APPROXIMATE $l_0$-PENALIZED ESTIMATION OF PIECEWISE-CONSTANT SIGNALS ON GRAPHS

ZHOU FAN AND LEYING GUAN

ABSTRACT. We study recovery of piecewise-constant signals on graphs by the estimator minimizing an $l_0$-edge-penalized objective. Although exact minimization of this objective may be computationally intractable, we show that the same statistical risk guarantees are achieved by the $\alpha$-expansion algorithm which computes an approximate minimizer in polynomial time. We establish that for graphs with small average vertex degree, these guarantees are minimax rate-optimal over classes of edge-sparse signals. For spatially inhomogeneous graphs, we propose minimization of an edge-weighted objective where each edge is weighted by its effective resistance or another measure of its contribution to the graph’s connectivity. We establish minimax optimality of the resulting estimators over corresponding edge-weighted sparsity classes. We show theoretically that these risk guarantees are not always achieved by the estimator minimizing the $l_1$/total-variation relaxation, and empirically that the $l_0$-based estimates are more accurate in high signal-to-noise settings.

1. INTRODUCTION

Let $G = (V,E)$ be a known (undirected) graph, with vertices $V := \{1, \ldots, n\}$ and edge set $E$. At each vertex $i \in \{1, \ldots, n\}$, an unknown signal value $\mu_{0,i}$ is observed with noise:

$$Y_i = \mu_{0,i} + \varepsilon_i.$$ 

For simplicity, we assume $\varepsilon_1, \ldots, \varepsilon_n \overset{iid}{\sim} \text{Normal}(0, \sigma^2)$ and $G$ is fully connected. This paper studies the problem of estimating the true signal vector $\mu_0 := (\mu_{0,1}, \ldots, \mu_{0,n})$ from observed data $Y := (Y_1, \ldots, Y_n)$, when $\mu_0$ is (or is well-approximated by) a piecewise-constant signal over $G$. Informally, this will mean that the set of edges $\{i,j\} \in E$ where $\mu_{0,i} \neq \mu_{0,j}$ is a small subset of all edges.

Examples of this problem occur in a number of applications:

• **Multiple changepoint detection.** The graph $G$ is a linear chain with $n$ vertices and $n-1$ edges, which identifies a sequential order to the observations. The signal $\mu_0$ is piecewise constant in the sense $\mu_{0,i} \neq \mu_{0,i+1}$ for a small number of changepoints $i$.

• **Image segmentation.** The graph $G$ is a 2-D (or 3-D) lattice graph, and $\mu_0$ corresponds to the pixels (or voxels) of a digital image. The assumption of piecewise-constancy implies that $\mu_0$ has regions of approximately constant pixel value.

• **Anomaly identification in networks.** The graph $G$ represents a network. The signal $\mu_0$ indicates locations of anomalous clusters of vertices, for example representing individuals infected by a disease or a computer virus. Piecewise-constancy of $\mu_0$ reflects the assumption that the anomaly spreads along the network connections.

Early and pioneering works include [CZ64, Yao84, BH93] on multiple changepoint detection and [GG84, Bes86] on image segmentation. For general graphs and networks, [ACCHZ08, ABBDL10, ACCD11, ACG13, SKS13, SSR13] studied related hypothesis testing problems, and [HR16, WSST16, HMPSST16] also recently considered estimation. We discuss some connections of our work to this existing literature in Section 1.1.

The focus of our paper is the method of “$l_0$-edge-denoising”, which seeks to estimate $\mu_0$ by the values $\mu \in \mathbb{R}^n$ minimizing the residual squared error $\frac{1}{2}||Y - \mu||^2$ plus a penalty for each edge \{i, j\} $\in E$ where $\mu_i \neq \mu_j$. (Here and throughout, $\| \cdot \|$ without a subscript denotes the standard Euclidean norm.) More formally, this estimate minimizes the objective function

$$F_0(\mu) := \frac{1}{2}||Y - \mu||^2 + \lambda \|D\mu\|_0, \quad \|D\mu\|_0 := \sum_{\{i, j\} \in E} 1\{\mu_i \neq \mu_j\}. \quad (L0)$$

Here, $D : \mathbb{R}^n \to \mathbb{R}^E$ denotes a vertex-edge incidence matrix with entries in \{-1, 0, 1\} that maps $\mu \in \mathbb{R}^n$ to the vector of edge differences $(\mu_i - \mu_j)_{(i, j) \in E}$ (with an arbitrary sign for each edge). The penalty term $\|D\mu\|_0$ denotes the usual “$l_0$-norm” of $D\mu$, and $\lambda$ is a user-specified tuning parameter that controls the magnitude of this penalty.

For reasons to be discussed, we will also consider procedures that seek to minimize a more general weighted version of the above objective function,

$$F_w(\mu) := \frac{1}{2}||Y - \mu||^2 + \lambda \|D\mu\|_w, \quad \|D\mu\|_w := \sum_{\{i, j\} \in E} w(i, j) 1\{\mu_i \neq \mu_j\}, \quad (W)$$

where $w : E \to \mathbb{R}_+$ assigns a non-negative weight to each edge. This allows possibly different penalty values to be applied to different edges of the graph.

The combinatorial nature of (L0) and (W) render exact minimization of these objectives computationally intractable for general graphs. A primary purpose of this paper is to show, however, that approximate minimization is sufficient to obtain statistically rate-optimal guarantees. We study one such approximation algorithm by Boykov, Veksler, and Zabih [BVZ01], suggest its use in minimizing (W) for applications involving inhomogeneous networks, and provide a unified analysis of minimax squared-error risk for this estimation problem over edge-sparse signal classes on general graphs.

We summarize our results as follows:

1. A polynomial-time algorithm using the $\alpha$-expansion procedure of [BVZ01] yields approximate minimizers $\hat{\mu}$ of (L0) and (W) that achieve the same statistical risk guarantees as the exact minimizers, up to constant factors. Computation of $\hat{\mu}$ is reasonably efficient in practice and yields good empirical signal recovery in our tested examples. In this sense, inference based on minimizing (L0) or (W) is computationally tractable, even for large graphs.

2. For any graph $G$, the estimate $\hat{\mu}$ (exactly or approximately) minimizing (L0) with $\lambda \asymp \sigma^2 \log |E|$ satisfies an “edge-sparsity” oracle inequality

$$\mathbb{E}[||\hat{\mu} - \mu_0||^2] \lesssim \inf_{\mu \in \mathbb{R}^n} ||\mu - \mu_0||^2 + \sigma^2 \max(||D\mu||_0, 1) \log |E|. \quad (1)$$

This bounds the squared-error risk of $\hat{\mu}$ in terms of the approximability of $\mu_0$ by any piecewise-constant signal $\mu$. If it is known that $||D\mu_0||_0 \leq s$, then setting instead $\lambda \asymp \sigma^2(1 + \log \frac{|E|}{s})$ yields

$$\mathbb{E}[||\hat{\mu} - \mu_0||^2] \lesssim \sigma^2 s \left(1 + \log \frac{|E|}{s}\right). \quad (2)$$

The risk bound (2) is rate-optimal in a minimax sense over the edge-sparse signal class $\{\mu_0 : ||D\mu_0||_0 \leq s\}$ up to a multiplicative factor depending on the mean vertex degree of $G$.

3. An alternative to minimizing (L0) is to minimize its $l_1$/total-variation relaxation,

$$F_1(\mu) := \frac{1}{2}||Y - \mu||^2 + \lambda ||D\mu||_1, \quad ||D\mu||_1 := \sum_{(i, j) \in E} |\mu_i - \mu_j|. \quad (TV)$$

One advantage of this approach is that (TV) is convex and can be exactly minimized in polynomial time. However, whether the risk guarantees (1) and (2) hold for $\hat{\mu}$ minimizing (TV)
depends on properties of the graph. In particular, they do not hold for the linear chain graph, where instead
\[ \inf_{\lambda \geq 0} \sup_{\mu_0: \|D\mu_0\|_0 \leq s} \mathbb{E}[\|\hat{\mu}^\lambda - \mu_0\|^2] \geq \sigma^2 (\log n)^{-5} \sqrt{s n}, \] (3)
\( \hat{\mu}^\lambda \) denoting the minimizer of \((\text{TV})\) for each \(\lambda\). This result is connected to the “slow rate” of convergence in prediction risk for the Lasso [Tib96, CDS01] in certain linear regression settings with correlated predictors.

4. When \(G\) has regions of differing connectivity, \(\|D\mu\|_0\) is not a spatially homogeneous measure of complexity, and it may be more appropriate to minimize the edge-weighted objective \((W)\) where \(w(i,j)\) measures the contribution of edge \(\{i,j\}\) to the connectivity of the graph. One such weighting, inspired by the analyses in [SKS13, SSR13], weighs each edge by its effective resistance when \(G\) is viewed as an electrical resistor network. In simulations on real networks, this weighting can yield a substantial reduction in error over minimizers of the unweighted objective \((L_0)\). For general weightings \(w : E \to \mathbb{R}_+\) belonging to the spanning tree polytope of \(G\), the guarantee (2) holds over the larger class \(\{\mu_0 : \|D\mu_0\|_w \leq s\}\) for \(\hat{\mu}\) minimizing \((W)\), and this guarantee is minimax rate-optimal up to a graph-independent constant factor, for all graphs.

We provide a more detailed discussion of these results in Sections 2 to 5. Simulations comparing minimization of \((L_0)\), \((W)\), and \((\text{TV})\) over several graphs are presented in Section 6. Proofs are deferred to the appendices.

1.1. Related work. For changepoint problems where \(G\) is the linear chain, \((L_0)\) may be exactly minimized by dynamic programming in quadratic time [ALS9, WL02, JWZ05]. Pruning ideas may reduce runtime to be near-linear in practice [KFE12]. Correct changepoint recovery and distributional properties of \(\hat{\mu}\) minimizing \((L_0)\) were studied asymptotically in [Yao88, YA89] when the number of true changepoints is fixed. Non-asymptotic risk bounds similar to (1) and (2) were established for estimators minimizing similar objectives in [Leb05, BM07]; we discuss this further below. Extension to the recovery of piecewise-constant functions over a continuous interval was considered in [BKL+09].

In image applications where \(G\) is the 2-D lattice, \((L_0)\) is closely related to the Mumford-Shah functional [MS89] and Ising/Potts-model energies for discrete Markov random fields [GG84]. In the latter discrete setting, where each \(\mu_i\) is allowed to take value in a finite set of “labels”, a variety of algorithms seek to minimize \((L_0)\) using minimum s-t cuts on augmented graphs; see [KZ01] and the contained references for a review. For an Ising model with only two distinct labels, [GPS89] showed that the exact minimizer may be computed via a single minimum s-t cut. For more than two distinct labels, exact minimization of \((L_0)\) is NP-hard [BVZ01]. We analyze a graph-cut algorithm from [BVZ01] that applies to more than two labels, where the exact minimization property is replaced by an approximation guarantee. We show that the deterministic guarantee of this algorithm implies rate-optimal statistical risk bounds, for the 2-D lattice as well as for general graphs.

For an arbitrary graph \(G\), the estimators \(\hat{\mu}\) exactly minimizing \((L_0)\) and \((W)\) are examples of general model-complexity penalized estimators studied in [BBM99, BM07]. The penalties we impose may be smaller than those needed for the analyses of [BBM99, BM07] by logarithmic factors, and we instead control the supremum of a certain Gaussian process using an argument specialized to our graph-based problem. A theoretical focus of [BBM99, BM07] was on adaptive attainment of minimax rates over families of models—for example, for the linear chain graph, [Leb05, BM07] considered penalties increasing but concave in the number of changepoints, and the resulting estimates achieve the guarantee (2) simultaneously for all \(s\). Instead of using such a penalty, which poses additional computational challenges, we will apply a data-driven procedure to choose \(\lambda\), although we will not study the adaptivity properties of the procedure in this paper.

The method of \(l_0\)-edge-denoising and the characterization of signal complexity by \(\|D\mu_0\|_0\) are “nonparametric” in the sense of [ACDH05, ACCD11]. This is in contrast to methods that employ
additional prior knowledge about $\mu_0$, for instance that its constant regions belong to parametric classes of shapes \cite{ACDH05}, are thick and blob-like in nature \cite{ACCD11}, or have sufficiently smooth boundaries when $G$ is embedded in a Euclidean space \cite{KT93,Don99}. In this regard, our study is more closely related to the hypothesis testing work of \cite{ACG13,SKS13,SSR13} in similar non-parametric contexts. An advantage of this perspective is that the inference algorithm is broadly applicable to general graphs and networks, where appropriate notions of boundary smoothness or support constraints for $\mu_0$ are less naturally defined. A disadvantage is that such an approach may not be statistically optimal in more specialized settings when such prior assumptions hold true.

A connection between this problem, effective edge resistances, and graph spanning trees emerged in the analyses of \cite{SKS13,SSR13}. In \cite{SSR13}, a procedure was proposed to construct an orthonormal wavelet basis over a spanning tree of $G$ and to perform inference by thresholding in this basis. Our proposal to minimize $\|W\|$ for $w : E \to \mathbb{R}_+$ in the spanning tree polytope of $G$ may be viewed as a derandomization of this idea when the spanning tree is chosen at random; we discuss this connection in Remark 5.7. Sampling edges by effective resistances is also a popular method of graph sparsification \cite{ST04,SS11}, and effective-resistance edge weighting may be viewed as a derandomization of procedures such as in \cite{SWT16b} that operate on a randomly sparsified graph.

There is a large body of literature on the $l_1$-relaxation \cite{TV}. This method and generalizations were suggested in different contexts and guises for the linear chain graph in \cite{LF97, MvdG97, DK01, CDS01, TSR05} and also studied theoretically in \cite{Rin99, HLL10, DHL17, LSRT16, GLCS17}. For 2-D lattice graphs in image denoising, variants of \cite{TV} were proposed and studied in \cite{ROF92, CL97, GO09}. For more general graphs, this method and generalizations have been studied in \cite{Hoe10, KS11, TT11, SRS12, TS15, HR16, WSST16, SWT16a}, among others. In particular, \cite{Cha05, DS05, XKWG14} developed algorithms for minimizing \cite{TV} and related objectives also using iterated graph cuts, although these algorithms yield exact solutions and are different from the algorithm we study. A body of theoretical work establishes that $\hat{\mu}$ minimizing \cite{TV} is (or is nearly) minimax rate-optimal over signal classes of bounded variation, $\{\mu_0 : \|D\mu_0\|_1 \leq s\}$, for the linear chain graph and higher-dimensional lattices \cite{MvdG97, SWT16a, WSST16, HR16}. Several risk bounds over the exact-sparsity classes $\{\mu_0 : \|D\mu_0\|_0 \leq s\}$ that we consider were also established for the linear chain graph in \cite{DHL17, LSRT16, GLCS17} and for general graphs in \cite{HR16, HMPSST16}; we discuss some of these results in Section 4. We believe that benefits of using effective resistance weighted edge penalties may also apply to the $l_1$/TV setting, and we leave further exploration of this to future work.

1.2. Notation and conventions. We assume throughout that $G$ is fully connected with $n \geq 3$ vertices. Theoretical results are non-asymptotic, in the sense that they are valid for all finite $n$ and $s$ with universal constants $C, c > 0$ independent of $n, s$, and the graph $G$. For positive $a$ and $b$, we write informally $a \lesssim b$ if $a \leq Cb$ and $a \asymp b$ if $ca \leq b \leq Ca$ for universal constants $C, c > 0$ and all $n \geq 3$.

For a vector $v$, $\|v\| := \left(\sum_i v_i^2\right)^{1/2}$ is the Euclidean norm, $\|v\|_0 := |\{i : v_i \neq 0\}|$ the \textquotedblleft$l_0$-norm\textquotedblright, $\|v\|_1 := \sum_i |v_i|$ the $l_1$-norm, and $\|v\|_\infty := \max_i |v_i|$ the $l_\infty$-norm. For vectors $v$ and $w$, $\langle v, w \rangle = \sum_i v_iw_i$ is the Euclidean inner-product.

$\mathbb{R}_+$ denotes the non-negative reals. For an edge weighting $w : E \to \mathbb{R}_+$, $w(i, j)$ is shorthand for $w(\{i, j\})$, and we denote $w(E') := \sum_{\{i,j\} \in E'} w(i, j)$ for any edge subset $E' \subseteq E$. For two edge weightings $w, r : E \to \mathbb{R}_+$, we write $w \geq r$ if $w(i, j) \geq r(i, j)$ for all edges $\{i, j\} \in E$. For $v \in \mathbb{R}^E$, $\|v\|_w := \sum_{\{i,j\} \in E} w(i, j)|v_{i,j}|$ denotes the $l_0$-norm weighted by $w$.

$1\{\cdot\}$ denotes the indicator function, i.e. $1\{\mathcal{E}\} = 1$ if condition $\mathcal{E}$ is true and 0 otherwise.

