Abstract: This study investigated the effect of sodium bicarbonate (NaHCO₃) ingestion on the Yo-Yo intermittent recovery test 1 (IR1). We tested the hypothesis that acute ingestion of NaHCO₃ would increase blood lactate concentrations ([BLa]), enhance performance, and reduce rating of perceived exertion (RPE) in the Yo-Yo IR1. Eight recreationally active males (N=8, age: 26±4 yr, height: 178±6 cm, body mass: 82±10 kg) participated in the Yo-Yo IR1 on two separate occasions, separated by 1 wk, in a randomized crossover design. Following familiarization, during seated rest, participants’ pretest [BLa] was taken, and participants then consumed either a placebo of 0.3 g·kg⁻¹ body weight sodium chloride or 0.3 g·kg⁻¹ body weight NaHCO₃. Sixty minutes post-ingestion, a standardized warm-up preceded the Yo-Yo IR1. Upon completion, postexercise [BLa] (mmol·L⁻¹), RPE (arbitrary units) and Yo-Yo IR1 time to fatigue (s) were recorded. Paired t-test revealed a small but significant improvement in Yo-Yo IR1 performance under the NaHCO₃ condition (610±267 sec), compared to the placebo condition (556±259 sec; p=0.01; Cohen’s d=0.20). [BLa] increased more under the NaHCO₃ condition (1.6±0.7 to 17.5±5.2 mmol·L⁻¹; p<0.001; Cohen’s d=4.29), compared to the placebo condition (2.0±0.7 to 11.5±5.0 mmol·L⁻¹; p=0.001; Cohen’s d=2.66). Postexercise RPE was not significantly different between conditions. The results of this study suggest that acute NaHCO₃ ingestion improves Yo-Yo IR1 performance without altering RPE, likely through an increased lactate efflux, demonstrated by increased [BLa].

Keywords: alkalosis, anaerobic, blood lactate, ergogenic aid, performance, repeated sprints

Introduction

Muscular performance declines during prolonged and intense activity, with changes in metabolites contributing to reductions in force production, muscle shortening velocity, and prolongation of relaxation.¹ Mechanisms such as acid excretion via the kidneys, hyperventilation, and blood bicarbonate (HCO₃⁻) operate to offset increased production and release of hydrogen (H⁺) during times of accelerated metabolism.² Changes in muscle pH have been suggested to play a critical role in fatigue,³ while reduced ability of muscle to maintain force may be related to accumulating H⁺.⁴ However, in a recent special communication, Westerblad⁵ suggested that while temporal correlations between change in intracellular pH and decrease in muscle force have been observed, recovery of force in the absence of pH recovery has been observed.

Intermittent high-intensity exercise decreases blood and muscle pH, ostensibly contributing to skeletal muscle fatigue.³ Repeated high-intensity exercise performance therefore depends largely upon metabolic buffering capacity.⁶ Sodium bicarbonate (NaHCO₃) is an ergogenic aid, employed by athletes prior to exercise, to increase...
buffering capacity of $\text{H}^+$ ions, in an attempt to delay fatigue. While muscle cell membranes are impervious to $\text{HCO}_3^-$, increasing extracellular $\text{HCO}_3^-$ increases the pH gradient between intracellular and extracellular environments. As a result, significantly higher blood lactate concentrations [BLa] have been observed following $\text{NaHCO}_3$ supplementation, suggesting $\text{NaHCO}_3$ increases the efflux of $\text{H}^+$ and $\text{La}^-$ from working muscle into general circulation. As such, during specific exercise protocols (those involving a large anaerobic component), $\text{NaHCO}_3$ may be efficacious in enhancing exercise performance. \textsuperscript{10}

Lavender and Bird\textsuperscript{11} reported that peak power output during 10-sec sprints on a cycle ergometer was significantly greater following $\text{NaHCO}_3$ ingestion compared to a placebo. Yet Vanhatalo et al\textsuperscript{12} observed that despite pre-exercise alkalosis being achieved by $\text{NaHCO}_3$ ingestion, critical power, work done above the critical power ($H^+$; considered as energy available from anaerobic sources), and total work done during a 3-min all-out test were unaltered. However, performance enhancement has been demonstrated during repeated sprint swimming,\textsuperscript{13} and high-intensity running\textsuperscript{14} was preceded by $\text{NaHCO}_3$ ingestion. Moreover, some authors have reported improved performance during the Yo-Yo intermittent recovery test 2 (IR2).\textsuperscript{15,16} However, some ambiguity remains regarding the effectiveness of $\text{NaHCO}_3$ ingestion prior to the Yo-Yo test.\textsuperscript{17}

Given that numerous sporting events are characterized by repeated periods of intense anaerobic activity,\textsuperscript{18,19} tolerance to repeated bouts of intense exercise is necessary. As proposed by Bangsbo et al,\textsuperscript{18} the Yo-Yo IR1 appears well suited to this purpose. The test is conducted to volitional exhaustion, or an inability to maintain running speed. Repeated sprints of progressively increasing velocities are required, interspersed with 10 sec of active recovery. This test has been proposed as an estimation of match-related fitness in handball,\textsuperscript{20} soccer,\textsuperscript{21} and rugby league.\textsuperscript{22}

While the influence of $\text{NaHCO}_3$ during the Yo-Yo IR2 is well characterized,\textsuperscript{15,16} there remains a paucity of data concerning the effect of $\text{NaHCO}_3$ ingestion prior to the Yo-Yo IR1. Therefore, the aim of the present investigation was to examine the influence of acute $\text{NaHCO}_3$ ingestion on [BLa], rating of perceived exertion (RPE), and performance during the Yo-Yo IR1.

