Scheduling under dynamic speed-scaling for minimizing weighted completion time and energy consumption

Christoph Dürr∗ Lukasz Jeż† Oscar C. Vásquez‡

May 30, 2018

Abstract

Since a few years there is an increasing interest in minimizing the energy consumption of computing systems. However in a shared computing system, users want to optimize their experienced quality of service, at the price of a high energy consumption. In this work, we address the problem of optimizing and designing mechanisms for a linear combination of weighted completion time and energy consumption on a single machine with dynamic speed-scaling. We show that minimizing linear combination reduces to a unit speed scheduling problem under a polynomial penalty function. In the mechanism design setting, we define a cost share mechanism and studied its properties, showing that it is truthful and the overcharging of total cost share is bounded by a constant.

Keywords: scheduling, energy management, quality of service, optimization, mechanism design.

1 Introduction

Humanity has entered a period when natural resources become rare. This situation triggered consciousness in responsible consumption, and many countries, companies and individuals aim to minimize their energy consumption. Minimizing energy consumption is a relatively new topic in decision theory, giving rise to new problems and research areas.

An area of increasing interest is the energy consumption minimization of computing systems with dynamic speed-scaling, allowed in modern microprocessors by technologies such as Intel SpeedStep, AMD PowerNow!, or IBM EnergyScale. The theoretical energy consumption model has been introduced in [17], and triggered the development of offline and online algorithms; see [1] for an overview.

In these systems, minimizing energy consumption of the machines and minimizing waiting times of the users are opposed goals [12]. Small waiting times improve the quality of service experienced by the users, which generally comes at the price of high energy consumption.

The online and offline optimization problem for minimizing flow time, while respecting a maximum energy consumption, has been studied for a single machine in [2 5 15 7] and for parallel machines in [3]. For the variant where an aggregation of energy and flow time is considered, polynomial time approximation algorithms have been presented in [6 4 13].

In this paper, we study this problem from a decentralized and realistic perspective. Here in order to optimize the objective function, a service operator needs specific information from the users together with the characteristics of the submitted jobs. This situation creates the need for a truthful mechanism.

Specifically, we consider a simplified computing system with a single shared machine using dynamic speed-scaling, meaning it can run at a variable continuous speed to influence the completion times of the jobs. Users submit jobs to this system, each job has some workload, representing a number of instructions to execute and a delay penalty factor. All jobs are available from time 0 on. During the submission of a job, only the workload is publicly known, while the players might announce false delay penalties in order to influence the game towards their interest.

The machine is controlled by an operator who aims to minimize the sum of the total weighted completion time and of the energy consumption cost. To this end he decides both on the speed function of the machine, and the order in which jobs are to be scheduled. The energy cost consumed by the schedule needs to be charged to the users. The individual goal of each user is to minimize the sum of waiting time and the energy cost share. Therefore it is the charging scheme chosen by the operator that influences the players’ behavior.

In a companion paper [9], we study a similar game, where the players announce a strict deadline for their job, while keeping the delay penalty factor private. This way the players control the quality of service guaranteed by the operator, leaving to the operator the goal of optimizing the consumed energy under this constraint.

2 The Model

Consider a non-cooperative game with \( n \) users and a computing system with a single shared machine using dynamic speed-scaling. Each player has a single job \( i \) with a positive workload \( w_i \) and a positive delay penalty \( p_i \). When the player submits his job, he announces the workload and some delay penalty \( \hat{p}_i \). The announced value might differ from the real value, in order to influence the game towards his advantage, while the workload has to be the true value. The latter assumption makes sense, since it is a quantity observable by the operator, who could punish players in case they lied on the workload.

The machine is controlled by an operator, who upon reception of the jobs, has to produce a schedule. This schedule generates some energy consumption, and the controller needs to charge this value to the players, according to some charging scheme. This charging scheme is known in advance to all users.