2. Approximation algorithm

As discussed in Section 1.1, whether \cite{L0} and \cite{W} may be minimized exactly in polynomial time depends on the graph $G$. However, good approximation of the solution is tractable for any graph.
Algorithm 1 Algorithm to compute a \((\tau, \delta \mathbb{Z})\)-local-minimizer of \([W]\)

1: Let \(\bar{Y}, Y_{\text{min}}, \) and \(Y_{\text{max}}\) be the mean, minimum, and maximum of \(Y\), rounded to \(\delta \mathbb{Z}\).
2: Initialize \(\hat{\mu} \in \mathbb{R}^n\) by setting \(\hat{\mu}_i = \bar{Y}\) for all \(i \in \{1, \ldots, n\}\).
3: loop
4: for each \(c \in \delta \mathbb{Z} \cap [Y_{\text{min}}, Y_{\text{max}}]\) do
5: Compute the best \(\delta \mathbb{Z}\)-expansion \(\tilde{\mu}\) of \(\hat{\mu}\) with new value \(c\) using Algorithm 2
6: if \(F_w(\tilde{\mu}) \leq F_w(\hat{\mu}) - \tau\), then set \(\hat{\mu} = \tilde{\mu}\).
7: end for
8: if \(\hat{\mu}\) was unchanged, then return \(\hat{\mu}\).
9: end loop

Algorithm 2 \(\alpha\)-expansion sub-routine [BVZ01]

1: Construct the following edge-weighted augmentation \(G_{c, \hat{\mu}}\) of \(G\):
2: Introduce a source vertex \(s\) and a sink vertex \(t\).
3: Connect \(s\) to each \(i \in \{1, \ldots, n\}\) with weight \(\frac{1}{2}(Y_i - c)^2\).
4: Connect \(t\) to each \(i \in \{1, \ldots, n\}\) with weight \(\frac{1}{2}(Y_i - \hat{\mu}_i)^2\) if \(\hat{\mu}_i \neq c\), or weight \(\infty\) if \(\hat{\mu}_i = c\).
5: for each edge \(\{i, j\} \in E\) do
6: if \(\hat{\mu}_i = \hat{\mu}_j\) then
7: Assign weight \(\lambda w(i, j) 1\{\hat{\mu}_i \neq c\}\) to \(\{i, j\}\).
8: else
9: Introduce a new vertex \(a_{i,j}\).
10: Replace edge \(\{i, j\}\) by the three edges \(\{i, a_{i,j}\}, \{j, a_{i,j}\}, \) and \(\{t, a_{i,j}\}\), with weights \(\lambda w(i, j) 1\{\hat{\mu}_i \neq c\}, \lambda w(i, j) 1\{\hat{\mu}_j \neq c\}, \) and \(\lambda w(i, j)\), respectively.
11: end if
12: end for
13: Find the minimum s-t cut \((S, T)\) of \(G_{c, \hat{\mu}}\) such that \(s \in S, t \in T\).
14: For each vertex \(i \in \{1, \ldots, n\}\), set \(\tilde{\mu}_i = c\) if \(i\) belongs to \(T\) and \(\tilde{\mu}_i = \hat{\mu}_i\) otherwise.
15: Return \(\tilde{\mu}\).

We review in this section one approach that achieves such an approximation, based on discretizing the range of values of the entries of \(\mu\) and applying the \(\alpha\)-expansion local move of [BVZ01] for discrete Markov random fields. We describe the algorithm for \([W]\), as \([L0]\) is a special case.

The fundamental property of this algorithm will be that its output is a \((\tau, \delta \mathbb{Z})\)-local-minimizer for the objective function \([W]\), defined as follows:

**Definition 2.1.** For \(\delta > 0\), denote by
\[
\delta \mathbb{Z} := \{\ldots, -3\delta, -2\delta, -\delta, 0, \delta, 2\delta, 3\delta, \ldots\}
\]
the set of all integer multiples of \(\delta\). For any \(\mu \in \mathbb{R}^n\), a \(\delta \mathbb{Z}\)-expansion of \(\mu\) is any other vector \(\tilde{\mu} \in \mathbb{R}^n\) such that there exists a single value \(c \in \delta \mathbb{Z}\) for which, for every \(i \in \{1, \ldots, n\}\), either \(\tilde{\mu}_i = \mu_i\) or \(\tilde{\mu}_i = c\). For \(\delta > 0\) and \(\tau \geq 0\), a \((\tau, \delta \mathbb{Z})\)-local-minimizer of \([W]\) is any \(\mu \in \mathbb{R}^n\) such that for every \(\delta \mathbb{Z}\)-expansion \(\tilde{\mu}\) of \(\mu\),
\[
F_w(\mu) - \tau \leq F_w(\tilde{\mu}).
\]

More informally, a \(\delta \mathbb{Z}\)-expansion of \(\mu\) can replace any subset of vertex values by a single new value \(c \in \delta \mathbb{Z}\), and a \((\tau, \delta \mathbb{Z})\)-local-minimizer is such that no further \(\delta \mathbb{Z}\)-expansion reduces the objective value by more than \(\tau\). This definition does not require \((\tau, \delta \mathbb{Z})\)-local-minimizers to have all entries belonging to \(\delta \mathbb{Z}\)—hence, in particular, a global minimizer of \([W]\) is also a \((\tau, \delta \mathbb{Z})\)-local-minimizer for any \(\delta > 0\) and \(\tau \geq 0\). We define analogously \((\tau, \delta \mathbb{Z})\)-local-minimizers for \([L0]\).
The α-expansion procedure of \cite{BVZ01} may be used to compute a \((\tau, \delta Z)\)-local-minimizer efficiently with graph cuts. We review this procedure and how we apply it to our problem in Algorithm 1. We will use a small discretization \(\delta\) so as to yield a good solution to the original continuous problem.

The following propositions verify that this algorithm returns a \((\tau, \delta Z)\)-local-minimizer in polynomial time; proofs are contained in Appendix A.

**Proposition 2.2.** Algorithm 1, using Edmonds-Karp or Dinic’s algorithm for solving minimum s-t cut, has worst-case runtime \(O(n|E|^3(Y_{\max} - Y_{\min})^3/|\delta\tau|))\).

**Proposition 2.3.** Among all \(\delta Z\)-expansions of \(\hat{\mu}\) with new value \(c\), the vector \(\tilde{\mu}\) returned by Algorithm 1 is a \((\tau, \delta Z)\)-local-minimizer of \((W)\). The estimate \(\hat{\mu}\) returned by Algorithm 1 is a \((\tau, \delta Z)\)-local-minimizer of \((W)\).

In particular, if \(Y_{\max} - Y_{\min}, 1/\delta\), and \(1/\tau\) are polynomial in \(n\), then Algorithm 1 is polynomial-time in \(n\). We will use the Boykov-Kolmogorov algorithm \cite{BK04} instead of Edmonds-Karp or Dinic to solve minimum s-t cut. This has slower worst-case runtime but is much faster in practice on our tested examples. We have found Algorithm 1 to be fast in practice, even with \(\tau = 0\), and we discuss empirical runtime in Section 6.2.

The \(l_2\) vertex-cost \((Y_i - \mu_i)^2\) and \(l_0\) edge cost \(1\{\mu_i \neq \mu_j\}\) of \((L0)\) and \((W)\) are not intrinsic to this algorithm, and the same method may be applied to approximately minimize

\[
F(\mu) = \sum_{i=1}^{n} c_i(Y_i, \mu_i) + \sum_{\{i,j\} \in E} c_{i,j}(\mu_i, \mu_j)
\]

for any vertex cost functions \(c_i\) and edge cost functions \(c_{i,j}\) such that each \(c_{i,j}\) satisfies a triangle inequality. Thus the algorithm is easily applicable to other likelihood models and forms of edge penalties.

### 3. Theoretical guarantees for \(l_0\) denoising

In this section, we describe squared-error risk guarantees for \(\hat{\mu}\) (exactly or approximately) minimizing \((L0)\). Although these results are corollaries of those in Section 5 for the weighted objective \((W)\), we state them here separately as they are simpler to understand and also provide a basis for comparison with total-variation denoising discussed in the next section. We defer discussion of the proofs to Section 5.

Recall Definition 2.1 of \((\tau, \delta Z)\)-local-minimizers, which include both the exact minimizer and the estimator computed by Algorithm 1. A sparsity-oracle inequality for any such minimizer holds when the penalty \(\lambda\) in \((L0)\) is set to a “universal” level \(C\sigma^2 \log |E|\):

**Theorem 3.1.** Let \(\delta \leq \sigma/\sqrt{n}\) and \(\tau \leq \sigma^2\). For any \(\eta > 0\), there exist constants \(C_\eta, C'_\eta > 0\) depending only on \(\eta\) such that if \(\lambda \geq C_\eta \sigma^2 \log |E|\) and \(\hat{\mu}\) is any \((\tau, \delta Z)\)-local-minimizer of \((L0)\), then

\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq \inf_{\mu \in \mathbb{R}^n} (1 + \eta)\|\mu - \mu_0\|^2 + (\eta C'_\eta \lambda \max(\|D\mu\|_0, 1)).
\]

The upper bound in (4) trades off the edge-sparsity of \(\hat{\mu}\) and its approximation of the true signal \(\mu_0\). Setting \(\lambda = C_\eta \sigma^2 \log |E|\) yields the guarantee (1) described in the introduction. If \(\mu_0\) is exactly edge-sparse with \(\|D\mu_0\|_0 = s\), then evaluating (4) at \(\mu = \mu_0\) yields a risk bound of order \(\sigma^2 s \log |E|\).

When \(s\) is known, we may obtain the tighter guarantee (2) by using a smaller penalty:

**Theorem 3.2.** Let \(\delta \leq \sigma/\sqrt{n}\) and \(\tau \leq \sigma^2\). There exist universal constants \(C, C' > 0\) such that for any \(s \in [1/|E|]\), if \(\lambda \geq C\sigma^2(1 + \log(|E|/s))\) and \(\hat{\mu}\) is any \((\tau, \delta Z)\)-local-minimizer of \((L0)\), then

\[
\sup_{\|D\mu_0\|_0 \leq s} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq C' \lambda s.
\]
Theorems 3.1 and 3.2 are analogous to estimation guarantees in the sparse normal-means problem: For estimating a signal $\mu_0 \in \mathbb{R}^n$ with at most $k$ nonzero entries, asymptotically if $n \to \infty$ and $k/n \to 0$, then
\[
\inf_{\hat{\mu}} \sup_{\mu_0 : \|\mu_0\| \leq k} \mathbb{E}[\|\hat{\mu} - Y\|^2] \sim 2\sigma^2 k \log \frac{n}{k}.
\] (6)
This risk is achieved by $\hat{\mu} = \arg\min_{\mu} \frac{1}{2}\|Y - \mu\|^2 + \lambda\|\mu\|$ for $\lambda = \sigma^2 \log \frac{n}{k}$, corresponding to entrywise hard-thresholding at level $\sqrt{2\lambda}$ [Joh94, Theorem 8.20]. Setting $\lambda = \sigma^2 \log n$ hard-thresholds instead at the universal level $\sqrt{2\sigma^2 \log n}$, and Lemma 1 of [DJ94] implies an oracle bound
\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq \inf_{\mu \in \mathbb{R}^n} 1.2\|\mu - \mu_0\|^2 + \sigma^2 (2 \log n + 1)(\|\mu\|_0 + 1)
\]
for any true signal $\mu_0 \in \mathbb{R}^n$.

When there is an underlying graph $G$, the sparsity condition $\|\mu_0\|_0 \leq k$ is a notion of vertex sparsity, in contrast to our notion of edge-sparsity. The edge-sparsity of a “typical” piecewise-constant signal may be graph-dependent—for example, if $G$ is a $K$-dimensional lattice graph with side length $n^{1/K}$ and $\mu_0$ consists of two constant pieces separated by a smooth boundary, then $s \approx n^{1-1/K}$. For such choices of $\mu_0$ and for $K \geq 2$, the risk in (5) grows polynomially in $n$ and does not represent a parametric rate. On the other hand, vertex-sparse signals are also edge-sparse for low-degree graphs. This containment may be used to show, when $G$ has bounded average degree, that the above nonparametric rate is optimal in a minimax sense over \{\$\mu_0 : \|D\mu_0\|_0 \leq s\}:

**Theorem 3.3.** Suppose $G$ has average vertex degree $d$. There exists a universal constant $c > 0$ such that for any $s \in [4d, |E|]$,\n
\[
\inf_{\hat{\mu}} \sup_{\mu_0 : \|\mu_0\|_0 \leq s} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \geq c\sigma^2 \frac{s}{d} \left(1 + \log \frac{|E|}{s}\right),
\]
where the infimum is taken over all possible estimators $\hat{\mu} := \hat{\mu}(Y)$.

When the average degree $d$ is not small, there is a gap between (5) and (7) of order $d$, which we will discuss in Section 5.

**Remark 3.4.** We assume $s \geq 4d$ for (7) so that the result does not depend on the exact structure of near-minimum cuts in $G$. For example, if vertices $\{1, \ldots, n-1\}$ are connected in a single cycle and vertex $n$ is connected to vertex 1 by a single edge, then for $s = 1$, any $\mu_0$ with $\|D\mu_0\|_0 \leq 1$ must be constant over vertices $\{1, \ldots, n-1\}$ and take a possibly different value on vertex $n$. The minimax risk over this class is then $2\sigma^2$, rather than order $\sigma^2 \log n$. Considering the graph tensor product of this example with the complete graph on $d$ vertices, a similar argument shows that a general lower bound must restrict to $s \geq cd$ for some small constant $c > 0$.

While our main focus is estimation, let us state a result relevant to testing:

**Theorem 3.5.** Let $\delta \leq \sigma/\sqrt{n}$ and $\tau \leq \sigma^2$, and suppose $\mu_0$ is constant over $G$. There exist universal constants $C, C' > 0$ such that if $\lambda \geq C\sigma^2 \log |E|$ and $\hat{\mu}$ is any $(\tau, \delta \mathbb{Z})$-local-minimizer of $\|L\nu\|$, then
\[
\mathbb{P}[\hat{\mu} \text{ is constant over } G] \geq 1 - C' n^{-3}.
\]

This implies that we may test the null hypothesis
\[
H_0 : \mu_0 \text{ is constant}
\]
by setting $\lambda \approx \sigma^2 \log |E|$ and rejecting $H_0$ if $\hat{\mu}$ is not constant. Denoting by $P^\perp$ the orthogonal projection onto the space orthogonal to the all-1’s vector, since
\[
\min_{\mu \in \text{supp} \hat{\mu}} \|\mu - \mu_0\|^2 = \|P^\perp \mu_0\|^2,
\]
the risk bound (5) (or more precisely, Lemma B.3(b)) which establishes an analogous bound in probability) implies that this test can distinguish a non-constant alternative \( \mu_0 \) with probability approaching 1 as long as \( \|P_{\perp} \mu_0\|^2 \geq C\sigma^2\|D\mu_0\|_0 \log |E| \), for a universal constant \( C > 0 \).

4. Comparison with \( l_1 \)/total-variation denoising

We compare the guarantees of the preceding section with those attainable by \( \hat{\mu} \) minimizing \( TV \). Theoretical risk bounds for the TV-penalized estimator have been established for both piecewise-constant classes \( \{ \mu_0 : \|D\mu_0\|_0 \leq s \} \) and bounded-variation classes \( \{ \mu_0 : \|D\mu_0\|_1 \leq s \} \), and we focus our comparison on the former. We will empirically explore in Section 6 some trade-offs between the \( l_0 \) and TV approaches for signals that are both piecewise-constant and of small total-variation norm.

One general risk bound for \( \hat{\mu} \) minimizing \( TV \) was established in [HR16]. For an arbitrary graph \( G \), let \( D : \mathbb{R}^n \to \mathbb{R}^E \) be its vertex-edge incidence matrix, \( S = D^\dagger \) the Moore-Penrose pseudo-inverse of \( D \), and \( \rho \) the maximum Euclidean norm of any column of \( S \). Theorem 2 of [HR16] implies, for the estimator \( \hat{\mu} \) minimizing \( TV \) with the choice \( \lambda = \rho \sqrt{2(1 + \log(|E|)/\delta)} \), and for any \( \mu \in \mathbb{R}^n \), with probability at least 1 \(-\delta\),

\[
\|\hat{\mu} - \mu_0\|^2 \leq \|\mu - \mu_0\|^2 + 8\sigma^2 \left( \frac{\rho^2\|D\mu_0\|_0}{\kappa^2} \left( 1 + \log \frac{|E|}{\delta} \right) + \log \frac{e}{\delta} \right),
\]

where \( \kappa \) is a compatibility constant bounded as \( \kappa^{-2} \leq 4 \min(d, \|D\mu_0\|_0) \) and \( d \) is the mean vertex degree of \( G \). (The result of [HR16] is more general, involving both \( \|D\mu\|_1 \) and \( \|D\mu\|_0 \), and we have specialized to the “pure-\( l_0 \)” setting.)