Methods

Participants

In a randomized, single-blinded, repeated measures crossover design, participants reported to the laboratory following familiarization on two separate occasions, separated by 1 wk with a 7-day washout period considered sufficient to ameliorate the residual effects of $\text{NaHCO}_3$.\textsuperscript{14} Testing was completed at the same time of day (19:00–20:00 h) to abrogate the influence of diurnal variation in exercise performance.\textsuperscript{23}

Prior to enrollment, participants completed a physical activity readiness questionnaire and provided written informed consent. The investigation was approved by the London Metropolitan University Research Ethics Committee. An a priori power calculation using mean ± standard deviation (SD) from previous literature\textsuperscript{15} suggested a sample size of $N=6$ would be adequate to obtain statistical power of 0.8 for a two-tailed test. Therefore, to allow for dropouts, eight recreationally active males (age: 26±4 yr, body height: 178±6 cm, body mass: 82±10 kg) volunteered to participate in the study. Participants had abstained from exercise and alcohol for the previous 24 h.

Experimental procedures

Participants arrived at the laboratory 3–4 h postprandial; thereafter body height (Seca Leicester Height Measurer; Birmingham, UK) and mass (Salter Touch Analyser Digital Scales; Kent, UK) were recorded. On each occasion, [BLa] concentration was measured at rest and postexercise, using a handheld portable analyzer measuring whole blood (LactatePro 2; Arkay, Kyoto, Japan). Following piercing of the skin using a retractable lancet, a 0.3-μL blood sample was obtained from the fingertip and drawn directly from the sample site into the coded reagent strips of the device. This method has demonstrated interclass correlations (ICCs) of 0.989.\textsuperscript{24} Following resting samples, participants consummed 500 mL, sugar-free beverage containing either 1) 0.3 g·kg\textsuperscript{-1} body weight $\text{NaHCO}_3$ or 2) an equimolar amount of the placebo, sodium chloride. This dosage strategy has previously been used by Higgins et al.\textsuperscript{25} Sodium chloride was consumed to ensure participants’ inability to identify the $\text{NaHCO}_3$ solution, as previously demonstrated.\textsuperscript{14}

Yo-Yo IR1

Sixty minutes postingestion, participants completed a standardized 5-min warm-up involving walking at a self-selected pace, interspersed with two 5- to 10-sec all-out sprints. A recovery period of 2 min was permitted between warm-up and test. The Yo-Yo IR1 requires participants to perform $2 \times 20$ m shuttle runs at speeds indicated by beeps on an audio recording, interspersed by 10-sec active recovery, 5 m behind the starting marker. Participants performed the Yo-Yo IR1 until volitional exhaustion, or when participants
were incapable of maintaining the designated running speed. On the first occasion, participants were unable to maintain the designated running speed, a warning was given from the researcher, and on the second time, participants were withdrawn from the test. When individuals twice failed to reach the finishing line in the time allocated, or reached volitional exhaustion, cumulative time (sec) was recorded. Following test completion, RPE were recorded within 30 sec, and [BLa] concentrations were collected within 2 min. The Yo-Yo IR1 has demonstrated reliability and validity in measurement of match-related fitness, capable of distinguishing between competition level, playing position, and training adaptation. A recent investigation observed ICCs of 0.82–0.92.

**Statistical analysis**

Data were analyzed using SPSS (version 22; IBM North America, New York, NY, USA). To determine parametricity, Levene’s tests (homogeneity of variance) and Shapiro–Wilk (normal distribution) were employed. Where parametric assumptions were met, data were analyzed using a paired samples t-test to examine differences in Yo-Yo IR1 performance between conditions. A 2 × 2 (time point × condition) repeated measures analysis of variance (ANOVA) was used to test for differences in [BLa], and a Wilcoxon signed rank test was used to examine differences between conditions for RPE. In all instances, significance was set a priori at \( p < 0.05 \), and effect size is reported for primary outcome measures. Effect sizes are considered trivial (<0.2), small (0.2–0.49), medium (0.5–0.79), or large (≥0.8). Data are presented as mean ± SD in all instances.

**Results**

Due to 100% adherence, eight participants (N=8) completed both conditions, and statistical power was confirmed as 0.981 for cumulative time. Paired samples t-test revealed significantly improved Yo-Yo IR1 under the NaHCO₃ condition compared to placebo (610±267 sec and 556±259 sec, respectively: \( p = 0.01 \); Cohen’s \( d = 0.20 \) [Figure 1A]). Postexercise RPE was not significantly different (\( p = 1.00 \)) between NaHCO₃ and placebo conditions (16±2 and 16±1 for NaHCO₃ and placebo, respectively [Figure 1B]).