A schedule is defined by an execution order \( \pi \) and an execution speed. Following [17] it is assumed that every job \( i \) is scheduled at constant speed, and for the purpose of simplifying notation we rather specify the execution length \( \ell_i \) of every job \( i \), rather than its speed \( s_i \), which is \( w_i/\ell_i \). Two costs are associated with a schedule: the energy cost

\[
E(\ell, w) := \sum_i \ell_i s_i^\alpha = \sum_i w_i^\alpha \ell_i^{1-\alpha}
\]

defined for some fixed physical constant \( 2 \leq \alpha \leq 3 \), and the weighted flow time, representing the quality of service delivered to the users,

\[
F(\pi, \ell, p) := \sum_i p_i C_i,
\]

where \( C_i \) is the completion time of job \( i \), defined as \( \sum_{j: \pi(j) \leq \pi(i)} \ell_j \), with \( \pi(j) \) being the rank of job \( j \) in the schedule.

Ideally the operator would like to minimize the total cost \( E(\ell, w) + F(\pi, \ell, p) \), which we call the social cost. When adding the two costs, we consider the conversion of energy and completion time into monetary values, and assume for simplification that the conversion factors are hidden in the penalty factors. When optimizing the social cost, some balance between the two components has to be found, because the energy cost is small when the execution lengths are large, while for the weighted flow time it is exactly opposite. Several problems arise in this situation.

First, the game operator knows only the announced penalty factors \( \hat{p}_i \), so the game has to be truthful. This means that every player optimizes his cost by announcing the true value \( \hat{p}_i = p_i \).
Second, no polynomial algorithm for finding a schedule $\pi, \ell$ that minimizes $E(\ell, w) + F(\pi, \ell, p)$ for arbitrary value $\alpha$ is known. In fact, it is also not known whether this problem is NP-hard. However, a PTAS is known \[13\]. Dominance properties for this problem have been established in \[19\]. We note that the solution boils down to finding the right order of scheduling, since once $\pi$ is fixed, the optimum durations (speeds) for processing each job can be easily determined, cf. \[13\] or Section 3.

The operator charges to every player $i$ some value $b_i$, depending on the submitted jobs and on the constructed schedule. This charge has two roles. On one side it is supposed to cover the energy cost of the schedule, and on the other side it influences the players behavior, as every player $i$ wants to minimize the sum of the weighted completion time of his job plus his cost share $p_i C_i + b_i$.

2.1 Desirable properties

In summary, we want to design a cost sharing mechanism that is

- **truthful**, meaning that every player minimizes his penalty by announcing his true value, i.e., $\hat{\beta} = \beta$. This implies that the strategy profile $\beta$ is a pure Nash equilibrium.
- **$\beta$-budget-balanced** for some constant $\beta$, meaning that the sum of cost shares is at least the energy cost and at most $\beta$ times this value.
- **efficient**, meaning that the social cost of the Nash equilibrium is close to the social cost optimum.

3 Optimizing social cost

We consider the centralized optimization problem consisting in minimizing the sum of the energy consumption and of the total weighted completion times, under the assumption that the regulator knows the true penalty factors $p$ of all players. Formally it can be stated as follows.

**Problem A** Given $n$ jobs with workloads $w$ and penalty factors $p$, find a schedule defined by $\pi, \ell$ which minimizes $A_{w,p}(\pi, \ell) = E(\ell, w) + F(\pi, \ell, p)$.

This problem is equivalent to another scheduling problem. Here the machine runs at uniform speed, and the role of the speed is encoded in the objective function. Note that the two values of the input $w, p$ play opposite roles in both problems.

**Problem B** Given $n$ jobs with priority weights $w$ and processing times $p$, find a schedule defined by an order $\sigma$ which minimizes $B_{w,p}(\sigma) = \sum w_j C_j^{(\alpha-1)/\alpha}$, where the completion time $C_j$ is defined as $\sum_{i} p_i$ over all jobs $i$ with $\sigma(i) \leq \sigma(j)$.

In this section we show equivalence between the two problems. Our proof uses the Hessian conditions. Independently, a similar reduction has been discovered in \[13\] using Karush-Kuhn-Tucker conditions, relating Problem B and a variant of Problem A, with the goal of minimizing total weighted completion time under a given energy budget.

