not derivable by using the deconvolved moment. The line width, $\Delta V$, and the CO luminosity, $L_{\text{CO}}$, are less sensitive to the beam dilution than the cloud size, so that we can determine $\Delta V$ and $L_{\text{CO}}$ of both the Group A and B GMCs. Then, $M_{\text{CO}}$, the molecular cloud mass, is derived from $L_{\text{CO}}$ by using $X_{\text{CO}} = 7 \times 10^{20} \text{cm}^{-2} (\text{K km s}^{-1})^{-1}$, as derived in § 4.2 by assuming virial equilibrium and the mass fraction of helium to be 36%. The procedure to derive these properties is described by Rosolowsky & Leroy (2006) in detail. The derived properties are presented in Table 3.

3.3. Properties of the Molecular Clouds

In this section, we consider the Group A GMCs, which are resolved by NANTEN. The Group A GMCs have radii ranging from 10 to 220 pc, line widths between 1.6 and 20.2 km s$^{-1}$, CO luminosities between $1.4 \times 10^3$ and $7.1 \times 10^5$ K km s$^{-1}$ pc$^2$, and virial masses ranging from $9 \times 10^3$ to $9 \times 10^6 M_\odot$.

Figure 7 shows the frequency distribution of the $V_{\text{LSR}}$ of the clouds. The distribution is rather nonuniform having peaks at $\sim 220$–250 and $\sim 280$–290 km s$^{-1}$. The one at $V_{\text{LSR}} \sim 220$–250 km s$^{-1}$ represents the clouds in the southern part of the LMC, including the molecular ridge and the CO Arc as seen in Figures 5c–5e. The other at $V_{\text{LSR}} \sim 280$–290 km s$^{-1}$ is dominated by the emission from the LMC 4, N44, and N11 regions (Figs. 5i–5j).

Figures 8 and 9 are the histograms of the ratio of the major and minor axes and the P.A. of the GMCs, respectively. The frequency distribution of P.A. is rather uniform. The distribution of the ratio of the major and minor axes has a peak at $\sim 1.7$, with an average of 2.5, indicating that clouds are generally elongated.

In order to see if the cloud has an alignment with the large-scale structure of the galaxy, such as a spiral pattern, here we introduce a parameter, $\theta$, the angle between the major axis and the tangent at the molecular cloud of a circle with a radius, $d_{\text{cen}}$ (Fig. 10a). Figure 10b shows the frequency distribution of $\theta$. Since the uncertainties of the P.A., as well as of $\theta$, depend on the ratio of the major and minor axes, the histogram of $\theta$ is divided into three groups according to the axial ratio. The histogram of $\theta$ shows the number distribution is nearly uniform and does not have any particularly favorable angles. To see if the distribution of $\theta$ has any characteristics with the galactocentric distance, Figure 10c shows a plot of $d_{\text{cen}}$ versus $\theta$. Again, the plots are distributed quite uniformly, showing no strong dependence of $\theta$ on $d_{\text{cen}}$.

3.3.1. Line Width–Size relation

In this section, we present the correlation between the line width and the radius of the GMCs. The size, $R$, of the cloud is computed as a geometric mean of the “deconvolved” second spatial moments along the major and minor axes, which were derived by using principal component analysis; we “deconvolve” the beam by subtracting its size from the measured cloud size in quadrature. A FWHM line width, $\Delta V$, is derived by multiplying
the moment of the velocity within a GMC by $8 \ln(2)^{1/2}$ (see also Rosolowsky & Leroy 2006). Figure 11 shows a plot of $\log(\Delta V)$ versus $\log(R)$ of the Group A GMCs. It has been known that the line width and the size of molecular clouds have a good correlation of $\Delta V \sim R^{0.5}$ in the solar vicinity (Larson 1981) and in the inner Galaxy (e.g., Dame et al. 1986; Solomon et al. 1987), while the correlation in the GMCs in this work is rather weak, and the best-fitting power law is $\Delta V = 1.3 R^{0.2}$, with a Spearman rank coefficient of 0.3. It is likely that the lack of the dynamic range in size may make the correlation lower in the present study than for the Galactic clouds, although we see a weak positive correlation in the LMC GMCs.