NaHCO₃ and placebo pretest [BLa] were not significantly different (\( p = 0.209 \)). A significant, large effect of time point (\( p = 0.002; \eta^2 = 0.758 \)) and condition (\( p < 0.001; \eta^2 = 0.900 \)) was observed for [BLa] (Figure 2). Moreover, a significant, large interaction effect (\( p = 0.001; \eta^2 = 0.824 \) was detected. Blood lactate increased more under NaHCO₃ (1.6±0.7 to 17.5±5.2 mmol·L⁻¹; \( p < 0.001 \); Cohen’s \( d = 4.29 \)) compared to placebo (2.0±0.7 to 11.5±5.0 mmol·L⁻¹; \( p = 0.001 \); Cohen’s \( d = 2.66 \).
Discussion
The present study examined the effects of acute NaHCO$_3$ ingestion on Yo-Yo IR1 performance, [BLa], and RPE. The primary finding of this investigation was that acute supplementation of NaHCO$_3$ improved Yo-Yo IR1 performance. Moreover, greater [BLa] was observed postexercise under the NaHCO$_3$ condition compared to placebo.

The present study is in line with previous investigations in reporting a 52% increase in [BLa] following NaHCO$_3$ ingestion compared to placebo. Bishop and Claudius$^{14}$ reported [BLa] increased 26% following NaHCO$_3$ ingestion. Differences in the magnitude of [BLa] increase may be explained by dissimilar exercise protocols, as the present investigation examined the influence of NaHCO$_3$ ingestion on Yo-Yo IR1 performance, whereas the study by Bishop and Claudius$^{14}$ investigated the effect during intermittent sprint cycling.

Substantial research exists examining the ergogenic effect of NaHCO$_3$ on exercise performance.$^{5,30,31}$ In a double-blinded, crossover study, Hobson et al$^{31}$ examined the performance of 20 male rowers undertaking two 2,000 m rowing time trials, and reported 0.3 g·kg$^{-1}$ NaHCO$_3$ enhanced rowing performance, particularly in the final 500 m (by 1.1±1.7 sec). Likewise, Higgins et al$^{32}$ reported NaHCO$_3$ ingestion increased cycling capacity by 17% at 100% power output determined using a 3-min stage-ramp protocol, although not at 110% or 120%, suggesting NaHCO$_3$ ingestion significantly improves continuous constant load cycling at 100% peak minute power, but not at 110% or 120%. Goldfinch et al$^{33}$ similarly reported six male athletes ran 400 m significantly faster following 0.4 g·kg$^{-1}$ body weight NaHCO$_3$ compared to placebo (56.94±2.25 sec vs 58.63±2.25 sec for NaHCO$_3$ and placebo, respectively).

Recently, NaHCO$_3$ supplementation has garnered interest in relation to intermittent sprint performance, as this modality is more representative of sprint profiles of team sports.$^{33}$ Glaister$^{33}$ suggested the ability to repeat maximal, short-duration sprint efforts, while resisting fatigue is a determining factor in many team sports. Although mean heart rate and oxygen uptake (VO$_2$) during team sports are approximately 80% and 70% maximum, respectively,$^{34-36}$ expressing intensity as an average during these events belies the complexity of physiological processes. For example, in soccer, high-intensity movements typically last ~4 sec, and ~22 m, although this is position dependent.$^{37}$ Despite the intricacies of determining intensity of repeated sprints during match play, it is evident that repeated sprint ability is a key determinant of field-based team sports,$^{38}$ and therefore strategies to improve this ability via ergogenic aids are of interest to practitioners and athletes alike.

The present investigation reports a 9.7% improvement in Yo-Yo IR1 performance in a group of recreationally active males and is therefore in line with previous research in suggesting NaHCO$_3$ ingestion improves intermittent exercise performance.$^{31}$ Krustup et al$^{31}$ reported a 14% improvement in the Yo-Yo IR2 as a result of NaHCO$_3$ ingestion in a group of trained athletes. Data from the same laboratory suggest that when preceded by intense arm cranking exercise, NaHCO$_3$ ingestion improved performance in the Yo-Yo IR2 by 23% compared to placebo.$^{16}$

Conclusion
The present study demonstrates acute NaHCO$_3$ ingestion improves performance in the Yo-Yo IR1 without concomitant change in perception of effort. One limitation of the present study is that we did not measure blood gas parameters, which would add confirmatory evidence that the performance enhancement observed was a result of NaHCO$_3$ ingestion. However, given the design of our investigation (randomized crossover), and increased [BLa], we find it difficult to provide an alternative explanation. As such, the current study is the first to observe increased performance during the Yo-Yo IR1 following NaHCO$_3$ ingestion, which adds to the body of literature supporting the ergogenic effect of NaHCO$_3$ on intermittent sprint exercise.