**Theorem 1.** Let $\pi$ be a job order, and denote by $\sigma$ its reverse, i.e. $\sigma(i) = n + 1 - \pi(i)$. Let $\ell$ be the execution length vector minimizing $A_{w,p}(\pi, \ell)$. Then $A_{w,p}(\pi, \ell) = \alpha(\alpha - 1)^{(\alpha-1)/\alpha} \cdot B_{w,p}(\sigma)$.

**Proof.** Fix permutations $\pi, \sigma$ and vector $\ell$ with the required condition. Without loss of generality, we assume that $\pi(i) = i$ (and $\sigma(i) = n + 1 - i$). This can always be achieved by renaming the jobs, since the problems are independent on the actual job indices.

The objective value of problem A is

$$A_{w,p}(\pi, \ell) = \sum_{j=1}^{n} w_j^{\alpha} \ell_j^{1-\alpha} + \sum_{j=1}^{n} p_j \sum_{k=1}^{j} \ell_k.$$

(1)
For any job $j$, the value above must be a local minimum with respect to $\ell_j$, meaning that its derivative is zero. In other words

$$(1 - \alpha)w_j^\alpha \ell_j^{-\alpha} + \sum_{k=j}^{n} p_k = 0,$$

or equivalently

$$s_j = w_j / \ell_j = \left( \frac{\sum_{k=j}^{n} p_k}{\alpha - 1} \right)^{\frac{1}{\alpha}},$$

$$\ell_j = w_j \cdot \left( \frac{(\alpha - 1)}{\sum_{k=j}^{n} p_k} \right)^{\frac{1}{\alpha}}.$$  

This condition is sufficient, since the Hessian is positive definite. In fact, the first derivative in $\ell_j$ is independent of $\ell_i$ for any $i \neq j$, and so the Hessian of $A$ has zero non-diagonal terms, whereas the second derivative of $A$ in $\ell_j$ is

$$w_j^\alpha (\alpha - 1) / \ell_j^{\alpha+1},$$

which is positive for positive $\ell_j$ and $\alpha > 1$. Thus, we have that the diagonal terms of the Hessian of $A$ are positive, the Hessian is positive definite and then, $A$ is minimized by a vector $\ell$ which sets to zero the first derivative for every $j$.

Now, we rewrite the second term of the sum in (1)

$$\sum_{j=1}^{n} \sum_{k=1}^{j} \ell_k = \sum_{j=1}^{n} \ell_j \sum_{i=1}^{n} p_i$$

and have,

$$A_{w, p}(\pi, \ell) = \sum_{j=1}^{n} w_j^\alpha \ell_j^{-\alpha} + \sum_{j=1}^{n} \sum_{k=j}^{n} p_k = \sum_{j=1}^{n} \ell_j \left( w_j^\alpha \ell_j^{-\alpha} + \sum_{k=j}^{n} p_k \right)$$

Finally, we replace (2) for $w_j^\alpha \ell_j^{-\alpha}$ and then (3) for $\ell_j$ in (5) yields

$$A_{w, p}(\pi, \ell) = \sum_{j=1}^{n} \ell_j \left( \frac{\sum_{k=j}^{n} p_k}{\alpha - 1} + \sum_{k=j}^{n} p_k \right)$$

$$= \frac{\alpha}{\alpha - 1} \sum_{j=1}^{n} \ell_j \sum_{k=j}^{n} p_k$$

$$= \frac{\alpha}{\alpha - 1} \sum_{j=1}^{n} \left( \frac{w_j^\alpha (\alpha - 1)}{\sum_{k=j}^{n} p_k} \right)^{\frac{1}{\alpha}} \sum_{k=j}^{n} p_k$$

$$= \alpha (\alpha - 1)^{\frac{1}{\alpha}} \sum_{j=1}^{n} w_j \left( \sum_{k=j}^{n} p_k \right)^{\frac{1}{\alpha}}$$

$$= \alpha (\alpha - 1)^{\frac{1}{\alpha}} \cdot B_{w, p}(\sigma),$$

since scheduling jobs with processing times $p$ in order $n, n-1, \ldots, 1$ on a uniform speed machine, results in completion time

$$C_j = \sum_{k=j}^{n} p_k$$

for every job $j$. 