We have applied the cloud-identifying algorithm of Rosolowsky & Leroy (2006) with the parameters used in the current study to identify the GMCs in the LMC to the molecular clouds in the Small Magellanic Cloud (SMC; Mizuno et al. 2001a) as well as those in the outer Galaxy, the Warp region (Nakagawa et al. 2005), and derived the physical properties. When we add the clouds in the SMC and the Warp region to the plot of Figure 11, the dynamic range in $R$ becomes larger, and a positive correlation is seen. A line width–size relation $\sigma_v \propto R^{0.5}$ seen in the inner Galaxy by Solomon et al. (1987) is also shown as an example in Figure 11 (thin dotted line). The correlation between the line width and size of the clouds in the LMC, the SMC, and the Warp region does seem to be consistent with a power-law relation $\sigma_v \propto R^{0.5}$ but with a clear offset from the relation determined for the inner Galaxy (Solomon et al. 1987). Note that at least a part of this offset can be attributed to differences in the methods used to measure cloud properties. The sense of the offset is that for a given radius, the clouds in the inner Galaxy have larger line widths. This may be partially due to the relatively high value of $T_A$ used by Solomon et al. (1987) to define the cloud radius, implying that the clouds might be smaller for a given value of $\Delta V$.

### 3.3.2. Virial Mass–CO Luminosity Relation

The determination of the mass of molecular hydrogen gas is fundamental for understanding the physics of the ISM and star formation in galaxies. In this subsection, we compare the virial mass and the CO luminosity and discuss the conversion factor from the CO line intensity to the H$_2$ column density in the LMC.

Figure 12 shows the virial mass, $M_{\text{vir}}$, as a function of luminosity, $L_{\text{CO}}$, of the clouds in the LMC (filled circles). The plot shows a tight power law for the mass-luminosity relation with some dispersion. A least-squares fit to the data gives a power law, $[M_{\text{vir}}/M_\odot] = 26 [L_{\text{CO}}/(\text{K km s}^{-1} \text{ pc}^2)]^{1.1 \pm 0.3}$, with a Spearman rank correlation of 0.8. This relation suggests that clouds are virialized and the CO luminosity can be a good tracer of mass in the LMC with a quite-constant conversion factor from $L_{\text{CO}}$ to mass throughout the mass range $10^4 \leq M_{\text{vir}}/M_\odot \leq 10^7$. We have added the reidentified clouds in the SMC (Mizuno et al. 2001a).
and the Warp region (Nakagawa et al. 2005) to Figure 12 as in § 3.3.1. The clouds in the SMC and the Warp region lie along the best-fitting power law of GMCs in the LMC.

3.3.3. Mass Spectrum

The frequency distribution of the cloud masses has an important impact not only on the star formation but also on cloud formation and destruction. The mass spectrum of the clouds is well fitted by a power law and often presented as $dN/dM \propto M^{-(\alpha + 1)}$ or $N_{\text{cloud}}(M) \propto M^{-\alpha}$. The preliminary results of the mass spectrum by the second NANTEN survey in the LMC have been already presented and discussed in Fukui et al. (2001). They found the mass spectrum derived from the CO luminosity has a slope with $\alpha = 0.9 \pm 0.1$ above the completeness limit of $8 \times 10^4 \, M_\odot$.

In this section, we present the spectra of the masses, $M_{\text{CO}}$, derived from the CO luminosity, $L_{\text{CO}}$, and a conversion factor, $X_{\text{CO}} = 7 \times 10^{20} \, \text{cm}^{-2} \, \text{K} \, \text{km} \, \text{s}^{-1}$ (§ 3.2 and § 4.2). Here, the CO luminosity, $L_{\text{CO}}$, is less sensitive to the beam dilution than the cloud size, so that we can consider that not only the Group A GMCs but also the $L_{\text{CO}}$ of the Group B GMCs, for which we could not derive a size and $M_{\text{vir}}$, are determined well enough to obtain $M_{\text{CO}}$ (§ 3.2 and Table 3). The mass spectrum of $M_{\text{CO}}$ including both the Group A and B GMCs is shown in Figure 13. The maximum likelihood method (Crawford et al. 1970) was applied to obtain the best-fitting power law above the completeness limit, $5 \times 10^7 \, M_\odot$. The best-fitting power law above the completeness limit is $N_{\text{cloud}}(M_{\text{CO}}) = 6.6 \times 10^5 M_\odot^{-0.75 \pm 0.06} - 3.4$.