An important difference between this result and Theorem 3.1 is the appearance of \( \rho^2 \), which is graph-dependent. Assuming \( G \) has small average degree \( d \), the above guarantee is similar to Theorem 3.1 if \( \rho^2 \) is small. It is shown in [HR16] that \( \rho^2 \lesssim 1 \) for 3-D (and higher-dimensional) lattice graphs and \( \rho^2 \lesssim \log n \) for 2-D lattice graphs, indicating that \( \hat{\mu} \) is nearly rate-optimal over \( \{\mu_0 : \|D\mu_0\|_0 \leq s\} \) for these graphs. However, for example, when \( G \) is the linear chain, \( \rho^2 \approx n \) and the bound (9) is larger than those of the preceding section by a factor of \( n \).

More specialized analyses were performed for the linear chain in [DHL17] [LSRT16], where sharper results were obtained that depend on the minimum spacing \( \Delta(\mu_0) \) between two changepoints of \( \mu_0 \). More precisely, denoting by \( 1 \leq i_1 < \ldots < i_s < n \) the values \( i \) for which \( \mu_{0,i} \neq \mu_{0,i+1} \) and letting \( i_0 := 0 \) and \( i_{s+1} := n \), define \( \Delta(\mu_0) := \min_{i \leq r \leq s} |i_r - i_{r+1}| \). Then Theorem 4 of [LSRT16] shows, if \( \|D\mu_0\|_0 = s \) and \( \lambda = \sigma(n\Delta(\mu_0))^{1/4} \), then

\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \lesssim \sigma^2 s \left( (\log s + \log \log n) \log n + \sqrt{n/\Delta(\mu_0)} \right).
\]

If \( \Delta(\mu_0) \gtrsim n/(s + 1) \) so that changepoints are nearly equally-spaced, then this bound is of order \( s^{3/2} \) times logarithmic factors, and furthermore this has been improved to the optimal bound \( \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \lesssim \sigma^2 s \log(1 + n/s) \) in [GLCS17]. However, if \( \Delta(\mu_0) \lesssim n^\alpha \) for any \( \alpha < 1 \), then the above bound differs from the guarantee of Theorem 3.2 by a factor of roughly \( n^{(1-\alpha)/2} \), and in the worst case this suboptimality is of order \( \sqrt{n} \).

It has been conjectured, for example in Remark 3 of [LSRT16] and Remark 2.3 of [GLCS17], that this suboptimality is not an artifact of the theoretical analysis, but rather that the TV-penalized estimate \( \hat{\mu} \) exhibits a slower rate of convergence when the equal spacing condition \( \Delta(\mu_0) \gtrsim n/(s + 1) \) is not met. We provide in this section a theoretical validation of this conjecture; proofs are given in Appendix C.

First, suppose the true signal \( \mu_0 \) is constant and equal to zero:

**Theorem 4.1.** Let \( G \) be the linear chain graph with \( n \) vertices, and suppose \( \mu_0 = 0 \). There exists a constant \( c > 0 \) such that for any fixed \( \lambda \in [0, \sigma \sqrt{cn/\log n}] \), if \( \hat{\mu} \) is the minimizer of \( TV \), then the following hold:
(a) For some constants $C, c' > 0$, letting $\hat{k} := \|D\hat{\mu}\|_0 + 1$ be the number of constant intervals of $\hat{\mu}$, 
\[ P\left[ \hat{k} > \frac{cn}{\max(\lambda^2/\sigma^2, 1) \log n} \right] \geq 1 - C e^{-c' n/\max(\lambda^2/\sigma^2, 1)}.
\]

(b) For some constant $c' > 0$, the squared-error risk of $\hat{\mu}$ satisfies 
\[ E[\|\hat{\mu}\|^2] \geq \frac{c' \sigma^2 n}{\max(\lambda^2/\sigma^2, 1)(\log n)^4}.
\]

Hence if $\mu_0 = 0$ and $\lambda \asymp \sigma n^\alpha$ for any $\alpha < 1/2$, then the number of changepoints and the squared-error risk of the TV-penalized estimator $\hat{\mu}$ are (up to logarithmic factors) at least of order $n^{1-2\alpha}$ and $\sigma^2 n^{1-2\alpha}$, respectively. As a consequence, we obtain the following lower bound in a minimax sense:

**Theorem 4.2.** Let $G$ be the linear chain graph with $n$ vertices, and let $\Delta(\mu_0)$ denote the minimum distance between two changepoints in $\mu_0$. For each fixed $\lambda \geq 0$, let $\hat{\mu}^\lambda$ denote the minimizer of (TV) for this $\lambda$. Then there exists a constant $c > 0$ such that for any $s \in [2, n - 1]$ and $\Delta \leq n/(s + 1)$,
\[ \inf_{\lambda \geq 0, \mu_0 \|D\mu_0\|_0 \leq s, \Delta(\mu_0) \geq \Delta} \sup_{\mu_0} E[\|\hat{\mu}^\lambda - \mu_0\|^2] \geq \frac{c\sigma^2}{(\log n)^5} \sqrt{\frac{s\Delta}{n}}.
\]

In particular, setting $\Delta = 1$ removes restrictions on the minimum spacing between changepoints and yields [3] stated in the introduction.

Theorem 4.2 may be re-interpreted in the context of the Lasso estimate for sparse linear regression: Setting $\beta_0 := D\mu_0$ and
\[ X := D^\dagger = \begin{pmatrix}
\frac{n}{2} & \frac{n}{2} & \frac{n}{2} & \cdots & \frac{n}{2} \\
\frac{n}{2} & \frac{n}{2} & \frac{n}{2} & \cdots & \frac{n}{2} \\
\vdots & \vdots & \vdots & \cdots & \vdots \\
\frac{n}{2} & \frac{n}{2} & \frac{n}{2} & \cdots & \frac{n}{2} \\
\frac{n}{2} & \frac{n}{2} & \frac{n}{2} & \cdots & \frac{n}{2} \\
\frac{n}{2} & \frac{n}{2} & \frac{n}{2} & \cdots & \frac{n}{2} \\
\end{pmatrix} \in \mathbb{R}^{n \times (n-1)},
\]

minimizing (TV) is equivalent to minimizing the Lasso objective
\[ \frac{1}{2} \|\hat{Y} - X\beta\|^2 + \lambda \|\beta\|_1
\]
over $\beta \in \mathbb{R}^{n-1}$, where $\hat{Y} = (Y_1 - \bar{Y}, \ldots, Y_n - \bar{Y})$ denotes $Y$ centered by its mean. The maximum column norm of $X$ is $\sqrt{n/4}$, the error $\|\hat{\mu} - \mu_0\|^2$ corresponds to $n$ times the “prediction loss” $n^{-1} \|X\hat{\beta} - X\beta_0\|^2$, and in this context Theorem 4.2 (with $\Delta = 1$) implies
\[ \inf_{\lambda \geq 0, \beta_0 \|\beta_0\|_0 \leq s} \sup_{\beta_0} E\left[ \frac{1}{n} \|X\hat{\beta}^\lambda - X\beta_0\|^2 \right] \geq \frac{c\sigma^2}{(\log n)^5} \sqrt{\frac{s}{n}}.
\]

Hence the minimax prediction risk for the Lasso estimate over $\{\beta_0 : \|\beta_0\|_0 \leq s\}$ decays essentially no faster than order $n^{-1/2}$. This is in contrast to the faster rate of $n^{-1}$ that is achievable when $X$ has well-behaved restricted eigenvalue constants (see, for example, [BRT09, VDGB09] and the references contained therein).

More generally, for any connected graph $G$, noting that $D^\dagger \in \mathbb{R}^{n \times E}$ is of rank $n - 1$ with range orthogonal to the all-1’s vector, minimizing (TV) is equivalent to minimizing
\[ \frac{1}{2} \|\hat{Y} - D^\dagger \beta\|^2 + \lambda \|\beta\|_1 \text{ subject to } \beta \in \text{range}(D),
\]
where $\text{range}(D)$ denotes the column span of $D$ in $\mathbb{R}^E$. The results of the two preceding sections imply that whenever $G$ has small average degree, the “fast” optimal rate for prediction risk over the class $\{\beta_0 \in \text{range}(D) : \|\beta_0\|_0 \leq s\}$ for the above problem is attainable in polynomial time,
even if it is not achieved by the $l_1$ estimator. This may be contrasted with the negative results of [ZWJ14, ZWJ17], which show that there exist adversarial design matrices $X$ for sparse regression where such fast rates are not achieved by a broad class of $M$-estimators or by any polynomial-time algorithm returning an $s$-sparse output.

5. Edge-weighting for inhomogeneous graphs

In this section, we generalize the results of Section 3 by considering (exact or approximate) minimizers $\hat{\mu}$ of the edge-weighted objective (W). Proofs are contained in Appendix B, with a brief summary of proof ideas at the end of this section.

We motivate our discussion by the following example, which examines the factor-$d$ gap between the upper and lower bounds of (5) and (7):

**Example 5.1.** Let $G$ be the complete graph on $n$ vertices. Then the average vertex degree of $G$ is $d = n - 1$, and (7) implies

$$\inf_{\hat{\mu}} \sup_{\mu_0: \|D\mu_0\|_0 \leq s} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \gtrsim \sigma^2 \frac{s}{n} \left(1 + \log \frac{|E|}{s}\right). \quad (10)$$

This lower bound is in fact tight, and the upper bound of (5) is loose by a factor of $n$: Theorem 5.5 below will imply that setting $\lambda \approx \sigma^2 \frac{1 + \log |E|}{s}$ in (L0) achieves the above level of risk, when $G$ is the complete graph.

On the other hand, let $G$ be a “tadpole” graph consisting of a linear chain of $n/2$ vertices with one endpoint connected by an edge to a clique of $n/2$ remaining vertices. The average vertex degree of $G$ in this case is $d = (n + 1)/2$, so a direct application of (7) still yields (10). However, by restricting to the sub-class of signals that take a constant value on the $n/2$-clique, it is clear that the minimax risk over $\{\mu_0: \|D\mu_0\|_0 \leq s\}$ is at least that of estimating the signal over only the linear chain portion of $G$ with $n/2$ vertices. The lower bound (7) applied to only this sub-graph implies that in this case, the upper bound (5) is tight up to a constant factor, and the lower bound (10) is loose by a factor of $1/n$.

This example highlights the problem that the complexity measure $\|D\mu_0\|_0$ is not necessarily spatially homogeneous over $G$. For example, when $G$ is the tadpole graph, a signal $\mu_0$ that is constant over all but one vertex belonging to the $n/2$-clique has $\|D\mu_0\|_0 = n/2 - 1$, but a signal taking a different value at each of the vertices of the linear chain also has $\|D\mu_0\|_0 = n/2 - 1$. A theoretical consequence is that the minimax risk over $\{\mu_0: \|D\mu_0\|_0 \leq s\}$ is controlled by the least well-connected portion of the graph. A practical consequence is that any choice of $\lambda$ will either oversmooth the signal over the $n/2$-clique or undersmooth the signal over the linear chain, and no single choice of $\lambda$ leads to good signal recovery in both of these regions.

While the tadpole graph is an extreme example, the same phenomenon arises in any graph with regions of varying connectivity. In such applications, we propose to consider the weighted objective function (W) where each edge is weighted by a measure of its contribution to the connectivity of $G$. We believe both that minimizing this weighted objective is usually a more reasonable procedure in practice and that the value $\|D\mu_0\|_w$ provides a better indication of the complexity of the piecewise-constant signal $\mu_0$.

One specific weighting $w : E \to \mathbb{R}_+$ that implements this idea is to weigh each edge by its effective resistance.

**Definition 5.2.** Let $G$ be a connected graph and $\{i, j\}$ an edge in $G$. The effective resistance $r(i, j)$ of this edge has the following four equivalent definitions:

1. $r(i, j)$ is the effective electrical resistance measured across vertices $i$ and $j$ when $G$ represents an electrical network where each edge is a resistor with resistance 1.
(2) Let \( L \) be the (unweighted) Laplacian matrix of \( G \), \( L^\dagger \) the pseudo-inverse of \( L \), and \( e_i \) the basis vector with \( i \)th entry 1 and remaining entries 0. Then \( r(i, j) = (e_i - e_j)L^\dagger(e_i - e_j) \).

(3) Consider a simple random walk on \( G \) starting at vertex \( i \), and let \( t \) be the number of steps taken to reach vertex \( j \) and then return to vertex \( i \) for the first time. Then \( r(i, j) = \frac{1}{2t} \mathbb{E}[t] \).

(4) Let \( T \) be (the edges of) a random spanning tree of \( G \) chosen uniformly from the set of all spanning trees of \( G \). Then \( r(i, j) = \mathbb{P}\{\{i, j\} \in T\} \).

For verification of the equivalence of these definitions, see [L93, GBS08]. In practice, \( r(i, j) \) may be computed via the second characterization using fast Laplacian solvers [ST04, LB12].

The fourth characterization above describes one sense in which \( r(\cdot, \cdot) \) minimizes \((W)\) for any edge-weighting \( w \) : \[ \text{for every edge } \{i, j\} \in E, \quad \sum_{m=1}^M \lambda_m 1\{\{i, j\} \in T_m\} \]

for every \( \{i, j\} \in E \). The weighting \( r \) is thus identified with the probability distribution of a random spanning tree \( T \), where \( T = T_m \) with probability \( \lambda_m \). This distribution satisfies the property, for all \( \{i, j\} \in E \),

\[ r(i, j) = \mathbb{P}\{\{i, j\} \in T\} \]

For any subset of edges \( E' \subseteq E \) and weighting \( w : E \to \mathbb{R}_+ \), let us denote \( w(E') = \sum_{\{i, j\} \in E'} w(i, j) \) as the total weight of these edges. Then the above implies, for the random spanning tree \( T \) associated to \( r \in \mathcal{ST}(G) \),

\[ r(E') = \mathbb{E}[|E' \cap T|]. \] (11)

The effective resistance weighting of Definition 5.2 corresponds to the uniform distribution for \( T \).

The results below describe the squared-error risk of the estimator \( \hat{\mu} \) that (exactly or approximately) minimizes \((W)\) for any edge-weighting \( w : E \to \mathbb{R}_+ \). We derive, for all graphs \( G \), minimax upper and lower bounds on this risk over the class \( \{\mu_0 : \|D\mu_0\|_w \leq s\} \). The tightness of these bounds will depend on how close \( w \) is to the spanning tree polytope \( \mathcal{ST}(G) \)—for effective resistance weighting, or more generally for any \( r \in \mathcal{ST}(G) \), these bounds are tight up to a universal constant factor independent of the graph.

Let us make a remark about scaling, which is important for the interpretation of the below results: As rescaling \( w \) by \( c > 0 \) and \( \lambda \) by \( 1/c \) leads to the same penalty in \((W)\), we will state all of our results, for simplicity and without loss of generality, under a scaling such that \( w \geq r \) for some \( r \in \mathcal{ST}(G) \), meaning \( w(i, j) \geq r(i, j) \) for every edge. For any \( w \) (where \( G \) remains connected by edges with positive weight), there is a smallest constant \( c > 0 \) for which this property holds for \( \tilde{w} = cw \); the below results yield the tightest risk bounds when applied to \( \tilde{w} \) scaled in this way. Whenever \( w \geq r \) for some \( r \in \mathcal{ST}(G) \), (11) implies that the total weight of all edges satisfies

\[ w(E) \geq r(E) = n - 1, \] (12)
since every spanning tree has \( n - 1 \) edges. The ratio \( w(E)/(n - 1) \) provides a measure of the distance of \( w \) to \( ST(G) \). Furthermore, if \( E' \) is any subset of edges whose removal disconnects \( G \) into \( k + 1 \) connected components, then every spanning tree contains at least \( k \) edges of \( E' \), so \( w(E') \geq r(E') \geq k \). In particular,

\[
\mu \in \mathbb{R}^n \text{ has } k + 1 \text{ distinct values } \Rightarrow \|D\mu\|_w \geq k. \tag{13}
\]

The following results generalize Theorems 3.1, 3.2, and 3.3.