□
4 Mechanism design problem

Clearly the operator can optimize the social cost only if the players announce the true penalty factors, otherwise the operator optimizes with false values, and we have no guarantee on the outcome. This motivates the design of a truthful mechanism.

We design the mechanism as follows. Fix an arbitrary job order \( \pi \). Denote the workload vector and the penalty vector as declared by the players by \( w \) and \( \hat{p} \) respectively. Note that we do assume that \( w \) is the vector of true workloads but do not assume that \( \hat{p} \) is the vector of true penalties. Given \( \pi, w, \) and \( \hat{p}, \) the mechanism is going to schedule all jobs in the order given by \( \pi, \) setting the speed for job \( j \) so that the time it takes to process it is \( \ell_j \) given by equation (3). We stress again that the mechanism can choose any order, for example uniformly at random, but it is crucial that the order is independent of the players strategies, i.e., the penalty factors they declare.

As suggested, with fixed order \( \pi, \) Theorem 1 applies, providing the vector \( \ell \) of processing times that minimizes the social cost for this particular \( \pi. \) In particular, with fixed order the underlying optimization problem is solved in polynomial time, enabling practical implementation.

Let \( \text{OPT}_\pi(\hat{p}) \) denote the value \( E(\ell, w) \) with \( \ell \) being the minimizer for \( E(\ell, w) + F(\pi, \ell, \hat{p}), \) which is the energy component of the social optimum. In addition we denote by \( \text{OPT}_\pi(\hat{p}_{-i}) \) the similar value when player \( i \) is excluded from the game. Formally if for a vector \( v \) of dimension \( n \) we denote by \( v_{-i} \) the \((n - 1)\)-dimensional vector resulting from the deletion of the \( i \)-th element, then \( \text{OPT}_\pi(\hat{p}_{-i}) \) denotes the value \( E(\ell', w_{-i}) \) with \( \ell' \) being the minimizer for \( E(\ell', w_{-i}) + F(\pi_{-i}, \ell', \hat{p}_{-i}). \) Note that in order to simplify the notation, we dropped the \(-i\) subscript on \( \pi, \) in the notation \( \text{OPT}_\pi(\hat{p}_{-i}). \)

The operator defines a cost sharing scheme where player \( i \) pays the penalty

\[
b_i := \alpha \left( \text{OPT}_\pi(\hat{p}) - \text{OPT}_\pi(\hat{p}_{-i}) \right) - \hat{p}_i C_i,
\]

and the executing length and speed vector are the minimizers for \( \text{OPT}_\pi(\hat{p}). \)

Note that lengths and speeds of job \( j > i \) minimizing \( \text{OPT}_\pi(\hat{p}_{-i}) \) and \( \text{OPT}_\pi(\hat{p}) \) are the same, by equation (3).

4.1 Truthfulness

In this section, we prove that the mechanism admits a unique Nash equilibrium, which is truthful. Formally, we claim that for every player \( i \) the strictly dominant strategy is \( \hat{p}_i = p_i. \)

To show the above claim, we will need the following technical lemma.

**Lemma 1.** Consider \( \alpha > 1, \) a fixed order \( \pi, \) and an arbitrary player \( i = \pi(j). \) For all \( k \leq \pi(j), \) we have:

\[
\alpha \frac{\partial s_k \ell_k}{\partial \hat{p}_i} = \ell_k \tag{6}
\]

\[
\frac{\partial \ell_k}{\partial \hat{p}_i} < 0. \tag{7}
\]

**Proof.** Fix a permutation \( \pi, \) a value \( \alpha > 1 \) and an arbitrary player \( i. \) Without loss of generality, we assume that \( i = \pi(i) \) for all \( i = 1, \ldots, n. \)