The results indicate that the mass of the molecular gas in the LMC is concentrated in the massive clouds, since $\alpha < 2$. The slope of the mass spectrum, and thus the fact that the massive clouds contribute to the galactic total mass, is consistent within the current results, as well as with those presented by Fukui et al. (2001), although the current results show a shallower slope than the other. This difference in the index values of the best-fitting power law may be explained by the difference in the completeness limit. Table 4 shows the index value, $\alpha$, of the power-law fit to the different mass ranges of the GMCs. The best-fitting power law obtained for the clouds with $M_{\text{CO}} \geq 3 \times 10^5 \, M_\odot$ is shown in Figure 13 as an example. Table 4 indicates that the slope of the mass spectrum becomes steeper if we fit only the massive clouds, e.g., $N_{\text{cloud}}(M_{\text{CO}}) \propto M_{\text{CO}}^{-1.2 \pm 0.2}$ for $M_{\text{CO}} \geq 3 \times 10^5 \, M_\odot$, and the logarithmic slope of the mass spectrum becomes steeper at $\sim 3 \times 10^5 \, M_\odot$.

4. DISCUSSION

4.1. Comparison with the First Survey

The current survey was carried out to cover the regions where the molecular clouds are detected in the first survey. The S/N
Fig. 5—Continued

Fig. 6.—(a) Spatial distribution of the noise fluctuations per AOS channel of the current survey and (b) frequency distribution of the noise fluctuations.
of the present observations was higher by a factor of 2 than those in the first NANTEN survey (Fukui et al. 1999; Mizuno et al. 2001b; Yamaguchi et al. 2001c). This increase in sensitivity made it possible to increase the number of significant detections and identified clouds. Different cloud-identification criteria are used in the current study and in Fukui et al. (1999) and Mizuno et al. (2001b). Nevertheless, the number of the clouds with more than two observing positions ("the large clouds" in Mizuno et al. 2001b) is a factor of 3 larger in the present survey even if we use the same algorithm and criteria.

Here we compare the line width–size relation and the virial mass–CO luminosity relation of the molecular clouds from the first and the current surveys. To compare the results, we recalculated the size and the virial mass of the large clouds of the first survey by subtracting the NANTEN beam from the size in Table 1 of Mizuno et al. (2001b).

Figure 14 is a plot of the line width and the size of the clouds derived from both the first survey (gray filled circles) and the current survey (filled circles). The clouds from both the current and the first survey show a large scatter with little positive correlation of the line width and the size. An offset from the correlation of the inner Galaxy is also seen. The scatter is larger in the current survey. This may be explained by the difference in the sensitivity; the high sensitivity of the current survey made it possible to decompose a cloud into several individual clouds with different velocities along the same line of sight, although these clouds may have been identified as a single entity by the first survey.

Figure 15 is a plot of the virial mass, $M_{\text{vir}}$, as a function of luminosity, $L_{\text{CO}}$, of the Group A GMCs from the current survey (filled circles) and the 55 clouds from the first survey (open circles). The correlations between the $M_{\text{vir}}$ and $L_{\text{CO}}$ in both surveys are consistent within the error. Again, the scatter in the current survey is larger, but because the higher sensitivity limit of the current survey enlarges the dynamic range in $M_{\text{vir}}$ and $L_{\text{CO}}$, the correlation coefficient remains as high as 0.85. The ratio of the $M_{\text{vir}}$ and $L_{\text{CO}}$ is related to the conversion factor, $X_{\text{CO}}$-factor, from the CO luminosity to the hydrogen column density, $N(\text{H}_2)$. The consistency of the $M_{\text{vir}}$ and $L_{\text{CO}}$ relation in both surveys suggests that the $X_{\text{CO}}$-factors derived from both surveys are also consistent.

### 4.2. CO to N(\text{H}_2) Conversion Factor

In the following, we derive the $X_{\text{CO}}$-factor from the current survey. The determination of the mass of $\text{H}_2$ in galaxies is fundamental for an understanding of interstellar physics and star formation. The principal method for obtaining $\text{H}_2$ masses converts the intensity of the CO molecular line emission, $I_{\text{CO}}$, into the column density of $\text{H}_2$ molecules. The conversion factor, or $X$-factor [$X \equiv N(\text{H}_2)/I_{\text{CO}} = M_{\text{H}_2}/L_{\text{CO}}$], has been derived for molecular clouds in the solar vicinity based on the assumption of virial equilibrium of individual clouds (e.g., Young & Scoville 1991). This method has been also used to derive the conversion factors in nearby galaxies where individual clouds are resolved, such as the LMC, SMC, M31, M33, etc., (e.g., Mizuno et al. 2001a, 2001b; Wilson & Scoville 1990).