**Theorem 5.4.** Let \( w : E \to \mathbb{R}_+ \) be such that \( w \geq r \) for some \( r \in ST(G) \), and let \( \delta \leq \sigma/\sqrt{n} \) and \( \tau \leq \sigma^2 \). For any \( \eta > 0 \), there exist constants \( C_\eta, C'_\eta > 0 \) depending only on \( \eta \) such that if \( \lambda \geq C_\eta \sigma^2 \log w(E) \) and \( \hat{\mu} \) is any \((\tau, \delta \mathbb{Z})\)-local-minimizer of \([\bar{W}]\), then

\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq \inf_\mu (1 + \eta)\|\mu - \mu_0\|^2 + C'_\eta \lambda \max(\|D\mu\|_w, 1). \tag{14}
\]

**Theorem 5.5.** Let \( w : E \to \mathbb{R}_+ \) be such that \( w \geq r \) for some \( r \in ST(G) \), and let \( \delta \leq \sigma/\sqrt{n} \) and \( \tau \leq \sigma^2 \). There exist universal constants \( C, C' > 0 \) such that for any \( s \in [1, w(E)] \), if \( \lambda \geq C\sigma^2 (1 + \log \frac{w(E)}{s}) \) and \( \hat{\mu} \) is any \((\tau, \delta \mathbb{Z})\)-local-minimizer of \([\bar{W}]\), then

\[
\sup_{\mu_0 : \|D\mu_0\|_w \leq s} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq C' s. \tag{15}
\]

Conversely, there exists a universal constant \( c > 0 \) such that for any \( s \in \left[\frac{4w(E)}{n}, w(E)\right] \),

\[
\inf_{\hat{\mu}} \sup_{\mu_0 : \|D\mu_0\|_w \leq s} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \geq c\sigma^2 s \frac{n}{w(E)} \left(1 + \log \frac{w(E)}{s}\right),
\]

where the infimum is taken over all possible estimators \( \hat{\mu} := \hat{\mu}(Y) \).

The restriction to \( s \geq w(E)/n \) in the lower bound is necessary for generality of the result to all graphs \( G \), for the same reason as in Remark 3.4.

The minimax upper and lower bounds above differ by the factor \( n/w(E) \). Recall from (12) that \( w(E) \geq n - 1 \), with \( w(E) = n - 1 \) precisely when \( w \in ST(G) \). Hence the above immediately implies the following corollary:

**Corollary 5.6.** If \( w = r \) where \( r(i, j) \) is the effective resistance of each edge \( \{i, j\} \), or more generally where \( r \in ST(G) \), then for any \( s \in [4, n - 1] \),

\[
\inf_{\hat{\mu}} \sup_{\mu_0 : \|D\mu_0\|_w \leq s} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \asymp \sigma^2 s \left(1 + \log \frac{n}{s}\right). \tag{16}
\]

**Remark 5.7.** One may compare (15) with a guarantee achieved by the wavelet spanning tree method of [SSR13]: In this method, for a fixed spanning tree \( T \) of \( G \), an orthonormal basis of Haar-like wavelet functions is constructed over \( T \) such that a signal \( \mu_0 \) cutting \( s \) edges of \( T \) has a representation of sparsity \( s(\log d_{\max}(T))(\log n) \) in this basis, where \( d_{\max}(T) \) is the maximal vertex degree of \( T \). The corresponding wavelet thresholding estimator then satisfies

\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq \sigma^2 s(\log d_{\max}(T))(\log n)^2.
\]

If \( T \) is chosen at random from the spanning tree distribution corresponding to any weighting \( w \in ST(G) \), then bounding \( d_{\max}(T) \leq d_{\max}(G) \) and averaging over the random choice of \( T \) yields

\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq \sigma^2 (\log d_{\max}(G))(\log n)^2 \|D\mu_0\|_w,
\]

which agrees with (15) up to extra logarithmic factors. Whereas this defines a randomized algorithm and the above risk is averaged also over the algorithm execution, minimizing \([\bar{W}]\) for \( w \in ST(G) \) directly penalizes the number of edges cut by \( \hat{\mu} \) in the average spanning tree, and thus may be interpreted loosely as a derandomization of this wavelet approach.

Finally, we state a result of relevance to testing the null hypothesis (5):
Theorem 5.8. Let \( w : E \to \mathbb{R}_+ \) be such that \( w \geq r \) for some \( r \in \mathcal{ST}(G) \), and let \( \delta \leq \sigma / \sqrt{n} \) and \( \tau \leq \sigma^2 \). There exist universal constants \( C, C' > 0 \) such that if \( \mu_0 \) is constant over \( G \), \( \lambda \geq C \sigma^2 \log w(E) \), and \( \hat{\mu} \) is any \((\tau, \delta \mathbb{Z})\)-local-minimizer of \( W \), then
\[
\mathbb{P}[\hat{\mu} \text{ is constant over } G] \geq 1 - C'' n^{-3}.
\]

Thus we may test \( H_0 \) in (8) by setting \( \lambda \propto \sigma^2 \log w(E) \) and rejecting \( H_0 \) if \( \hat{\mu} \) minimizing \( W \) is not constant. Denoting by \( P^\perp \) the projection orthogonal to the all-1’s vector, the risk bound (15) (or more precisely, the probability guarantee of Lemma B.3(b)) implies that this test can distinguish a non-constant alternative \( \mu_0 \) with probability approaching 1 as long as \( \|P^\perp \mu_0\|^2 \geq C \sigma^2 \|D\mu_0\|_W \log w(E) \), for a universal constant \( C > 0 \). When \( w : E \to \mathbb{R}_+ \) is the effective resistance weighting, this recovers a similar detection threshold as established for the tests in [SSR13, SKS13].

In the case of uniform edge weights \( w \equiv 1 \), it is clear that \( w(E) = |E| \) and \( w \geq r \) for all \( r \in \mathcal{ST}(G) \). Then Theorems 3.1, 3.2, 3.3, and 3.5 follow directly by specializing these results. If there exists \( r \in \mathcal{ST}(G) \) such that \( r(i, j) < 1 \) for every edge, then the results of Section 3 are trivially strengthened by rescaling \( \lambda \) by \( \max_{(i, j) \in E} r(i, j) \). For example, if \( G \) is the complete graph, then every edge has effective resistance \( r(i, j) = 1/n \), and Theorems 5.4 and 5.5 imply that \( \lambda \) may in fact be set to \( C n^{-1} \log |E| \) and \( C n^{-1} \log |E|/s \) in Theorems 3.1 and 3.2 respectively, as claimed in Example 5.1.

We prove Theorems 5.4, 5.5, and 5.8 in Appendix B. The upper bound in Theorem 5.5 uses the idea of [KS96, Theorem 3.3] for bounding the number of small graph cuts by controlling the number of cut edges in a given spanning tree. We apply this idea in Lemma B.2, controlling a standard Cauchy-Schwarz argument, this establishes (14) and (15) for the exact minimizer of (W).

6. Simulations

We study empirically the squared-errors of the approximate minimizers of \( L_0 \) and \( W \) as returned by Algorithm 1, as well as the exact minimizer of \( TV \) (computed using the pygfl library [TS15]). We denote these estimates by \( \hat{\mu}^{L_0} \), \( \hat{\mu}^W \), and \( \hat{\mu}^{TV} \). We consider piecewise-constant signals over various graphs, corrupted by Gaussian noise for various noise levels \( \sigma \). We report in each setting the standardized mean-squared-error
\[
\frac{1}{n \sigma^2} \|\hat{\mu} - \mu_0\|^2.
\]

Due to this normalization by \( \sigma^2 \), one may equivalently interpret these results as for a fixed noise level \( \sigma \) under various rescalings of the true \( \mu_0 \).

6.1. Parameter tuning. For Algorithm 1, we fix throughout \( \delta = 0.01 \) and \( \tau = 0 \). This value of \( \delta \) may be larger than that prescribed by the theory of the preceding section, but represents a compromise to yield faster runtime.
We select $\lambda$ by minimizing an empirical estimate of $\mathbb{E}[\|\hat{\mu} - \mu_0\|^2]$. Typically, cross-validation is used to obtain such an estimate. However, we observe that naive cross-validation does not necessarily work well for all graphs and signals. (Consider, for example, a case where the primary contribution to error comes from vertices $i$ near the boundaries of the constant pieces of $\mu_0$, and estimation of these values $\mu_{0,i}$ is more difficult when $Y_i$ is removed.) We instead use the following procedure based on [TT15, Har16]:

1. Compute an estimate $\hat{\sigma}$ for $\sigma$. Set $\alpha = 0.04$.
2. For repetitions $b = 1, \ldots, B$:
   a. Generate $z = (z_1, \ldots, z_n) \sim \text{Normal}(0, \alpha \hat{\sigma}^2 \text{Id})$, and set $Y^* = Y + z$ and $\hat{Y}^* = Y - z/\alpha$.
   b. For each $\lambda$, compute $\hat{\mu}$ based on data $Y^*$, and compute $\text{err}^{(b)}(\lambda) = \|\hat{\mu} - \hat{Y}^*\|^2$.
3. Choose $\lambda$ that minimizes the average error $\hat{\text{err}}(\lambda) = \frac{1}{B} \sum_{b=1}^B \text{err}^{(b)}(\lambda)$.

This is motivated by the insight that if $\hat{\sigma} = \sigma$, then $Y^*$ and $\hat{Y}^*$ are independent, so $\mathbb{E}[\text{err}^{(b)}(\lambda)] = n\sigma^2(1 + \alpha^{-1}) + \mathbb{E}[\|\hat{\mu} - \mu_0\|^2]$. Hence $\hat{\text{err}}(\lambda)$ estimates a constant plus the risk of $\hat{\mu}$ applied to data at the slightly elevated noise level $\sigma(1 + \sqrt{\alpha}) = 1.2\sigma$. Due to this elevation in noise level, this procedure has a slight tendency to oversmooth.

For each edge $\{i,j\}$ where $\mu_{0,i} = \mu_{0,j}$, we have $V_i - Y_j \sim \text{Normal}(0, 2\sigma^2)$. Hence $\sigma$ may be estimated from the edge differences $(Y_i - Y_j)_{\{i,j\} \in E}$ by identifying a normal mixture component corresponding to this subset of values; we used the method of [Efr04] as implemented in the locfdr R package. Increasing $B$ reduces the variability of the selection procedure. For the smaller graphs (linear chain, Oldenburg, Gnutella P2P) we set $B = 20$, and for the larger graphs (2-D cow, San Francisco, Enron email) we set $B = 5$.

We will report both the st.MSE achieved using this method, as well as the best-attained st.MSE corresponding to retrospective optimal tuning of $\lambda$. For (TV), $\lambda$ may alternatively be selected by minimizing Stein’s unbiased risk estimate (SURE) using the simple degrees-of-freedom formula derived in [TT11]. We found results of the SURE approach to be very close to those obtained using the above procedure.

6.2. Empirical runtime. For Algorithm [1], we computed minimum s-t cuts using the method of [BK04]. The outer loop required no more than 15 iterations, and typically fewer than 10 iterations, in all tested examples. Table 1 displays the average runtime of this algorithm on our personal computer for computing $\hat{\mu}^{L0}$ with a single value of $\lambda$. The runtime of this algorithm for computing $\hat{\mu}^{W}$ was comparable, although computing effective resistance weights required an additional a priori cost of 10 seconds, 3 hours, 45 seconds, and 30 minutes for the four networks in the order listed, using the approxCholLap method of the Laplacians-0.2.0 Julia package with error tolerance 0.01. (The effective resistance computation is a one-time cost per network, reusable across different $\lambda$ values and data vectors $Y$.) Parameter tuning using the approach of Section 6.1 is slower as it requires running the method multiple times over a range of $\lambda$ values, although this computation is easily parallelized.

6.3. Linear chain graph. Two signals on a linear chain graph with $n = 1000$ vertices are depicted in Figure 1. The first signal has 19 equally-spaced break points, while the second has 20 break points at unequal spacing. We studied recovery for noise levels $\sigma = 0.1$ to $\sigma = 1$. Figure 1 displays one instance of simulated noise and the resulting estimates $\hat{\mu}^{L0}$ and $\hat{\mu}^{TV}$. In both examples, for data-tuned $\lambda$, $\hat{\mu}^{L0}$ tends to over-smooth (missing two and four changepoints respectively) and $\hat{\mu}^{TV}$ tends to undersmooth.

| Graph          | 1-D cow | Oldenburg | San Fran. | Gnutella | Enron |
|----------------|---------|-----------|-----------|----------|-------|
| Runtime (seconds) | 0.13    | 45        | 0.7       | 40       | 240   |

Table 1. Average computational time of Algorithm [1] for one value of $\lambda$.
Figure 1. Signals on a linear chain graph. Top: Equally-spaced breaks, $\sigma = 0.5$. Bottom: Unequally-spaced breaks, $\sigma = 0.3$. The true signal $\mu_0$ is displayed on the left, $\hat{\mu}^{L0}$ in the middle, and $\hat{\mu}^{TV}$ on the right (both with data-tuned $\lambda$).

Figure 2. Comparisons of st.MSE in (left) the equally-spaced and (right) unequally-spaced examples of Figure 1 for $\hat{\mu}^{L0}$, $\hat{\mu}^{TV}$, the exact minimizer of (L0), and $\hat{\mu}^{TV,\text{relaxed}}$. Solid lines correspond to data-tuned $\lambda$, and dashed transparent lines to best-achieved error. All errors are averaged over 100 replicates of the simulated noise.
Figure 3. (Left) Comparisons of st.MSE for signals of fixed total-variation $\|D\mu_0\|_1/\sigma = 20$ and increasing numbers of segments/decreasing jump sizes. (Right) Raw data and true signal in black, $\hat{\mu}^{L0}$ in red, and $\hat{\mu}^{TV}$ in blue, for the signal with 20 segments.

Figure 2 plots st.MSE comparisons for $\hat{\mu}^{L0}$ and $\hat{\mu}^{TV}$. The $\hat{\mu}^{L0}$ estimate achieves significantly smaller risk than $\hat{\mu}^{TV}$ at higher signal-to-noise regimes, for example those displayed in Figure 1, while $\hat{\mu}^{TV}$ becomes competitive or better in lower signal-to-noise regimes, corresponding to lower values of normalized total-variation $\|D\mu_0\|_1/\sigma$ for the true signal. Figure 3 presents a different example to further explore this trade-off, in which the normalized total-variation of the signal is fixed at $\|D\mu_0\|_1/\sigma = 20$, and we increase the number of changepoints while simultaneously decreasing the jump sizes. (Changepoints are equally spaced, and distinct signal values are normally distributed.) The estimate $\hat{\mu}^{L0}$ is better under strong edge-sparsity, while $\hat{\mu}^{TV}$ becomes better as we transition to weaker edge-sparsity.

For the linear chain, we may compare $\hat{\mu}^{L0}$ with the exact minimizer of (L0) (computed using PELT in the changepoint R package [KFE12]). Algorithm 1 achieves risk comparable to the exact minimizer in all tested settings. One may ask, at the higher signal-to-noise regimes, how much of the sub-optimality of $\hat{\mu}^{TV}$ is due to estimator bias incurred by shrinkage. To address this, we computed also the “relaxed” TV estimate

$$\hat{\mu}^{TV,\text{relaxed}} = \alpha \hat{\mu}^{TV} + (1 - \alpha) \hat{\mu}^{TV,\text{debiased}}$$

where $\alpha \in \{0, 0.1, 0.2, \ldots, 1\}$ is an additional tuning parameter, and where $\hat{\mu}^{TV,\text{debiased}}$ replaces each constant interval of $\hat{\mu}^{TV}$ with the mean of $Y$ over this interval. The error of $\hat{\mu}^{TV}$ at high signal-to-noise is partially reduced, but not to the same levels as $\hat{\mu}^{L0}$.

6.4. 2-D lattice graph. Figure 4 displays a cartoon gray-scale image of a cow, represented by its pixel values on a 2-D lattice graph of size $320 \times 283$. Pure white corresponds to $\mu_0 = 1$, and pure black to $\mu_0 = 0$. The figure also displays $\hat{\mu}^{L0}$ and $\hat{\mu}^{TV}$ when the image is contaminated by noise at level $\sigma = 0.3$. We again observe that $\hat{\mu}^{L0}$ oversmooths, missing details in the cow’s feet, right horn, and the shadows of the image. In contrast, $\hat{\mu}^{TV}$ undersmooths and returns a blotchy cow.

Table 2 reports st.MSE comparisons for $\sigma = 0.1$ to $\sigma = 0.5$. At the level $\sigma = 0.3$ displayed in Figure 4, the st.MSE of $\hat{\mu}^{L0}$ is slightly greater than that of $\hat{\mu}^{TV}$. At higher signal-to-noise levels, $\hat{\mu}^{L0}$ is better, while it is worse at lower signal-to-noise.
6.5. Road and digital networks. We tested signal recovery over four real networks: the Oldenburg and San Francisco road networks from [www.cs.utah.edu/~lifeifei/SpatialDataset.htm](http://www.cs.utah.edu/~lifeifei/SpatialDataset.htm), and the Gnutella08 peer-to-peer network and Enron email network from [snap.stanford.edu/data](http://snap.stanford.edu/data). Duplicate edges were removed, and only the largest connected component of each network was retained.

For each network, we simulated an epidemic according to a simple graph-based discrete-time SI model [MN00], randomly selecting a source vertex to infect at time \( t = 0 \) and, for each of \( T \) timesteps, allowing each infected vertex to independently infect each non-infected neighbor with probability 0.5. We associated the values \( \mu_0 = 1.005 \) and \( \mu_0 = 0.005 \) to infected and non-infected vertices. For each network, we considered three signals corresponding to observations of the epidemic at three different times \( T \). Various properties of these networks and signals are summarized in Table 3.