Note that it follows from (2) and (3) that for every \( k \leq i, \) we have

\[
s_k^\alpha \ell_k = \left( \frac{w_k}{\ell_k} \right)^\alpha \ell_k = \frac{w_k}{(\alpha - 1)^{1-1/\alpha}} \left( \sum_{j=k}^{n} \hat{p}_j \right)^{1-1/\alpha}.
\]
By taking a partial derivative of the above expression in \( \hat{p}_i \), we obtain

\[
\frac{\partial s_\alpha^k \ell_k}{\partial \hat{p}_i} = \frac{w_k}{(\alpha - 1)^{1-1/\alpha}} \frac{\partial}{\partial \hat{p}_i} \left( \sum_{j=k}^{n} \hat{p}_j \right)^{1-1/\alpha} = \frac{w_k}{\alpha(\alpha - 1)^{-1/\alpha}} \left( \sum_{j=k}^{n} \hat{p}_j \right)^{-1/\alpha} = \frac{w_k}{\alpha} \left( \sum_{j=k}^{n} \hat{p}_j \right)^{1-1/\alpha} = \ell_k \alpha,
\]

where the last identity follows from (6). This immediately implies (6) by multiplying by \( \alpha \).

Finally, we note that (7) immediately follows from (3), as for all \( k \leq i \),

\[
\frac{\partial \ell_k}{\partial \hat{p}_i} = w_k(\alpha - 1)^{1/\alpha} \frac{\partial}{\partial \hat{p}_i} \left( \sum_{j=k}^{n} \hat{p}_j \right)^{-1/\alpha} = -\frac{w_k(\alpha - 1)^{1/\alpha}}{\alpha} \left( \sum_{j=k}^{n} \hat{p}_j \right)^{-1/\alpha - 1} < 0.
\]

We now show the main result.

**Theorem 2.** The mechanism is truthful.

**Proof.** We need to show that every player \( i \) minimizes his penalty when choosing the strategy \( \hat{p}_i = p_i \). For the ease of notation, without loss of generality we assume \( \pi(i) = i \). The total penalty of player \( i \) is:

\[
p_i C_i + \alpha \left( \text{OPT}_{\pi}(\hat{p}) - \text{OPT}_{\pi}(\hat{p}_{-i}) \right) - \hat{p}_i C_i = (p_i - \hat{p}_i) \sum_{k=1}^{i} \ell_k + \alpha \left( \text{OPT}_{\pi}(\hat{p}) - \text{OPT}_{\pi}(\hat{p}_{-i}) \right) .
\]

By taking a partial derivative in \( \hat{p}_i \), we get

\[
\left( -\sum_{k=1}^{i} \ell_k + (p_i - \hat{p}_i) \sum_{k=1}^{i} \frac{\partial \ell_k}{\partial \hat{p}_i} \right) + \alpha \left( \sum_{k=1}^{i} \frac{\partial s_\alpha^k \ell_k}{\partial \hat{p}_i} \right) = \left( p_i - \hat{p}_i \right) \sum_{k=1}^{i} \frac{\partial \ell_k}{\partial \hat{p}_i} ,
\]

by (6). By Lemma 1 and 2, each summand in the last expression is negative, which implies that \( \hat{p}_i = p_i \) minimizes the player’s total penalty.
4.2 Efficiency and overcharging

In this section, we estimate the efficiency and overcharging of the total cost share when at least 2 players participate in the game.

**Theorem 3.** The sum of the cost shares is at least one and at most $\alpha + 1$ times the optimum social cost.

**Proof.** Without loss of generality, we assume $\pi(i) = i$. We start with the lower bound, proving that the cost share $b_i$ of player $i$ is no smaller than the energy consumed by this player’s job. By repeatedly using (2) and (4), in particular observing that the speed and processing time of a job $k$ depends only on the parameters of jobs $i \geq k$, i.e., for $k > i$ they are the same in $\hat{\mathbf{p}}$ and $\hat{\mathbf{p}}_{-i}$, we can express $b_i$ as follows.