The plot of the $M_{\text{vir}}$ against $L_{\text{CO}}$ in § 3.3.2 (Fig. 12) from the current survey suggests that for massive clouds, $M_{\text{CO}} > 10^5 M_\odot$, it is reasonable to assume virial equilibrium. Here, we use the conventional method of applying the virial theorem to the clouds to estimate the $X_{\text{CO}}$-factor in the LMC. The average value of

...log($M_{\text{vir}}/L_{\text{CO}}$) is 1.2 ± 0.3, corresponding to $X_{\text{CO}} = (7 \pm 2) \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$, for the Group A GMCs with $L_{\text{CO}}$ higher than the completeness limit, 9 × 10$^3$ K km s$^{-1}$ pc$^2$, which is equivalent to $M_{\text{vir}} \geq 1.4 \times 10^5 M_\odot$. Figure 16 is a frequency distribution of log($M_{\text{vir}}/L_{\text{CO}}$) of the Group A GMCs, i.e., including all the clouds for which we derived virial masses. The geometric mean of $M_{\text{vir}}/L_{\text{CO}}$, and thus the $X_{\text{CO}}$-factor, does not differ from the values obtained by using the clouds with $L_{\text{CO}} \geq 9 \times 10^3$ K km s$^{-1}$ pc$^2$ only. This value is slightly less than what we obtained from the first survey, $X_{\text{CO}} \sim (8 \pm 2) \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$, after taking into account the beam deconvolution but is consistent within the error.

An $X_{\text{CO}}$-factor in the inner Galaxy has been derived by using a correlation between the $\gamma$-ray and the CO intensity along the Galactic plane (Bloemen et al. 1986). Bloemen et al. (1986) summarized the value of the $X$-factors, and the value for the inner Galaxy was derived to be $(1-3) \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$ on average. The $X$-factor obtained above is about twice that of the clouds in the inner Galaxy.

Bertoldi & McKee (1992) argue that the gravitational energy, $W$, of an ellipsoidal cloud is given by $W = -(3/5)(GM^2/R)|\arcsin(e)/e|$, (eq. [A9] of Bertoldi & McKee 1992) where $G$, $M$, and $R$ are the gravitational constant, mass, and the size of the clouds, respectively. Here, $e$ is an eccentricity of the cloud, $e = (1 - y^2)^{1/2}$, where $y$ is an axial ratio of the cloud. The current sample of the GMCs are not really spherical, with the mode of the ratio of the major and minor axes being ~1.7 and the average being 2.5, as shown in § 3.3 (see also Fig. 8). The shape-dependent factor, $a_2 = (R_m/R)|\arcsin(e)/e|$, (eq. [A8] of Bertoldi & McKee 1992), ranges from 1 to 0.88 for the current sample of the GMCs in the LMC, with $a_2 = 0.99$ for the axis ratio of 2.5. This means that the virial mass of the current sample of the GMCs differs from the derived virial mass with about 15% at most due to the elliptical shape of the clouds. The deviations of the estimated $M_{\text{vir}}$ from the true $M_{\text{vir}}$ affect the derived $X_{\text{CO}}$-factor linearly. Thus, the current estimate of the $X_{\text{CO}}$-factor can be overestimated...
by at most $\sim 15\%$ due to the deviation of the cloud shape from spherical symmetry.

Rubio et al. (1993) suggested a possible dependence of the $X_{\text{CO}}$-factor on cloud size from their observations toward the clouds in the SMC with SEST. Figure 17 is a plot of the $M_{\text{vir}}/L_{\text{CO}}$ against the cloud size. There is no significant correlation in the LMC clouds; the scatter is as large as an order of magnitude in $M_{\text{vir}}/L_{\text{CO}}$, although the range of the cloud sizes is the same as that of the SMC (Rubio et al. 1993).