For noise level \( \sigma = 0.3 \), the simulated signal, \( \hat{\mu}^{TV} \), and \( \hat{\mu}^{W} \) computed with effective-resistance edge weights are depicted in Figure 6 for the San Francisco road network at observation time \( T_2 \).

| sigma | 0.1 | 0.2 | 0.3 | 0.4 | 0.5 |
|-------|-----|-----|-----|-----|-----|
| \( \hat{\mu}^{L0} \) st.MSE | 0.041 | 0.067 | 0.076 | 0.081 | 0.082 |
| (0.039) | (0.067) | (0.071) | (0.081) | (0.082) |
| \( \hat{\mu}^{TV} \) st.MSE | 0.083 | 0.075 | 0.065 | 0.061 | 0.054 |
| (0.083) | (0.075) | (0.065) | (0.059) | (0.053) |

Table 2. Comparison of st.MSE for the cow image of Figure 4. Non-parenthesized values correspond to data-tuned \( \lambda \), and parenthesized values to best-attained error.

| Network | verts. | edges | res. var. | inf. \( T_1 \) | cut \( T_1 \) | inf. \( T_2 \) | cut \( T_2 \) | inf. \( T_3 \) | cut \( T_3 \) |
|---------|-------|-------|-----------|------------|-----------|------------|-----------|------------|-----------|
| Oldenburg | 6105 | 7029 | 0.118 | 57 | 16 | 515 | 75 | 2108 | 164 |
| San Fran. | 174956 | 221802 | 0.203 | 8574 | 306 | 27724 | 562 | 70925 | 774 |
| Gnutella | 6299 | 20776 | 0.826 | 19 | 91 | 67 | 477 | 271 | 3894 |
| Enron | 33696 | 180811 | 1.297 | 179 | 7319 | 2564 | 74117 | 16868 | 29253 |

Table 3. For each network: Number of total vertices, total edges, variability of effective edge resistances (measured by standard deviation / mean), and numbers of infected vertices and cut edges corresponding to the signal at three observation times.
Figure 5. Comparisons of st.MSE for recovery of epidemic signals on four networks, for $\hat{\mu}^{L0}$, $\hat{\mu}^{TV}$, and $\hat{\mu}^{W}$ with effective-resistance edge weights. Solid lines correspond to data-tuned $\lambda$, and dashed transparent lines to best-achieved error.
Figure 6. A simulated epidemic signal over the San Francisco road network is displayed on the far left. Three columns display (left) the true signal, (middle) $\hat{\mu}^W$, and (right) $\hat{\mu}^{TV}$ for the three boxed areas of the map. Both $\hat{\mu}^W$ and $\hat{\mu}^{TV}$ are estimated on noisy data with $\sigma = 0.3$, using data-tuned $\lambda$, and $\hat{\mu}^W$ uses effective-resistance edge weighting.

The most difficult regions to estimate are the signal boundaries; we zoom in on three regions of the map where $\hat{\mu}^{TV}$ is inaccurate at these boundaries, but $\hat{\mu}^W$ is mostly correct. At this noise level, the st.MSE of $\hat{\mu}^{TV}$ exceeds $\hat{\mu}^W$ by a factor of about 2.

Figure 5 displays st.MSE comparisons for $\hat{\mu}^{L0}$, $\hat{\mu}^{TV}$, and $\hat{\mu}^W$ with effective-resistance weighting at noise levels $\sigma = 0.1$ to $\sigma = 0.5$ in each example. We observe that $\hat{\mu}^W$ is not substantially worse than $\hat{\mu}^{L0}$ in any tested setting, and that in the Gnutella and Enron digital networks where there is large variation in effective edge resistances, $\hat{\mu}^W$ is sometimes substantially better. At the tested noise levels, these methods are (with the exception of Enron $T_3$) not substantially worse than $\hat{\mu}^{TV}$, and can be substantially better in the lower noise settings.

7. Conclusion

We have studied estimation of piecewise-constant signals over arbitrary graphs using an $l_0$ edge penalty, establishing minimax rate-optimal statistical guarantees for the local minimizer computed by an approximation algorithm for minimizing this objective. We have shown theoretically that the same guarantees are not necessarily achieved by total-variation denoising, and empirically that $l_0$-penalization may be more effective in high signal-to-noise settings. For application to networks with regions of varying connectivity, we have proposed minimization of an edge-weighted objective,
which achieves better empirical performance in tested examples and leads to theoretical guarantees that are spatially uniform over all graphs.

We note that while Algorithm 1 is provably polynomial-time, discretization of the continuous parameter domain yields poor worst-case runtime and may be computationally costly to extend to likelihood models with multi-dimensional parameters. The development of faster non-discretized algorithms is an interesting direction for future work. Finally, our problem may be reformulated as sparse regression with particular graph-based designs, and we believe it is an interesting question whether similar computational ideas may be used to achieve better prediction error in sparse regression for more general families of designs.

**Appendix A. Properties of Algorithm 2**

In this appendix, we prove Propositions 2.2 and 2.3.

**Proof of Proposition 2.2.** The initial objective value is \( \frac{1}{2} \| Y - \hat{Y} \|^2 = O(n(Y_{\text{max}} - Y_{\text{min}})^2). \) This value decreases by at least \( \tau \) in each outer loop of Algorithm 1, so there are at most \( O(n(Y_{\text{max}} - Y_{\text{min}})^2/\tau) \) outer iterations. Within each outer iteration, there are at most \( (Y_{\text{max}} - Y_{\text{min}})/\delta \) inner loop iterations. The augmented graph \( G_{c,\hat{\mu}} \) of Algorithm 2 has \( O(|E|) \) vertices and edges, so solving minimum s-t cut using either Edmonds-Karp or Dinic’s algorithm requires time \( O(|E|^3) \). This is the dominant cost of Algorithm 2, so combining these runtimes yields the proposition.

**Proof of Proposition 2.3.** The objective (W) may be written as

\[
F_w(\mu) = \frac{1}{2} \sum_{i=1}^{n} (Y_i - \mu_i)^2 + \sum_{(i,j) \in E} \lambda w(i,j) 1\{\mu_i \neq \mu_j\},
\]

and each edge-cost \( \lambda w(i,j) 1\{\mu_i \neq \mu_j\} \) satisfies the triangle inequality in the sense

\[
\lambda w(i,j) 1\{a \neq c\} \leq \lambda w(i,j) 1\{a \neq b\} + \lambda w(i,j) 1\{b \neq c\}
\]

for any \( a, b, c \in \mathbb{R} \). Hence, the first statement follows from Theorem 5.4 and Corollary 5.5 of [BVZ01]. Termination of the algorithm implies that \( F_w(\hat{\mu}) > F_w(\hat{\mu}) - \tau \) for every \( \delta \mathbb{Z} \)-expansion \( \hat{\mu} \) of \( \mu \) with new value \( c \in \delta \mathbb{Z} \cap [Y_{\text{min}}, Y_{\text{max}}] \), and hence also for every new value \( c \in \delta \mathbb{Z} \). Then \( \hat{\mu} \) is a \((\tau, \delta \mathbb{Z})\)-local-minimizer.

**Appendix B. Analysis of weighted \( l_0 \)-denoising**

In this appendix, we prove Theorems 5.4, 5.5 and 5.8. Recall from the end of Section 5 that these imply, as direct corollaries, Theorems 3.1, 3.2, 3.3 and 3.5. By rescaling, we will assume without loss of generality that \( \sigma^2 = 1 \).

**Terminology.** A multi-cut \( S := \{S_1, \ldots, S_k\} \) of \( G \) is a partition of its vertices \( V \) into non-empty disjoint vertex subsets \( S_1, \ldots, S_k \), which are called the elements of the multi-cut. In this appendix, we do not require each element \( S_\alpha \) of \( S \) to be connected in \( G \). The multi-cut \( S \) is trivial if \( k = 1 \), i.e. its only element is the entire vertex set \( V \). For two multi-cuts \( S \) and \( S' \), \( S' \) is a refinement of \( S \) if this holds in the usual sense of partitions: For every element \( S_\alpha \) of \( S' \), there exists an element of \( S \) that contains \( S_\alpha \) as a subset. For any two multi-cuts \( S \) and \( S' \), their least common refinement is denoted by \( S \lor S' \).

For every \( \mu \in \mathbb{R}^n \), the multi-cut induced by \( \mu \) is such that any two vertices \( i, j \in V \) are in the same element of the cut if and only if \( \mu_i = \mu_j \). (If \( \mu \) is constant on \( G \), then it induces the trivial multi-cut.) A multi-cut cuts an edge \( \{i, j\} \) if \( i \) and \( j \) belong to two different elements. The set of all cut edges of \( S \), i.e. the boundary of the multi-cut, is denoted

\[
\partial S := \{\{i, j\} \in E : S \text{ cuts } \{i, j\}\}.
\]
(\partial S is empty if \( S \) is trivial.) Recall \( w(E') := \sum_{(i,j) \in E'} w(i,j) \) for any \( E' \subseteq E \). It is then evident that if \( \mu \) induces \( S \), then

\[
\|D\mu\|_w = w(\partial S).
\]

Associated to each multi-cut \( S = \{S_1, \ldots, S_k\} \) is a \( k \)-dimensional subspace \( K \subseteq \mathbb{R}^n \), such that \( \mu \in K \) if and only if \( \mu \) takes a constant value on each element \( S_\alpha \). (I.e., \( \mu \in K \) if and only if \( S \) is equal to, or is a refinement of, the multi-cut induced by \( \mu \).) We denote the orthogonal projection onto \( K \) by \( P^S : \mathbb{R}^n \to K \).

We first recall a deterministic sub-optimality bound for any \((\tau, \delta \mathbb{Z})\)-local-minimizer of \([W]\). Such a bound was stated in [BVZ01] as a factor-2 approximation, \( F_w(\hat{\mu}) \leq 2F_w(\mu^*) \), where \( \hat{\mu} \) is any \((0, \delta \mathbb{Z})\)-local-minimizer of \([W]\) and \( \mu^* \) is the exact minimizer in \((\delta \mathbb{Z})^n \). In fact, this factor of 2 applies only to the penalty term, the resulting bound holds not only for \( \mu^* \) but also for any \( \mu \in (\delta \mathbb{Z})^n \), and it is easily extended to any \( \tau \geq 0 \). The proof is essentially the same, and we provide it here for completeness.

**Lemma B.1.** Let \( \delta > 0 \) and \( \tau \geq 0 \), and let \( \hat{\mu} \) be any \((\tau, \delta \mathbb{Z})\)-local-minimizer of \( F_w(\mu) \) in \([W]\). Then for any vector \( \mu^\delta \in (\delta \mathbb{Z})^n \) whose entries take \( k \) distinct values,

\[
F_w(\hat{\mu}) \leq \frac{1}{2}\|Y - \mu^\delta\|^2 + 2\lambda\|D\mu^\delta\|_w + k\tau.
\]

**Proof.** Let \( S = \{S_1, \ldots, S_k\} \) be the multi-cut induced by \( \mu^\delta \). Fix \( \alpha \in \{1, \ldots, k\} \) and denote by \( \mu^\delta_{S_\alpha} \) the (constant) value of \( \mu^\delta \) on \( S_\alpha \). Let \( \bar{\mu} \) be the \( \delta \mathbb{Z}\)-expansion of \( \hat{\mu} \) defined entrywise by

\[
\bar{\mu}_i = \begin{cases} 
\hat{\mu}_i & i \notin S_\alpha \\
\mu^\delta_{S_\alpha} & i \in S_\alpha.
\end{cases}
\]

Since \( \bar{\mu} \) is a \((\tau, \delta \mathbb{Z})\)-local-minimizer of \([W]\), by definition

\[
F_w(\bar{\mu}) = \frac{1}{2}\sum_{i=1}^n (Y_i - \bar{\mu}_i)^2 + \lambda \sum_{(i,j) \in E} w(i,j) \mathbb{1}\{\bar{\mu}_i \neq \bar{\mu}_j\}
\]

\[
\leq \frac{1}{2}\sum_{i=1}^n (Y_i - \hat{\mu}_i)^2 + \lambda \sum_{(i,j) \in E} w(i,j) \mathbb{1}\{\hat{\mu}_i \neq \hat{\mu}_j\} + \tau = F_w(\hat{\mu}) + \tau.
\]

As \( \hat{\mu}_i = \tilde{\mu}_i \) for \( i \notin S_\alpha \), we may cancel terms from both sides to yield

\[
\frac{1}{2}\sum_{i \in S_\alpha} (Y_i - \tilde{\mu}_i)^2 + \lambda \sum_{\substack{(i,j) \in E \mid |i,j| \cap S_\alpha \geq 1}} w(i,j) \mathbb{1}\{\tilde{\mu}_i \neq \tilde{\mu}_j\} \leq \frac{1}{2}\sum_{i \in S_\alpha} (Y_i - \mu^\delta_{S_\alpha})^2 + \lambda \sum_{\substack{(i,j) \in E \mid |i,j| \cap S_\alpha \geq 1}} w(i,j) \mathbb{1}\{\tilde{\mu}_i \neq \tilde{\mu}_j\} + \tau.
\]

For the right side above, note that \( \mathbb{1}\{\tilde{\mu}_i \neq \tilde{\mu}_j\} = 0 \) when \( i, j \in S_\alpha \), and apply the trivial bound \( \mathbb{1}\{\tilde{\mu}_i \neq \tilde{\mu}_j\} \leq 1 \) when \( \{i,j\} \cap S_\alpha = \emptyset \), i.e. when \( \{i,j\} \) is cut by \( S \). Then, summing the above over \( \alpha = 1, \ldots, k \),

\[
\frac{1}{2}\|Y - \hat{\mu}\|^2 + \lambda \sum_{\alpha=1}^k \sum_{\substack{(i,j) \in E \mid |i,j| \cap S_\alpha \geq 1}} w(i,j) \mathbb{1}\{\tilde{\mu}_i \neq \tilde{\mu}_j\} \leq \frac{1}{2}\|Y - \mu^\delta\|^2 + \lambda \sum_{\alpha=1}^k \sum_{\substack{(i,j) \in E \mid |i,j| \cap S_\alpha = \emptyset}} w(i,j) + k\tau
\]

\[
= \frac{1}{2}\|Y - \mu^\delta\|^2 + 2\lambda\|D\mu^\delta\|_w + k\tau,
\]

where the second line follows from noting that each edge \( \{i,j\} \) cut by \( S \) appears twice in the sum. The desired result then follows by noting that each edge \( \{i,j\} \in E \) appears at least once in the double sum on the left side. \( \square \)
Next, we control \( \|P^S\varepsilon\|^2 \) using the weighted cut-size \( w(\partial S) \) uniformly over all multi-cuts \( S \) of \( G \). As the number of distinct multi-cuts of \( G \) may be very large, we will first condition on a random spanning tree \( T \) of \( G \), consider the common refinement of those multi-cuts that cut the same set of edges of \( T \), and take a union bound over these refinements. The distribution of the random spanning tree \( T \) that we take is the one specified by the edge-weighting \( r \in ST(G) \) such that \( w \geq r \).

**Lemma B.2.** Let \( w : E \to \mathbb{R}_+ \) be such that \( w \geq r \) for some \( r \in ST(G) \), and let \( \varepsilon \in \mathbb{R}^n \) have coordinates \( \varepsilon_i \overset{iid}{\sim} \text{Normal}(0,1) \). Then there exist universal constants \( C, C' > 0 \) such that with probability at least \( 1 - C'w(E)^{-3} \), for every multi-cut \( S \) of \( G \),

\[
\|P^S\varepsilon\|^2 \leq C \max(w(\partial S), 1) \log \frac{e \cdot w(E)}{\max(w(\partial S), 1)}.
\]

**Proof.** If \( S \) is the trivial multi-cut consisting of the single element \( \{1, \ldots, n\} \), then \( w(\partial S) = 0 \) and \( \|P^S\varepsilon\|^2 \sim \chi^2_1 \), so \( \|P^S\varepsilon\|^2 \leq C \log(e \cdot w(E)) \) with probability at least \( 1 - C'w(E)^{-3} \) by a standard Gaussian tail bound.

Consider, then, non-trivial multi-cuts \( S \). By \( \|P^S\varepsilon\|^2 \leq \chi^2_1 \), \( w(\partial S) \geq 1 \). Observe that for any \( c > 0 \), the function \( x \mapsto x \log(ec/x) \) is increasing over \( x \in (0, c) \). Then, as \( w \geq r \),

\[
Cw(\partial S) \log \frac{e \cdot w(E)}{w(\partial S)} \geq Cr(\partial S) \log \frac{e \cdot w(E)}{r(\partial S)},
\]

and it suffices to establish the stronger bound given by the right side above.