$$
\begin{align*}
\hat{b}_i & = \alpha (OPT_\pi(\hat{\mathbf{p}}) - OPT_\pi(\hat{\mathbf{p}}_{-i})) - \hat{p}_i C_i \\
& = \alpha \left( \sum_{k=1}^{i} \hat{\ell}_k s_k^\alpha - \sum_{k=1}^{i-1} \hat{w}_k \left( \frac{\sum_{j=k}^{n} \hat{\mathbf{p}}_j - \hat{p}_i}{\alpha - 1} \right)^{1-1/\alpha} \right) - \hat{p}_i \sum_{k=1}^{i} \hat{\ell}_k \\
& = \alpha \ell_i s_i^\alpha - \ell_i \hat{p}_i + \sum_{k=1}^{i-1} \left( \alpha \ell_k s_k^\alpha - \ell_k \hat{p}_i - \alpha \hat{w}_k \left( \frac{\sum_{j=k}^{n} \hat{\mathbf{p}}_j - \hat{p}_i}{\alpha - 1} \right)^{1-1/\alpha} \right) \\
& = \ell_i (\alpha s_i^\alpha - \hat{p}_i) + \sum_{k=1}^{i-1} \left( \alpha \hat{w}_k \left( \frac{\sum_{j=k}^{n} \hat{\mathbf{p}}_j}{\alpha - 1} \right)^{1-1/\alpha} - \alpha \hat{w}_k \left( \frac{\sum_{j=k}^{n} \hat{\mathbf{p}}_j - \hat{p}_i}{\alpha - 1} \right)^{1-1/\alpha} - \ell_k \hat{p}_i \right) \\
& > \ell_i (\alpha s_i^\alpha - \hat{p}_i) + \sum_{k=1}^{1} \left( \frac{\alpha}{(\alpha - 1)^{1-1/\alpha}} \hat{w}_k \frac{\alpha - 1}{\alpha} \left( \sum_{j=k}^{n} \hat{\mathbf{p}}_j \right)^{1-1/\alpha} - \ell_k \hat{p}_i \right) \\
& = \ell_i (\alpha s_i^\alpha - \hat{p}_i) + \hat{p}_i \sum_{k=1}^{1} \left( \frac{\hat{w}_k}{(\alpha - 1)^{1-1/\alpha}} \left( \sum_{j=k}^{n} \hat{\mathbf{p}}_j \right)^{-1/\alpha} - \ell_k \right) \\
& = \ell_i (\alpha s_i^\alpha - \hat{p}_i) + \hat{p}_i \sum_{k=1}^{1} (\hat{\ell}_k - \ell_k) \\
& = \ell_i (\alpha s_i^\alpha - \hat{p}_i) \\
& = \ell_i (s_i^\alpha + (\alpha - 1) s_i^\alpha - \hat{p}_i) \\
& = \ell_i \left( s_i^\alpha + \sum_{k=i}^{n} \hat{\mathbf{p}}_k - \hat{p}_i \right) \\
& = \ell_i \left( s_i^\alpha + \sum_{k=i+1}^{n} \hat{\mathbf{p}}_k \right) \\
& > \ell_i s_i^\alpha,
\end{align*}
$$

where the inequality (8) follows from the strict concavity of function $f : t \mapsto t^{1-1/\alpha}$ for $\alpha > 1$, which implies

$$
f(t_1) - f(t_1 - a) = t_1^{1-1/\alpha} - (t_1 - a)^{1-1/\alpha} > a f'(t_1) = a(1 - 1/\alpha) t_1^{-1/\alpha}.
$$

Thus, we have that the energy consumption of user $i$ is $\ell_i s_i^\alpha$ and then, we have that the cost share $b_i$ is at least its cost energy consumption, which concludes the first part of the proof.
For the upper bound, we denote by \( \ell' \) the execution length vector which is the minimizer for \( OPT_{\pi}(\hat{\pi}) \). For convenience, we denote the corresponding speed \( s'_{k} := \frac{w_{k}}{\ell'_{k}} \).