It has been claimed that the metallicity is quite uniform in the LMC (e.g., Dufour 1984), while the metallicity of the outer part of a galaxy is suggested to be lower than that of its inner region for our Galaxy and some of the nearby galaxies (e.g., Nakanaga et al. 2005). Figure 18 shows a plot of $M_{\text{vir}}/L_{\text{CO}}$ against the distance from the center of the LMC derived from the H $\text{i}$ distribution (Kim et al. 1998). The current result shows no clear correlation of $M_{\text{vir}}/L_{\text{CO}}$ with the distance from the center, suggesting that the $X_{\text{CO}}$-factor does not depend on the distance from the center of the LMC. This is consistent with the idea that the metallicity is quite uniform in the LMC.

4.3. Mass Spectrum

The mass spectrum of the Galactic clouds ($^{12}\text{CO}$ or $^{13}\text{CO}$) is well fitted by a power law with index values of $\alpha \sim 0.5–1.0$ (e.g., Solomon et al. 1987; Solomon & Rivolo 1989; Casoli et al. 1984; Digel et al. 1996; Dobashi et al. 1996), of which the higher values are derived from the lower mass clouds in the outer Galaxy (e.g., Heyer et al. 2001) or from $^{13}\text{CO}$ observations (e.g., Yonekura et al. 1997; Kawamura et al. 1998). The mass distribution of the Galactic clouds and that of the clouds in nearby galaxies have been studied (Blitz et al. 2007 and references therein). Most of the...
galaxies have similar mass distributions, \( \alpha \sim 0.7 \); an exception is M33, which is steeper than the rest, but the data set has a higher completeness limit (Rosolowsky et al. 2003; Rosolowsky 2005). A number of numerical simulations have been conducted to obtain a mass spectrum of GMCs in galaxies (e.g., Vázquez-Semadeni et al. 1997; Wada et al. 2000, and references therein). Wada et al. (2000) carried out a simulation of the HI and CO distributions of an LMC-type galaxy, specifically at the highest spatial resolution \( \sim 7.8 \) pc, which incorporated fairly realistic star formation processes and supernova rates. They show that the GMC mass spectrum in an LMC-like galaxy is expected to have a power law with an index value of \( \alpha = 0.7 \) if no star formation is taken into account and that the index becomes steeper, around 1.0, if the dissipation of clouds due to star formation is incorporated. The present mass spectrum appears to be consistent with these values, while those of the non-star-forming models may fit the present result slightly better. According to Wada & Norman (2001), the absence of a massive GMC of \( \sim 3 \times 10^6 M_\odot \) is due to a well-mixed, turbulent...
ISM that tends to form smaller GMCs. The consistency of the mass spectrum among galaxies may suggest that the mechanism of cloud formation and disruption show similar characteristics among galaxies. Nevertheless, the truncation of very massive GMCs may suggest that the disruption of molecular clouds is faster in massive clouds. It may also suggest that cloud formation takes place inhomogeneously; the mass spectra in different regions of the galaxy may have different slopes, and the truncation of the slope might appear when we sum up all the mass spectra within the galaxy. The reason of the truncation is not yet known, but the current results present new information, leading to a better knowledge of cloud formation and disruption.

Fig. 14.—Line width–size relation of the Group A GMCs from the current survey (filled circles) and 55 “large clouds” from the first survey (gray filled circles). The size of a cloud from the first survey was recalculated from the catalog (Mizuno et al. 2001b) by subtracting the NANTEN beam size. The thick dashed line indicates the best-fitting power law of the GMCs from the second LMC survey. The relation found for the GMCs in the inner Galaxy from Solomon et al. (1987, thin dashed line) is shown as an example. [See the electronic edition of the Supplement for a color version of this figure.]

Fig. 15.—Virial mass, $M_{\text{vir}}$, of the 164 GMCs as a function of luminosity, $L_{\text{CO}}$, from the current survey (filled circles). The line present a best fit to the data with slope of 1.1 ± 0.1. Open circles are for the clouds from the first survey (Fukui et al. 1999; Mizuno et al. 2001b). The virial masses of clouds from the first survey were recalculated after subtracting the NANTEN beam size from the sizes of the clouds shown in the catalog of Mizuno et al. (2001b). [See the electronic edition of the Supplement for a color version of this figure.]