For any \( \eta > 0 \), we may bound

\[
p_n := \mathbb{P} \left[ \text{there exists a non-trivial multi-cut } S : \|P^S\varepsilon\|^2 > Cr(\partial S) \log \frac{e \cdot w(E)}{r(\partial S)} \right]
\]

\[
= \mathbb{P} \left[ \sup_S \|P^S\varepsilon\|^2 - Cr(\partial S) \log \frac{e \cdot w(E)}{r(\partial S)} > 0 \right]
\]

\[
= \mathbb{P} \left[ \sup_S \exp \left( \eta \|P^S\varepsilon\|^2 - \eta Cr(\partial S) \log \frac{e \cdot w(E)}{r(\partial S)} \right) > 1 \right]
\]

\[
\leq \mathbb{E} \left[ \sup_S \exp \left( \eta \|P^S\varepsilon\|^2 - \eta Cr(\partial S) \log \frac{e \cdot w(E)}{r(\partial S)} \right) \right],
\]

where the suprema are over all non-trivial multi-cuts \( S \) of \( G \). Corresponding to the weighting \( r : E \to \mathbb{R}_+ \) is a distribution over random spanning trees \( T \) of \( G \), satisfying the property \( [11] \). Let \( \mathbb{E}_\varepsilon \) and \( \mathbb{E}_T \) denote the expectations over \( \varepsilon \) and over \( T \). Then the above yields

\[
p_n \leq \mathbb{E}_\varepsilon \left[ \sup_S \exp \left( \eta \|P^S\varepsilon\|^2 - \eta C \mathbb{E}_T[|T \cap \partial S|] \log \frac{e \cdot w(E)}{\mathbb{E}_T[|T \cap \partial S|]} \right) \right].
\]

Observe that for any \( c > 0 \), \( x \mapsto x \log(ec/x) \) is concave over \( x \in (0, c) \), so \( x \mapsto \exp(-\eta C x \log(ec/x)) \) is convex over \( x \in (0, c) \). Also, \( |T \cap \partial S| \leq |T| = n - 1 = r(E) \leq w(E) \). Then applying Jensen’s inequality,

\[
p_n \leq \mathbb{E}_\varepsilon \left[ \sup_S \mathbb{E}_T \left[ \exp \left( \eta \|P^S\varepsilon\|^2 - \eta C |T \cap \partial S| \log \frac{e \cdot w(E)}{|T \cap \partial S|} \right) \right] \right]
\]

\[
\leq \mathbb{E}_\varepsilon \mathbb{E}_T \left[ \sup_S \exp \left( \eta \|P^S\varepsilon\|^2 - \eta C |T \cap \partial S| \log \frac{e \cdot w(E)}{|T \cap \partial S|} \right) \right].
\]
Fix $T$, and note that $|T \cap \partial S| \geq 1$ for any non-trivial multi-cut $S$. We now control the supremum over $S$ by a union bound over all possible non-empty edge sets $T \cap \partial S$:

$$\sup_S \exp \left( \eta \|P_S \varepsilon\|^2 - \eta C |T \cap \partial S| \log \frac{e \cdot w(E)}{|T \cap \partial S|} \right) \leq \sum_{E' \subseteq T : |E'| \geq 1} \sup_{S : T \cap \partial S = E'} \exp \left( \eta \|P_S \varepsilon\|^2 - \eta C |E'| \log \frac{e \cdot w(E)}{|E'|} \right)$$

Consider any fixed non-empty subset $E' \subseteq T$, and denote by $S^* := S^*(E', T)$ the multi-cut obtained in the following way: Remove the edges $E'$ from $T$, and let the elements of $S^*$ be the remaining connected components in the graph with edges $T \setminus E'$. If $S$ is any other multi-cut satisfying $T \cap \partial S = E'$, then any two vertices in the same element of $S^*$ are connected by a path of edges in $T$ that are not cut by $S$, and hence these vertices belong to the same element of $S$. Thus $S^*$ is a refinement of $S$. Then the range of the projection $P_S$ is a linear subspace of the range of $P_{S^*}$, and we consequently have $\|P_S \varepsilon\|^2 \geq \|P_{S^*} \varepsilon\|^2$ (deterministically for any $\varepsilon$). Then

$$p_n \leq E_T \left[ \sum_{E' \subseteq T : |E'| \geq 1} e^{-\eta C |E'| \log \frac{e \cdot w(E)}{|E'|}} E_{\varepsilon} \left[ e^{\eta \|P_{S^*} \varepsilon\|^2} \right] \right].$$

$S^*$ has $|E'| + 1$ elements, so $\|P_{S^*} \varepsilon\|^2 \sim \chi_{|E'|+1}^2$. Then for $\eta \in (0, 1/2)$, the chi-squared moment-generating-function yields $E_{\varepsilon}[e^{\eta \|P_{S^*} \varepsilon\|^2}] = (1 - 2\eta)^{|E'|+1}$, so

$$p_n \leq E_T \left[ \sum_{l=1}^{n-1} \sum_{E' \subseteq T : |E'| = l} e^{-\eta C l \log \frac{e \cdot w(E)}{l} (1 - 2\eta)^{l+1}} \right].$$

Applying $|\{E' \subseteq T : |E'| = l\}| = \binom{n-1}{l} \leq \exp(l \log \frac{e(n-1)}{l}) \leq \exp(l \log \frac{e \cdot w(E)}{l})$ for every spanning tree $T$,

$$p_n \leq \sum_{l=1}^{n-1} e^{(-\eta C + 1)l \log \frac{e \cdot w(E)}{l} (1 - 2\eta)^{l+1}} \leq \sum_{l=1}^{w(E)} e^{(-\eta C + 1)l \log \frac{e \cdot w(E)}{l} (1 - 2\eta)^{l+1}}.$$

Fixing $\eta$ to be a constant (say $\eta = 1/4$), it is easily verified that for $C > 1/\eta$, the function

$$l \mapsto (-\eta C + 1)l \log \frac{e \cdot w(E)}{l} + (l + 1) \log(1 - 2\eta)$$

is convex, so its maximum over $l \in [1, w(E)]$ is attained at either $l = 1$ or $l = w(E)$. Thus

$$p_n \leq w(E) \max \left( (e \cdot w(E))^{-\eta C + 1} (1 - 2\eta)^2, e^{(-\eta C + 1)w(E)} (1 - 2\eta)^{w(E)+1} \right) \leq C' w(E)^{-3}$$

for sufficiently large constants $C, C' > 0$, as desired.

The preceding two lemmas yield risk bounds for $\hat{\mu}$ in probability via a standard Cauchy-Schwarz argument, see e.g. [BM01, Theorem 2].

**Lemma B.3.** Let $\delta > 0$ and $\tau \geq 0$, and let $w : E \to \mathbb{R}_+$ be such that $w \geq r$ for some $r \in ST(G)$.

(a) For any $\eta > 0$, there exist constants $C, C', C'' > 0$ depending only on $\eta$ such that for any true signal $\mu_0 \in \mathbb{R}^n$, any (fixed) $\mu \in \mathbb{R}^n$, and any $\lambda \geq C \log w(E)$, with probability at least $1 - C' w(E)^{-3}$ all $(\tau, \delta \mathbb{Z})$-local-minima $\hat{\mu}$ of $[W]$ satisfy

$$\|\hat{\mu} - \mu_0\|^2 \leq (1 + \eta)\|\mu - \mu_0\|^2 + C'' ((\lambda + \tau) \max(\|D\mu\|_w, 1) + n\delta^2).$$
There exist universal constants $C, C' > 0$ such that for any $s \in [1, w(E)]$, any true signal
\[ \mu_0 \in \mathbb{R}^n \] with $\|D\mu_0\|_w \leq s$, and any $\lambda \geq C(1 + \log \frac{w(E)}{s})$, with probability at least $1 - C' w(E)^{-3}$ all $(\tau, \delta Z)$-local-minima $\hat{\mu}$ of $|W|$ satisfy
\[ \|\hat{\mu} - \mu_0\|^2 \leq C'' ((\lambda + \tau) s + n \delta^2). \]

**Proof.** For part (a), let $\mu^\delta \in (\delta Z)^n$ be the vector obtained by rounding each entry of $\mu$ to the nearest value in $\delta Z$, and let $\hat{\mu}$ be any $(\tau, \delta Z)$-local-minimizer. Recall that if the entries of $\mu^\delta$ take $k$ distinct values, then $\|D\mu^\delta\|_w \geq k - 1$ by [13]. Then by Lemma B.1
\[ \frac{1}{2} \|Y - \hat{\mu}\|^2 + \lambda \|D\hat{\mu}\|_w \leq \frac{1}{2} \|Y - \mu^\delta\|^2 + 2\lambda \|D\mu^\delta\|_w + 2\lambda \|\mu^\delta - \mu_0\|^2 + \lambda \|D\mu^\delta\|_w. \] Writing $Y = \mu_0 + \varepsilon$ and canceling $\|\varepsilon\|^2/2$ from both sides,
\[ \frac{1}{2} \|\hat{\mu} - \mu_0\|^2 + \langle \mu_0 - \hat{\mu}, \varepsilon \rangle \leq \frac{1}{2} \|\mu^\delta - \mu_0\|^2 + \langle \mu_0 - \mu^\delta, \varepsilon \rangle + 2\lambda \|D\mu^\delta\|_w + \lambda \|D\mu^\delta\|_w. \] Suppose $\mu^\delta$ induces the multi-cut $S^\delta$ of $G$, and $\hat{\mu}$ induces the multi-cut $\hat{S}$ of $G$. Denote by $S^\delta \lor \hat{S}$ the least common refinement of $S^\delta$ and $\hat{S}$, so
\[ \langle \hat{\mu} - \mu^\delta, \varepsilon \rangle = \langle P_{S^\delta \lor \hat{S}}(\hat{\mu} - \mu^\delta), \varepsilon \rangle = \langle \hat{\mu} - \mu^\delta, P_{S^\delta \lor \hat{S}}\varepsilon \rangle. \] For any positive constants $c_1, c_2$ such that $c_1 < \frac{1}{4}$ and $c_1 c_2 = \frac{1}{4}$, applying $xy \leq c_1 x^2 + c_2 y^2$ and $(x + y)^2 \leq 2(x^2 + y^2)$ yields
\[ \langle \hat{\mu} - \mu^\delta, \varepsilon \rangle \leq (\|\hat{\mu} - \mu_0\| + \|\mu^\delta - \mu_0\|) \|P_{S^\delta \lor \hat{S}}\varepsilon\| \leq 2c_1 \|\hat{\mu} - \mu_0\|^2 + \|\mu^\delta - \mu_0\|^2 + c_2 \|P_{S^\delta \lor \hat{S}}\varepsilon\|^2. \] Applying this to [18] and rearranging yields
\[ \left( \frac{1}{2} - 2c_1 \right) \|\hat{\mu} - \mu_0\|^2 \leq \left( \frac{1}{2} + 2c_1 \right) \|\mu^\delta - \mu_0\|^2 + c_2 \|P_{S^\delta \lor \hat{S}}\varepsilon\|^2 + 2\lambda \|D\mu^\delta\|_w + (\|D\mu^\delta\|_w + 1) - \lambda \|D\hat{\mu}\|_w. \] By Lemma B.2, there exist constants $C, C' > 0$ and an event of probability $1 - C' w(E)^{-3}$ on which we are guaranteed
\[ \|P_{S^\delta \lor \hat{S}}\varepsilon\|^2 \leq C \max(w(\partial(S^\delta \lor \hat{S})), 1) \log \frac{e \cdot w(E)}{\max(w(\partial(S^\delta \lor \hat{S})), 1)}. \] Note that $\partial(S^\delta \lor \hat{S}) \subseteq \partial S^\delta \cup \partial \hat{S}$, so
\[ w(\partial(S^\delta \lor \hat{S})) \leq w(\partial S^\delta) + w(\partial \hat{S}) = \|D\mu^\delta\|_w + \|D\hat{\mu}\|_w. \] Then on this event,
\[ \|P_{S^\delta \lor \hat{S}}\varepsilon\|^2 \leq C(\max(\|D\mu^\delta\|_w, 1) + \|D\hat{\mu}\|_w) \log(e \cdot w(E)). \] If $\lambda \geq c_2 C \log(e \cdot w(E))$, then applying this to [19] yields (on this event)
\[ \|\hat{\mu} - \mu_0\|^2 \leq \left( \frac{1 + 4c_1}{1 - 4c_1} \right) \|\mu^\delta - \mu_0\|^2 + C'' \left( (\lambda + \tau) \max(\|D\mu^\delta\|_w, 1) \right) \] for some constant $C'' > 0$. Part (a) follows by noting $\|D\mu^\delta\|_w \leq \|D\mu\|_w$, $\|\mu^\delta - \mu_0\|^2 \leq (1 + c_1) \|\mu - \mu_0\|^2 + (1 + c_1^{-1}) \|\mu - \mu^\delta\|^2 \leq (1 + c_1) \|\mu - \mu_0\|^2 + (1 + c_1^{-1}) n \delta^2$, and taking $c_1$ sufficiently small.
For part (b), let us apply the preceding arguments for $\mu = \mu_0$, so that $\mu^\delta$ is obtained by rounding the entries of the true signal $\mu_0$. Then $\|\mu^\delta - \mu_0\|^2 \leq n \delta^2$, $\|D\mu^\delta\|_w \leq \|D\mu_0\|_w \leq s$, and [20] implies...
max(w(∂(S^4 ∨ )), 1) ≤ s + ||Dμ||_w. Observing that s + ||Dμ||_w ≤ 2w(E) and that x → x log(ec/x) is increasing for x ∈ (0, c), on an event of probability 1 − C′w(E)^{-3} we have

\[ \|PS^4_0\| \leq C \max(w(\partial(S^4 ∨ S)), 1) \frac{2e \cdot w(E)}{\max(w(\partial(S^4 ∨ S)), 1)} \leq C(s + ||Dμ||_w) \frac{2e \cdot w(E)}{s} \leq C(s + ||Dμ||_w) \frac{2e \cdot w(E)}{s}. \]

If λ ≥ c_2C log(2e \cdot w(E)/s), then applying this to (19) yields ||μ̂ − μ_0||^2 ≤ C''((λ + τ)s + nδ^2) for a constant C'' > 0, as desired. □

Finally, we obtain bounds in expectation by applying Hölder’s inequality and a crude bound on the qth power of the squared-error risk for some q > 1.