\[
OPT_{\pi}(\hat{\pi}) - OPT_{\pi}(\hat{\pi}_{-i}) = \sum_{k=1}^{n} (\ell_{k}s_{k}^{\alpha} - \ell'_{k}s'_{k}^{\alpha})
\]

\[
= \sum_{k=1}^{i-1} (\ell_{k}s_{k}^{\alpha} - \ell'_{k}s'_{k}^{\alpha}) + \ell_{i}s_{i}^{\alpha}
\]

\[
= \sum_{k=1}^{i-1} \left( \ell_{k} \frac{\sum_{j=1}^{n} \hat{p}_{j}}{\alpha - 1} - \ell'_{k} \frac{\sum_{j=1}^{n} \hat{p}_{j} - \hat{p}_{i}}{\alpha - 1} \right) + \ell_{i}s_{i}^{\alpha}
\]

\[
< \frac{\hat{p}_{i}}{\alpha - 1} \sum_{k=1}^{i-1} \ell_{k} + \ell_{i}s_{i}^{\alpha}
\]

The inequality follows from \( \ell_{k} < \ell'_{k} \) for every \( 1 \leq k < i \).

We have the following bound on the cost share on player \( i \),

\[
\ell_{i}s_{i}^{\alpha} \leq b_{i} \leq \alpha \left( \frac{\hat{p}_{i}}{\alpha - 1} \sum_{k=1}^{i} \ell_{k} + \ell_{i}s_{i}^{\alpha} \right) - \hat{p}_{i} \sum_{k=1}^{i} \ell_{k},
\]

which summed up over all players leads to

\[
OPT_{\pi}(\hat{\pi}) \leq \sum_{i=1}^{n} b_{i} \leq \alpha OPT_{\pi}(\hat{\pi}) + \frac{1}{\alpha - 1} \sum_{i=1}^{n} \hat{p}_{i} \sum_{k=1}^{i} \ell_{k}
\]

\[
= \alpha OPT_{\pi}(\hat{\pi}) + \frac{1}{\alpha - 1} \sum_{i=1}^{n} \ell_{i} \sum_{k=1}^{i} \hat{p}_{k}
\]

\[
= \alpha OPT_{\pi}(\hat{\pi}) + \frac{1}{\alpha - 1} (\alpha - 1) \sum_{i=1}^{n} \ell_{i}s_{i}^{\alpha}
\]

\[
= \alpha OPT_{\pi}(\hat{\pi}) + OPT_{\pi}(\hat{\pi})
\]

\[
= (\alpha + 1)OPT_{\pi}(\hat{\pi}),
\]

concluding the proof.

**Corollary 1.** The social cost of Nash equilibrium is at least one and at most \( (\alpha + 1) \) times the optimal social cost.

**Proof.** Let \( \pi \) and \( \ell \) and be a fixed order job and the execution length vector minimizing

\[
A_{w,\pi}(\pi, \ell) = E(\ell, w) + F(\pi, \ell, p).
\]

It suffices to show

\[
A_{w,\pi}(\pi, \ell) = \alpha E(\ell, w),
\]

or equivalent

\[
(\alpha - 1)E(\ell, w) = F(\pi, \ell, p).
\]
We have
\[(\alpha - 1)E(\ell, w) = (\alpha - 1) \sum_{j=1}^{n} w_j^\alpha \ell_j^{1-\alpha}.\]

From (2), we have \((\alpha - 1)w_j^\alpha \ell_j^{-\alpha} = \sum_{k=j}^{n} p_k\), which implies
\[(\alpha - 1)E(\ell, w) = \sum_{j=1}^{n} \ell_j^{n} \sum_{k=j}^{n} p_k = \sum_{j=1}^{n} p_j \sum_{k=1}^{j} \ell_k = F(\pi, \ell, p),\]

which holds by (4).

\[\square\]

5 Final remark

The standard quality measure of the outcome of a game, is the ratio between the social cost of the Nash equilibria and the optimal social cost. Although we have that the ratio is between 1 and \(\alpha + 1\) when the job order is fixed, this constant upper bound does not hold when considering the optimal social cost for the best possible order, which might differ from the fixed order in the game. This observation motivates future work: the study of a different game, where the regulator organizes an auction over the rank positions of the schedule.

Finally, we leave open the question about the return of the overcharging to the players for our mechanism, which could improve the ratio between the social cost of the Nash equilibria and the optimal social cost, such as several authors have proposed for VCG mechanisms in the environmental economics setting (see [16, 11, 8, 14]).