Fig. 16.—Histogram of log($M_{\text{vir}}/L_{\text{CO}}$). The mean of log($M_{\text{vir}}/L_{\text{CO}}$) is 1.2 ± 0.3, corresponding to $X_{\text{CO}} = (7 \pm 2) \times 10^{20}$ cm$^{-2}$ (K km s$^{-1}$)$^{-1}$.

Fig. 17.—Dependence of $M_{\text{vir}}/L_{\text{CO}}$ on the size of the Group A GMCs. The solid line shows the weighted mean of the $M_{\text{vir}}/L_{\text{CO}}$ in each bin of log($R$); the last bin shown by the dashed line includes only one point of $M_{\text{vir}}/L_{\text{CO}}$. [See the electronic edition of the Supplement for a color version of this figure.]
5. SUMMARY

A large-scale $^{12}$CO ($J = 1 - 0$) survey for molecular clouds was made toward the Large Magellanic Cloud (LMC) by NANTEN. An area of $\sim 30$ deg$^2$ was covered, and significant $^{12}$CO emission (\geq 0.07 K) was detected at $\sim 1300$ out of the 26,900 observed positions. We identified 272 molecular clouds, 230 of which were detected at more than three observing positions. The positions, mean velocities, and velocity dispersions of the 272 clouds, and the extents, position angles, and CO luminosities of the 230 giant molecular clouds (GMCs) are derived. Reliable sizes and virial masses are determined for the well-resolved 164 GMCs (Group A). The main results are summarized as follows.

1. The Group A GMCs have radii ranging from 10 to 220 pc, line widths between 1.6 and 20.2 km s$^{-1}$, CO luminosities between 1.4 \times 10^3$ and 7.1 \times 10^4 K km s$^{-1}$ pc$^2$, masses derived from CO luminosities from 2 \times 10^4 to 7 \times 10^6 $M_\odot$, and virial masses from 9 \times 10^3 to 9 \times 10^6 $M_\odot$. The maximum temperature ($T_k$) of the CO line is as high as $\sim 2$ K, which was detected toward the N113 and N159 regions.

2. The line width, $\Delta V$, and the radius, $R$, of the Group A GMCs appear to satisfy the slope of the power law in the line width–size relation of the clouds in the Galaxy but with an offset in the constant of proportionality.

3. A least-squares fit to the virial mass versus CO luminosity relation shows a power law, $\langle M_{\text{vir}}/M_\odot \rangle = 26[L_{\text{CO}}/(K \text{ km s}^{-1} \text{ pc}^2)]^{1.1 \pm 0.3}$, with Spearman rank correlation of 0.8. This good correlation shows that the CO luminosity is a good tracer of the mass of molecular clouds in the LMC.

4. The integrated $^{12}$CO-N$^2$H$^+$ conversion factor is found to be $X_{\text{CO}} = 7 \times 10^{-20}$ cm$^{-3}$ (K km s$^{-1}$)$^{-1}$ by assuming virial equilibrium for the Group A GMCs.

5. The mass spectrum of the GMCs with $5 \times 10^4 \leq M_{\text{CO}}/M_\odot \leq 10^7$ is well fitted by a power law, $N_{\text{GMC}}(>M_{\text{CO}}) \propto (M_{\text{CO}}/M_\odot)^{-0.75 \pm 0.06}$. This slope is consistent with the previous results obtained from the Galaxy and nearby galaxies. The slope of the mass spectrum becomes steeper if we fit only the massive clouds, e.g., $N_{\text{GMC}}(>M_{\text{CO}}) \propto M_{\text{CO}}^{-1.1 \pm 0.2}$ for $M_{\text{CO}} \geq 3 \times 10^7 M_\odot$, which suggests mass truncation.

The NANTEN project is based on a mutual agreement between Nagoya University and the Carnegie Institution of Washington (CIW). We greatly appreciate the hospitality of all the staff members of the Las Campanas Observatory of CIW. We acknowledge Leo Blitz, Erik Rosolowsky, and Adam Leroy for their discussion and providing us with their cloud-identifying program.

We are thankful to many Japanese public donors and companies who contributed to the realization of the project. This work is financially supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan (15071203) and from the Japan Society for the Promotion of Science (JSPS) (14102003, core-to-core program 17004 and 18684003). T. M. is supported by the JSPS and M. R. by the Chilean Center for Astrophysics, FONDAP 15010003.