**Lemma B.4.** Let δ > 0, τ ≥ 0, and μ̂ be any (τ, δZ)-local-minimizer of [W]. Then for any q > 1, there exists a constant C_q depending only on q such that

\[ \mathbb{E}[\|μ - μ_0\|^{2q}] \leq C_q(\lambda w(E) + n + n\delta^2 + n\tau)^q. \]

**Proof.** Let μ^δ ∈ (δZ)^n denote the vector obtained by rounding each entry of μ_0 to the nearest value in δZ. For each vertex i ∈ {1, ..., n}, the vector μ̂ obtained by replacing μ̂_i with μ^δ_i and keeping all other coordinates of μ̂ the same is a δZ-expansion of μ̂. Since μ̂ is a (τ, δZ)-local-minimizer, this implies F_w(μ̂) ≤ F_w(μ̂_i) + τ and hence (cancelling terms not depending on the ith coordinate)

\[ \frac{1}{2}(μ̂_i - Y_i)^2 \leq \frac{1}{2}(μ^δ_i - Y_i)^2 + λ \sum_{j: \{i,j\} \in E} w(i, j) + τ. \]

Summing over i = 1, ..., n and applying \|μ^δ - Y\|^2 ≤ 2\|μ_0 - Y\|^2 + 2\|μ^δ - μ_0\|^2 ≤ 2\|μ_0 - Y\|^2 + 2nδ,

\[ \frac{1}{2}\|μ - Y\|^2 \leq \frac{1}{2}\|μ^δ - Y\|^2 + 2\lambda w(E) + n\tau \leq \|μ_0 - Y\|^2 + 2\lambda w(E) + n\delta^2 + n\tau. \]

Then, applying (a + b)^q ≤ 2^{q-1}(a^q + b^q),

\[ \|μ - μ_0\|^{2q} \leq 2^{2q-1}(\|μ - Y\|^{2q} + \|μ_0 - Y\|^{2q}) \leq 2^{2q-1}(2^{q-1}(\|μ_0 - Y\|^2)^q + (4\lambda w(E) + 2n\delta^2 + 2n\tau)^q) + \|μ_0 - Y\|^{2q}) \leq C_q(\|μ_0 - Y\|^{2q} + (λw(E) + n\delta^2 + n\tau)^q) \]

for a constant C_q > 0. Since \|μ_0 - Y\|^2 ≈ \lambda^2_n, this implies

\[ \mathbb{E}[\|μ - μ_0\|^{2q}] \leq C'_q(λw(E) + n + n\delta^2 + n\tau)^q \]

for a different constant C'_q > 0. □

**Proof of Theorem 3.4.** For μ ∈ R^n and λ, η, C'' > 0, denote

\[ M(μ, λ, η, C'') := (1 + η)\|μ - μ_0\|^2 + C''λ \max(||Dμ||_w, 1). \]

Note that n\delta^2 + τ max(||Dμ||_w, 1) ≤ 2λ max(||Dμ||_w, 1) whenever δ ≤ 1/√n, τ ≤ 1, and λ ≥ 1. Applying Hölder’s inequality and Lemma [B.3(a)], there exist constants C, C', C'' > 0 such that for any μ ∈ R^n, any λ ≥ C log w(E), and any constants p, q > 1 such that \frac{1}{p} + \frac{1}{q} = 1,

\[ \mathbb{E}[\|μ̂ - μ_0\|^2] \leq M(μ, λ, η, C'') + \mathbb{E}[\|μ̂ - μ_0\|^2 1\{\|μ̂ - μ_0\|^2 > M(μ, λ, η, C'')\}] \leq M(μ, λ, η, C'') + (\mathbb{E}[\|μ̂ - μ_0\|^{2q}])^{1/q} (\mathbb{P}[\|μ̂ - μ_0\|^2 > M(μ, λ, η, C'')])^{1/p} \leq M(μ, λ, η, C'') + (\mathbb{E}[\|μ̂ - μ_0\|^{2q}])^{1/q} (C'w(E)^{-3})^{1/p}. \]
Note that \( w(E) \geq \tau(E) = n - 1 \), so \( \lambda w(E) \geq n + n \delta^2 + n \tau \) for any \( \lambda \geq 3 \). Then, choosing \( p = 3 \), \( q = 3/2 \), and applying Lemma B.4
\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq M(\mu, \lambda, \eta, C''') + C'''\lambda
\]
for a constant \( C''' > 0 \). Taking the infimum over \( \mu \in \mathbb{R}^n \) yields the desired result. \( \square \)

**Proof of Theorem 5.3** The proof of the upper bound is the same as that of Theorem 5.4 (using Lemma B.3b) instead of Lemma B.3a): For universal constants \( C, C', C'', C''' > 0 \), any \( \delta \leq 1/\sqrt{n} \), \( \tau \leq 1 \), \( \lambda \geq C(1 + \log(nw(E)/\delta)) \), and \( p = 3 \) and \( q = 3/2 \),
\[
\mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \leq C''''\lambda s + \left(\mathbb{E}[\|\hat{\mu} - \mu_0\|^2]\right)^{1/q} (C'w(E)^{-3})^{1/p} \leq C''''\lambda s.
\]

For the lower bound, denote \( w(i) = \sum_{j: (i,j) \in E} w(i,j) \), and consider the vertex subset \( V' = \{i : w(i) \leq 4w(E)/n\} \). Then the class \( \{\mu_0 \in \mathbb{R}^n : \|D\mu_0\|_w \leq s\} \) contains the class of sparse vectors
\[
B_0 := \left\{ \mu_0 \in \mathbb{R}^n : \text{supp}(\mu_0) \subseteq V', \|\mu_0\|_0 \leq \left\lfloor \frac{sn}{4w(E)} \right\rfloor \right\},
\]
where \( \text{supp}(\mu_0) \) denotes the set of vertices \( i \) for which \( \mu_{0,i} \neq 0 \). (This is because for any \( \mu_0 \in B_0 \), \( \|D\mu_0\|_w \leq \sum_{i \in \text{supp}(\mu_0)} w(i) \leq \left\lfloor \frac{sn}{4w(E)} \right\rfloor \frac{4w(E)}{n} \leq s \). Then
\[
\inf_{\mu_0} \sup_{\mu_0 \in B_0} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \geq \inf_{\mu_0} \sup_{\mu_0 \in B_0} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2].
\]
For \( s \geq 4w(E)/n \), the lower-bound for the sparse normal-means problem (see e.g. Theorem 1(b) of [RWY11] in the case \( X = \sqrt{n} \text{Id} \)) yields, for a universal constant \( c > 0 \),
\[
\inf_{\mu_0} \sup_{\mu_0 \in B_0} \mathbb{E}[\|\hat{\mu} - \mu_0\|^2] \geq c \left( \frac{sn}{4w(E)} \right) \log \frac{|V'|}{\left( \frac{sn}{4w(E)} \right)} \geq c \frac{sn}{8w(E)} \log \frac{4w(E)}{sn}.
\]
Note that \( w(E) > 4w(E)/n \) for all \( i \in V' \), so
\[
2w(E) = \sum_{i=1}^n w(i) > \frac{4w(E)}{n} (n - |V'|) \cdot \frac{4w(E)}{n} (n - |V'|).
\]
Then \( |V'| > n/2 \), and the lower bound follows. \( \square \)

**Proof of Theorem 5.8** Let \( \mu^\delta \in (\delta \mathbb{Z})^n \) denote the (constant) vector obtained by rounding the value in \( \mu_0 \) to the closest value in \( \delta \mathbb{Z} \). As \( \mu^\delta \) is a \( \delta \mathbb{Z} \)-expansion of \( \hat{\mu} \), and \( \hat{\mu} \) is a \( (\tau, \delta \mathbb{Z}) \)-local-minimizer, we have
\[
F_w(\hat{\mu}) = \frac{1}{2} \|Y - \hat{\mu}\|^2 + \lambda \|D\hat{\mu}\|_w \leq \frac{1}{2} \|Y - \mu^\delta\|^2 + \tau = F_w(\mu^{\delta}) + \tau.
\]
Denoting by \( S \) the multi-cut induced by \( \hat{\mu} \), the same steps as leading to \([19]\) yield, for any positive constants \( c_1 < 1/4 \) and \( c_2 > 1 \) such that \( c_1 c_2 = 1/4 \),
\[
\left( \frac{1}{2} - 2c_1 \right) \|\hat{\mu} - \mu_0\|^2 \leq \left( \frac{1}{2} + 2c_1 \right) n\delta^2 + c_2 \|P^S \varepsilon\|^2 + \tau - \lambda \|D\hat{\mu}\|_w.
\]
Hence, for \( \delta \leq 1/\sqrt{n} \) and \( \tau \leq 1 \),
\[
\lambda \|D\hat{\mu}\|_w \leq C''''(1 + \|P^S \varepsilon\|^2)
\]
for a constant \( C'''' > 0 \). Lemma B.2 implies, with probability at least \( 1 - C'w(E)^{-3} \geq 1 - C'(n-1)^{-3} \),
\[
\|P^S \varepsilon\|^2 \leq C \max(\log(e \cdot w(E)), 1) \log(e \cdot w(E)) = C \max(\|D\hat{\mu}\|_w, 1) \log(e \cdot w(E)).
\]
Recall by \([13]\) that \( \|D\hat{\mu}\|_w \geq 1 \) if \( \|D\hat{\mu}\|_w \neq 0 \). Thus, if \( \lambda > C''''(1 + C \log(e \cdot w(E))) \), then the above two statements imply \( \|D\hat{\mu}\|_w = 0 \), and hence \( \hat{\mu} \) is constant with probability at least \( 1 - C'(n-1)^{-3} \), as desired. \( \square \)
APPENDIX C. TOTAL-VARIATION LOWER BOUND FOR THE LINEAR CHAIN

In this appendix, we prove Theorems 4.1 and 4.2. By rescaling, we will assume \( \sigma^2 = 1 \). We say that \( k \) consecutive intervals \( S := (S_1, \ldots, S_k) \) partition \( (1, \ldots, n) \) if there are integers \( 1 = i_1 < i_2 < \ldots < i_k < i_{k+1} = n + 1 \) such that \( S_\alpha = (i_\alpha, i_\alpha + 1, \ldots, i_{\alpha+1} - 1) \) for each \( \alpha \). We associate to each such partition \( S \) two orthogonal projections \( P^S : \mathbb{R}^n \to \mathbb{R}^n \) and \( Q^S : \mathbb{R}^n \to \mathbb{R}^n \), such that \( P^S \) projects onto the \( k \)-dimensional subspace of vectors assuming a constant value on each \( S_\alpha \), and \( Q^S \) projects onto the \((n-k)\)-dimensional orthogonal complement of this subspace. More formally, for each \( \alpha \) and each \( i \in S_\alpha \), \( P^S \) is defined by \( (P^S \mu)_i = |S_\alpha|^{-1} \sum_{j \in S_\alpha} \mu_j \), and \( Q^S = I - P^S \). We denote by \( P^S(\mathbb{R}^n) \) the range of \( P^S \), and for any \( v \in P^S(\mathbb{R}^n) \) we denote by \( v_{S_\alpha} \) the (constant) value of \( v \) over \( S_\alpha \).

We will say that \( \mu \in \mathbb{R}^n \) induces such a partition \( S = (S_1, \ldots, S_k) \) and a sign vector \( s = (s_1, \ldots, s_{k-1}) \in \{-1,1\}^{k-1} \) if \( \mu \in P^S(\mathbb{R}^n) \) and \( \mu(S_{\alpha+1} - S_{\alpha}) = s_\alpha \) for each \( \alpha = 1, \ldots, k-1 \). Recall the vertex-edge incidence matrix \( D \in \mathbb{R}^{n \times (n-1)} \). In this appendix, for the linear chain graph, let us fix the sign convention for \( D \) so that \( D\mu = (\mu_2 - \mu_1, \mu_3 - \mu_2, \ldots, \mu_n - \mu_{n-1}) \).

The following lemma is an implication of the subgradient condition for \( \hat{\mu} \) minimizing \( \|TV\| \); a similar result was stated as Lemmas 2.1 and A.1 of [Rin09].

**Lemma C.1.** Let \( \lambda > 0 \). Fix \( k \) consecutive intervals \( S := (S_1, \ldots, S_k) \) that partition \( (1, \ldots, n) \), and fix a sign vector \( s := (s_1, \ldots, s_{k-1}) \in \{-1,1\}^{k-1} \). Define \( v \in P^S(\mathbb{R}^n) \) such that, for each \( \alpha = 1, \ldots, k \),

\[
v_{S_\alpha} = \frac{\lambda(s_\alpha - s_{\alpha-1})}{|S_\alpha|},
\]

where we set \( s_0 = s_k := 0 \). Define also

\[
W := \{ w \in [-1,1]^{n-1} : w_i = s_\alpha \text{ if } i \in S_\alpha \text{ and } i + 1 \in S_{\alpha+1} \text{ for some } \alpha = 1, \ldots, k-1 \},
\]

\[
K := \{ x \in P^S(\mathbb{R}^n) : \text{sign}(x_{S_{\alpha+1}} - x_{S_\alpha}) = s_\alpha \text{ for all } \alpha = 1, \ldots, k-1 \}.
\]

Then the following two events are equivalent:

1. The minimizer \( \hat{\mu} \) of \( \|TV\| \) induces the partition \( S \) and the signs \( s \).
2. \( P^S Y + v \in K \) and \( Q^S Y - v \in \lambda D^T W \).

Furthermore, if this event holds, then \( \hat{\mu} = P^S Y + v \).

**Proof.** Suppose \( \hat{\mu} \) minimizes \( \|TV\| \) and induces \( S \) and \( s \). Then \( W \) is precisely the subdifferential of the \( l_1 \)-norm at \( D\hat{\mu} \), so \( \lambda D^T W \) is the subdifferential of \( \lambda \|D\hat{\mu}\|_1 \) with respect to \( \hat{\mu} \). Since \( \hat{\mu} \) minimizes \( \|TV\| \), it satisfies the subgradient condition \( Y - \hat{\mu} \in \lambda D^T W \). Apply \( P^S \) to both sides, noting that \( P^S \mu = \hat{\mu} \) and \( P^S x = -v \) for any \( x \in \lambda D^T W \). Then \( \hat{\mu} = P^S Y + v \). Since \( \hat{\mu} \) induces the signs \( s \), we have \( P^S Y + v \in K \). Also, \( Y - \hat{\mu} = Q^S Y - v \in \lambda D^T W \), as desired.

Conversely, suppose \( P^S Y + v \in K \) and \( Q^S Y - v \in \lambda D^T W \). Defining \( \hat{\mu} = P^S Y + v \), the first condition implies that \( \hat{\mu} \) induces \( S \) and \( s \), while the second implies \( Y - \hat{\mu} \in \lambda D^T W \). Since \( \lambda D^T W \) is the subdifferential of \( \lambda \|D\hat{\mu}\|_1 \) with respect to \( \hat{\mu} \), this implies that \( \hat{\mu} \) minimizes \( \|TV\| \). (The objective \( \|TV\| \) is strictly convex, so \( \hat{\mu} \) is the unique minimizer.)

Using this characterization, we may lower-bound the number of intervals in the partition induced by \( \hat{\mu} \) when the true signal \( \mu_0 \) is 0:

**Proof of Theorem 4.1(a).** For a fixed partition \( S := (S_1, \ldots, S_k) \) into \( k \) consecutive intervals, let us first bound

\[
\rho_S := P \left[ Q^S Y \in \lambda Q^S D^T [-1,1]^{n-1} \right].
\]

Denoting by \( B_m \) the Euclidean unit ball in \( \mathbb{R}^m \) centered at 0, clearly

\[
\rho_S \leq P[Q^S Y \in \lambda \sqrt{\mu_0} Q^S D^T B_{n-1}].
\]
The range of $D^T$ is the $(n-1)$-dimensional space orthogonal to the all-1’s vector, and $Q^S$ is a projection onto an $(n-k)$-dimensional subspace of this range—hence $Q^S D^T$ has rank $n-k$. Let $Q^S D^T = UTV^T$ denote the (reduced) singular value decomposition of $Q^S D^T$, where $\Gamma = \text{diag}(\gamma_1, \ldots, \gamma_{n-k})$ contains the singular values $\gamma_1 \leq \ldots \leq \gamma_{n-k}$, and $U \in \mathbb{R}^{n \times (n-k)}$ and $V \in \mathbb{R}^{(n-1) \times (n-k)}$ have orthonormal columns. Then, as $V^T B_{n-1} = B_{n-k}$, we have

$$p_S \leq \mathbb{P}[U^T Q^S Y \in \lambda \sqrt{\pi} B_{n-k}].$$

The set $E := \lambda \sqrt{\pi} B_{n-k}$ is an ellipsoid in $\mathbb{R}^{n-k}$, whose principal axes are aligned with the standard basis and have lengths $\lambda \sqrt{\pi} \gamma_i$. The vector $\varepsilon' := U^T Q^S Y$ of length $n-k$ has i.i.d. entries distributed as $\text{Normal}(0,1)$ (when $\mu_0 = 0$). Then, for any $l \in \{1, \ldots, n-k\}$, letting $\varepsilon'_{1:l}$ denote the first $l$ coordinates of $\varepsilon'$ and $E_{1:l}$ denote the projection of $E$ onto the first $l$ dimensions,

$$p_S \leq \mathbb{P}[\varepsilon'_{1:l} \in E_{1:l}] \leq (2\pi)^{-l/2} \text{Vol}(E_{1:l}) = \frac{(\lambda \sqrt{\pi})^l}{\Gamma(\frac{l}{2} + 1)} \prod_{i=1}^l \gamma_i.$$

Here, Vol($\cdot$) denotes the volume in $\mathbb{R}^l$, and we have used $\text{Vol}(B_l) = \pi^{l/2}/\Gamma(\frac{l}{2} + 1)$. Note, by Cauchy interlacing, that $\gamma_i \leq s_{i+k-1}(D^T)$ where $s_{i+k-1}(D^T)$ denotes the $i+k-1$th smallest non-zero singular value of $D^T$. (Equality holds if the $k-1$ directions in the column span of $D^T$ that are projected out by $Q^S$ are exactly those corresponding to the smallest $k-1$ non-zero singular values of $D^T$.) As $D^T D$ is the Laplacian of the linear chain graph, which has non-zero eigenvalues $4 \sin^2(i\pi/2n) \leq (i\pi/n)^2$ for $i = 1, \ldots, n-1$ [AJM85], this implies $\gamma_i \leq (i+k-1)\pi/n$ and hence, for any $l \in \{1, \ldots, n-k\}$,

$$p_S \leq \frac{(\lambda \sqrt{\pi})^l}{\Gamma(\frac{l}{2} + 1)} \frac{(l+k-1)!}{(k-1)!} = \frac{(\lambda \pi)^l}{\sqrt{2\pi}} \frac{\Gamma(\frac{l}{2} + 1)}{\Gamma(\frac{l}{2} + \frac{1}{2})} \left(\frac{n^2}{\pi}\right)^{l/2} \gamma_i.$$

Applying the Gamma function duplication formula $\sqrt{\pi}! = \Gamma(\frac{1}{2}) \Gamma(\frac{1}{2} + 1)$, and $(\frac{l+k-1}{k-1}) \leq \binom{n-1}{k-1} \leq \binom{n}{k}$, this yields

$$p_S \leq \frac{(\lambda \pi)^l}{\sqrt{2\pi}} \frac{\Gamma(\frac{l}{2} + 1)}{\sqrt{\pi}} \left(\frac{n}{k}\right).$$

(22)

Fix $k \geq 1$. Suppose $\hat{\mu}$ induces the partition $\hat{S}$ having $\hat{k}$ elements, and $\hat{k} \leq k$. Then Lemma C.1 implies $Q^S Y - v \in \lambda D^T W$, where $v$ and $W$ are defined in terms of $\hat{S}$ and $\hat{s}$. Applying $Q^S$ to both sides and noting $Q^S v = 0$,

$$Q^S Y \in \lambda Q^S D^T W \subseteq \lambda Q^S D^T [-1,1]^{n-1}.$$

Thus there exists some partition $S$ into exactly $k$ consecutive intervals (equal to or refining $\hat{S}$) for which applying $Q^S$ to both sides above yields $Q^S Y \in \lambda Q^S D^T [-1,1]^{n-1}$. As there are $\binom{n-1}{k-1} \leq \binom{n}{k}$ such partitions, applying a union bound, (22), and $\Gamma(x+1) \leq \sqrt{2\pi} ((x + 0.5)/e)^{x+0.5}$ for any $x > 0$ (see Theorem 1.5 of [Bat08]),

$$\mathbb{P}[k \leq k] \leq \binom{n}{k}^2 \left(\frac{\lambda \pi \sqrt{2/n}}{\sqrt{\pi}}\right)^l \frac{\Gamma(\frac{l+1}{2})}{\sqrt{\pi}} \leq \sqrt{2} \exp \left(2k \log \frac{cn}{k} + l \log \lambda \pi \sqrt{2/n} + \frac{l}{2} \log \frac{l}{2} - \frac{l}{2}\right).$$

Taking $l = \lfloor \max(\lambda^2, 1) \pi x \rfloor$ ensures $l \log \lambda \pi \sqrt{2/n} + \frac{l}{2} \log \frac{l}{2} \leq 0$, and taking $k = \lfloor \max(\sqrt{n/c}, \log \pi) \rfloor$ for a sufficiently small constant $c > 0$ then ensures $\mathbb{P}[k \leq k] \leq Ce^{-c/n/\max(\lambda^2, 1)}$, for constants $C, c' > 0$, as desired. \hfill $\square$
To show part (b) of Theorem 4.1, we will argue that on the event where \( \hat{\mu} \) induces a partition into at least \( k \) intervals, the squared-error of \( \hat{\mu} \) is typically also at least \( k \) (up to logarithmic factors). We establish this using the next two lemmas.

Suppose that \( \hat{\mu} \) induces the partition \( S = (S_1, \ldots, S_k) \) and the signs \( s = (s_1, \ldots, s_{k-1}) \in \{-1,1\}^{k-1} \). For any \( \alpha \in \{1, \ldots, k\} \), let us call \( S_\alpha \) a local maximum interval if \( s_{\alpha-1} \geq 0 \) and \( s_\alpha \leq 0 \), and a local minimum interval if \( s_{\alpha-1} \leq 0 \) and \( s_\alpha \geq 0 \), where by convention \( s_0 = s_k := 0 \).

**Lemma C.2.** Let \( \lambda > 0 \), let \( \hat{\mu} \) be the minimizer of \( \|TV\| \), and suppose \( \mu_0 \) is such that \( \|\mu_0\|_\infty \leq M \). There exists a constant \( c > 0 \) such that with probability at least \( 1 - 2/n \), every local minimum interval and local maximum interval of the partition and signs induced by \( \hat{\mu} \) has length at least \( c \min\left( \frac{\lambda^2}{\log n}, \frac{1}{M}\right) \).

**Proof.** For any \( v \in \mathbb{R}^n \) and any interval \( S \subseteq \{1, \ldots, n\} \), denote \( \bar{v}_S = |S^{-1}|\sum_{i \in S} v_i \). Define the event

\[
E := \left\{ \text{there exists an interval } S \subseteq \{1, \ldots, n\} : |\bar{v}_S| > \sqrt{(6 \log n)/|S|} \right\}.
\]

By a Gaussian tail bound and union bound, \( \mathbb{P}[E] \leq 2n^2e^{-3 \log n} = 2/n. \)

Let \( S = (S_1, \ldots, S_k) \) be the partition into consecutive intervals induced by \( \hat{\mu} \). Define \( A := \{\alpha : S_\alpha \text{ is a local maximum interval or local minimum interval}\} \).

Consider \( \alpha \in A \) corresponding to the smallest length \( |S_\alpha| \). Let \( \beta \in A \) be the element immediately before or after \( \alpha \) in \( A \), and note that if \( S_\alpha \) is a local maximum, then \( S_\beta \) is a local minimum, and vice versa. Then, letting \( v \in P^S(\mathbb{R}^n) \) be as defined in (21), \( |\bar{Y}_{S_\alpha} - \bar{Y}_{S_\beta}| \) exceeds \( |\hat{\mu}_{S_\alpha} - \hat{\mu}_{S_\beta}| \) by \( |v_{S_\alpha}| + |v_{S_\beta}| \), so we must have

\[
|\bar{Y}_{S_\alpha} - \bar{Y}_{S_\beta}| \geq |v_{S_\alpha}| + |v_{S_\beta}| \geq \frac{\lambda}{|S_\alpha|} + \frac{\lambda}{|S_\beta|} \geq \frac{\lambda}{|S_\alpha|}.
\]

On the event \( E \),

\[
|\bar{Y}_{S_\alpha} - \bar{Y}_{S_\beta}| \leq |\bar{v}_{S_\alpha} - \bar{v}_{S_\beta}| + 2M \leq \sqrt{6 \log n/|S_\alpha|} + \sqrt{6 \log n/|S_\beta|} + 2M \leq 2\sqrt{6 \log n/|S_\alpha|} + 2M,
\]

where the last bound recalls that \( S_\alpha \) has smallest length among \( \alpha \in A \). Then on \( E \),

\[
0 \leq 2M|S_\alpha| + 2\sqrt{6 \log n/|S_\alpha|} - \lambda,
\]

which implies

\[
\sqrt{|S_\alpha|} \geq \frac{\sqrt{24 \log n + 8M^2} - 2\sqrt{6 \log n}}{4M} = \frac{2\lambda}{\sqrt{24 \log n + 8M^2} + 2\sqrt{6 \log n}} \geq c \min\left( \frac{\lambda}{\sqrt{\log n}}, \frac{\lambda}{M}\right).
\]

\[ \Box \]

**Lemma C.3.** Fix any \( \mu \in \mathbb{R}^k \). Let \( \xi \in \mathbb{R}^k \) be a random vector distributed as \( \xi \sim \text{Normal}(\mu, \text{Id}) \), and let \( K \subseteq \mathbb{R}^k \) be any convex cone with vertex 0 and non-empty interior. Then there exists a universal constant \( c > 0 \) such that

\[
\mathbb{E}[\|\xi\|^2 \mid \xi \in K] \geq \frac{c k^2}{\max(\|\mu\|^2, k)}.
\]

**Proof.** Consider a change of variables to \( S = \|\xi\| \) and \( \Theta \) a set of \( k-1 \) angular variables representing the angle of \( \xi \). Since \( K \) is a cone with vertex 0, the condition \( \xi \in K \) is a function only of \( \Theta \). Hence the joint density of \( S \) and \( \Theta \) conditional on \( \xi \in K \) is given by

\[
p(s, \theta) = c(k, \theta, K)s^{k-1}e^{-\frac{\|\xi(\theta) - \mu\|^2}{2}},
\]
for some quantity \(c(k, \theta, K)\) independent of \(s\). Note that for any \(s \geq t \geq 0\) and any \(\theta\),
\[
\|\xi(t, \theta) - \mu\|^2 - \|\xi(s, \theta) - \mu\|^2 = t^2 - s^2 + 2\langle \xi(s, \theta) - \xi(t, \theta), \mu \rangle \\
\geq t^2 - s^2 - 2(s - t)\|\mu\| = (t + \|\mu\|)^2 - (s + \|\mu\|)^2.
\]

Letting \(R\) denote a positive random variable with density function
\[
q(r) = I(\mu)r^{k-1}e^{-\frac{(r+\|\mu\|)^2}{2}},
\]
where \(I(\mu)\) is the normalization constant such that \(\int_0^\infty q(r)dr = 1\), this implies \(p(s, \theta) \geq \frac{q(s)}{q(t)}p(t, \theta)\).

Integrating over \(\theta\) and denoting by \(p(s)\) the marginal distribution of \(S\) conditional on \(\xi \in K\), this implies \(p(s) \geq \frac{q(s)}{q(t)}p(t)\). The inequality is reversed for \(0 \leq s \leq t\), so
\[
\mathbb{P}[\|\xi\| \geq t \mid \xi \in K] = \frac{\int_0^t p(s)ds + \int_t^\infty p(s)ds}{\int_0^t p(s)ds} \geq \frac{\int_t^\infty q(s)ds}{\int_0^t p(s)ds + \int_t^\infty q(s)ds} \geq \frac{\int_0^t p(s)ds}{\int_0^t q(s)ds + \int_0^\infty q(s)ds} = \mathbb{P}[R \geq t].
\]

That is, the distribution of \(\|\xi\|\) conditional on \(\xi \in K\) stochastically dominates the (unconditional) distribution of \(R\).

Thus, to conclude the proof of the lemma, it suffices to lower bound
\[
\mathbb{E}[R^2] = \int_0^\infty r^{k+1}e^{-\frac{(r+\|\mu\|)^2}{2}}dr \geq \int_0^\infty r^{k-1}e^{-\frac{(r+\|\mu\|)^2}{2}}dr =: M_{k+1}/M_{k-1},
\]
where \(M_i\) is the \(i\)th moment of the Normal(\(-\|\mu\|, 1\)) distribution truncated on the left at 0. Integration by parts yields the recurrence \(M_{k+1} = -\|\mu\|M_k + kM_{k-1}\), and Cauchy-Schwarz yields \(M_{k+1}M_{k-1} \geq M_k^2\). Then
\[
\frac{M_{k+1}}{M_{k-1}} + \|\mu\|\sqrt{\frac{M_{k+1}}{M_{k-1}}} - k \geq \frac{M_{k+1}}{M_{k-1}} + \|\mu\|\sqrt{\frac{M_k}{M_{k-1}}} - k \geq 0,
\]
so
\[
\sqrt{\frac{M_{k+1}}{M_{k-1}}} \geq \frac{\sqrt{\|\mu\|^2 + 4k} - \|\mu\|}{2} = \frac{2k}{\|\mu\| + \sqrt{\|\mu\|^2 + 4k}},
\]
and the result follows by taking the square. \(\square\)

**Proof of Theorem 4.1(b).** For any positive constant \(n_0\), it suffices to consider graphs with \(n \geq n_0\). (For \(n < n_0\), the lower bound trivially holds by adjusting \(c'\) based on \(n_0\), as the risk is clearly non-zero for any graph.)

Let \(\hat{\nu}\) induce the partition \(\hat{S}\) and signs \(\hat{s}\). For any fixed partition \(S = (S_1, \ldots, S_k)\) and signs \(s\), by Lemma C.1
\[
\mathbb{E}[\|\hat{\nu}\|^2 \mid \hat{S} = S, \hat{s} = s] = \mathbb{E}[\|P^S Y + v\|^2 \mid P^S Y + v \in K, Q^S Y - v \in \lambda D^TW],
\]
where \(v, K, \) and \(W\) are fixed and defined by \(S\) and \(s\). Since the projections \(P^S\) and \(Q^S\) are orthogonal to each other, \(P^S Y\) is independent of \(Q^S Y\), so we may drop the conditioning on the event \(Q^S Y - v \in \lambda D^TW\). Define \(\xi \in \mathbb{R}^k\) by \(\xi_\alpha = \|S_\alpha\|^{1/2}(Y_{S_\alpha} + v_{S_\alpha})\) for each \(\alpha = 1, \ldots, k\), where \(Y_{S_\alpha} = |S_\alpha|^{-1} \sum_{i \in S_\alpha} Y_i\). Then \(\|P^S Y + v\|^2 = \|\xi\|^2\), \(\xi \sim \text{Normal}(w, \text{Id})\) for \(w = (|S_1|^{1/2}v_{S_1}, \ldots, |S_k|^{1/2}v_{S_k})\),
and the condition $P^S Y + v \in K$ is equivalent to $\xi \in \tilde{K}$ for some convex cone $\tilde{K} \in \mathbb{R}^k$ with vertex 0 and non-empty interior. Applying Lemma C.3 for a constant $c' > 0$,

$$E[\|\hat{\mu}\|^2 \mid \hat{S} = S, \hat{s} = s] = E[\|\xi\|^2 \mid \xi \in \tilde{K}] \geq \frac{c' k^2}{\max(\|w\|^2, k)}.$$ (23)

Let $\hat{k}, \hat{v},$ and $\hat{w}$ denote $k, v,$ and $w$ as defined above for the random induced partition and signs $\hat{S}$ and $\hat{s}$. By part (a) of this theorem (already established), for some constant $n_0$ and any $n \geq n_0$, on an event of probability at least $3/4$, $\hat{k} \geq \max(\lambda^2, 1) \log n$. Note that $\hat{v}$ is only non-zero on those intervals $S_\alpha$ which are local maxima or local minima, and that the (constant) value of $\hat{v}$ on any such interval has magnitude at most $2\lambda/|\hat{S}_\alpha|$. Applying Lemma C.2 with $M = 0$, on a different event of probability at least $3/4$, every local minimum and local maximum interval of $\hat{S}$ has length $|\hat{S}_\alpha| \geq c' \max(\lambda^2, 1)/(\log n)$. (For $\lambda < 1$ this statement is trivial.) Then, on this event, there are at most $\frac{n \log n}{c' \max(\lambda^2, 1)}$ such intervals, and hence

$$\|\hat{w}\|^2 = \sum_{\alpha=1}^{\hat{k}} |\hat{S}_\alpha| \hat{v}^2_{\hat{S}_\alpha} \leq \sum_{\alpha: S_\alpha \text{ local max or min}} 4\lambda^2 / |\hat{S}_\alpha| \leq \frac{4 \log n}{\lambda^2, 1} c' = \frac{4n(\log n)}{\lambda^2, 1}.$$ (24)

Taking the full expectation of (23) over the intersection of these two events of probability at least $1/2$, the theorem follows. \qed

Finally, we prove Theorem 4.2 using Theorem 4.1(b) and Lemma C.2.

**Proof of Theorem 4.2.** Let $c_0$ denote the constant in Lemma C.2 if

$$\lambda^2 \leq \frac{3 \log n}{c_0} \sqrt{\frac{n \Delta}{s}},$$

then the lower bound follows from Theorem 4.1(b) by considering the risk at $\mu_0 = 0$. Otherwise, construct a signal $\mu_0$ by the following procedure:

1. Choose disjoint intervals $I_1, \ldots, I_k$ in $(1, \ldots, n)$, each of length $3\Delta$.
2. Set $M = c_0 \lambda/(3\Delta)$. For each $\alpha = 1, \ldots, k$, divide $I_\alpha$ into three sub-intervals of length $\Delta$, and set $\mu_{0,i} = M$ for each $i$ belonging to the middle such sub-interval.
3. Set $\mu_{0,i} = 0$ for all remaining indices.

This signal satisfies $\|D\mu_0\|_0 \leq 2k \leq s$ and $\Delta(\mu_0) \geq \Delta$. We have

$$\frac{\lambda^2}{\log n} > \frac{3}{c_0} \sqrt{\frac{n \Delta}{s}} = \frac{3 \Delta}{c_0} = \frac{\lambda}{M},$$

so Lemma C.2 implies that on an event $\mathcal{E}$ of probability at least $1 - 2/n$, every local maximum or local minimum interval for the partition and signs induced by $\hat{\mu}$ has length at least $3\Delta$. On this event $\mathcal{E}$, there cannot be a sub-interval of any $I_\alpha$ that is a local maximum or local minimum, so the estimate $\hat{\mu}$ must be monotonically increasing or monotonically decreasing over each interval $I_\alpha$. Then it is easily verified that

$$\|\hat{\mu} - \mu_0\|^2 \geq \sum_{\alpha=1}^{k} \sum_{i \in I_\alpha} \|\hat{\mu}_i - \mu_{0,i}\|^2 \geq c k \Delta M^2 \geq c'(\log n) \sqrt{\frac{sn}{\Delta}},$$

for constants $c, c' > 0$, where the last inequality uses $\lambda^2 \geq (\log n) \sqrt{n \Delta / s}$ and $k \geq s$. The result follows upon taking the expectation over $\mathcal{E}$. \qed
ACKNOWLEDGMENTS

We would like to thank Professors Amin Saberi, James Sharpnack, and Emmanuel Candes for helpful and inspiring discussions on this problem and related literature.
