Hybridization-controlled charge transfer and induced magnetism at correlated oxide interfaces

M. N. Grisolia1, J. Varignon1†, G. Sanchez-Santolino2,3†, A. Arora4, S. Valencia4, M. Varela2,3,5, R. Abrudan4,6, E. Weschke4, E. Schierle4, J. E. Rault7, J.-P. Ruoff7,8, A. Barthélémy1, J. Santamaria3,9 and M. Bibes11

At interfaces between conventional materials, band bending and alignment are classically controlled by differences in electrochemical potential. Applying this concept to oxides in which interfaces can be polar and cations may adopt a mixed valence has led to the discovery of novel two-dimensional states between simple band insulators such as LaAlO3 and SrTiO3. However, many oxides have a more complex electronic structure, with charge, orbital and/or spin orders arising from strong Coulomb interactions at and between transition metal and oxygen ions. Such electronic correlations offer a rich playground to engineer functional interfaces but their compatibility with the classical band alignment picture remains an open question. Here we show that beyond differences in electron affinities and polar effects, a key parameter determining charge transfer at correlated oxide interfaces is the energy required to alter the covalence of the metal–oxygen bond. Using the perovskite nickelate (RNiO3) family as a template, we probe charge reconstruction at interfaces with gadolinium titanate GdTiO3. X-ray absorption spectroscopy shows that the charge transfer is thwarted by hybridization effects tuned by the rare-earth (R) size. Charge transfer results in an induced ferromagnetic-like state in the nickelate, exemplifying the potential of correlated interfaces to design novel phases. Further, our work clarifies strategies to engineer two-dimensional systems through the control of both doping and covalence.

between the $p$ and $d$ bands. To investigate interfacial doping into perovskite nickelate thin films, we combine first-principles calculations with hard X-ray photoemission (HXPS) and X-ray absorption spectroscopy (XAS). In particular, we examine details of Ni L$_{2,3}$, Ti L$_{2,3}$ and O K absorption edges which are known to provide direct information on charge and hybridization states. Further, we use X-ray magnetic circular dichroism (XMCD) and X-ray resonant magnetic scattering (XRMS) to probe magnetism in both GTO and the nickelates.

We have grown nickelate (LaNiO$_3$—LNO, NdNiO$_3$—NNO, SmNiO$_3$—SNO) films on top of GTO films using pulsed laser deposition on LaAlO$_3$ (LAO) substrates (see Methods and refs 20,21). Figure 1a shows reflection high-energy electron diffraction (RHEED) patterns before growth (LAO substrate, left) after growth of the GTO film (centre) and after deposition of the LNO film (right), indicative of two-dimensional growth. Clear RHEED oscillations were observed while growing the GTO film, which we used to fix the GTO thickness to 7 u.c. in all samples. For the nickelates, no oscillations were observed, but a high RHEED intensity was recovered during deposition. Through growth rate calibrations by X-ray reflectometry, the nominal thickness of the nickelate layers was set to 7 u.c. as well. Azimuthal RHEED analysis along with X-ray diffraction experiments attested to the epitaxial character of all three bilayers (LNO/GTO, NNO/GTO and SNO/GTO).

Figure 1b shows a high-resolution Z-contrast scanning transmission electron microscopy (STEM) image of a LNO/GTO sample, confirming epitaxy and sample quality. Low-magnification images and compositional electron energy-loss spectroscopy (EELS) maps obtained from the analysis of the Ti L$_{2,3}$, La M$_{4,5}$, Ni L$_{2,3}$ and Gd M$_{4,5}$ signals reveal layers that are flat and continuous over long lateral distances. Occasional defects are observed in high-magnification images (Fig. 1c), but the samples are epitaxial and sample quality is high. Elemental maps with atomic resolution reveal sharp interfaces between the LAO substrate and the GTO film, and between the GTO film and the nickelate layer. As expected, the LNO and GTO thicknesses were equivalent, within about one unit cell.

We first studied possible electronic reconstructions between a rare-earth titanate and a rare-earth nickelate using first-principles calculations. We used standard density functional theory (DFT) methods plus a Hubbard $U$ correction chosen to reproduce correctly the bulk properties of both titanates and nickelates (see Supplementary Information and Methods). We performed geometry relaxations on a (GdTiO$_3$)$_7$/GdNiO$_3$)$_7$ superlattice strained on a LAO substrate. The computed average valence states per BO$_3$ plane of Ti and Ni atoms along the growth direction are summarized in Fig. 2a. Away from the interface between GTO and the nickelate, the Ti valence is close to 3+ (as in the bulk), but closer to the interface, the Ti valence increases from 3+ to 4+. An opposite behaviour is observed on the nickelate side: the nickel valence decreases from 3+ towards 2+ on approaching the interface. This clearly indicates charge transfer, which spreads over 2–3 u.c., with a main contribution coming from the interfacial plane.

To look for changes in the valence of Ti ions at the interface, we have measured HXPS of Ti 2p$_{3/2}$ core levels on a LNO/GTO sample...
at two different photon incidence angles to probe either mainly the very first planes in the GTO layer (0.2°, grazing incidence) or the whole GTO layer (10°), see the cyan and blue circles in Fig. 2d. Both spectra clearly consist of multiple components. Those peaked at low binding energies are strongly enhanced in grazing incidence, which we interpret as reflecting the presence of a built-in electric field shifting the core levels of interfacial Ti ions to higher energies (see also Supplementary Information). To fit the experimental spectra we assume that the signal from each Ti plane has a Gaussian line shape, progressively shifted in binding energies, assuming a potential drop of 1.6 eV over ~3 u.c. in the GTO close to the interface (consistent with the 1.69 eV drop predicted from calculations). Figure 2b shows the dependence of the energy shift as a function of the position in the GTO film. In a rigid-band model, this upward band bending results from a progressive depletion of the 3d band as one gets closer to the interface—that is, it corresponds to an increase of the Ti valence from 3+ towards 4+ near the interface.

We have confirmed the change of the Ti valence near the GTO/LNO interface using EELS at the O K-edge. Indeed, the intensity of the pre-peak in the O K-edge spectrum is proportional to the number of holes in the hybridized p–d band. In titanates, in which the conduction band is more d-like, it is directly related to the number of holes in the d band, set by the oxidation state—that is, the peak is enhanced for Ti^{4+} compared to Ti^{3+}. Figure 2e shows O K-edge spectra collected at different distances from the interface in the GTO layer. The peak area seems to increase as one approaches the interface (from darker to lighter blue). The data are plotted as solid squares in Fig. 2c, along with the normalized height of the O K-edge pre-peak (blue open circles). Both sets of data indicate an increase of the pre-peak intensity near the interface with the nickelate, consistent with a Ti valence increasing towards 4+. Interestingly, a 'bulk-like' response is also recovered beyond 2 to 3 unit planes near the interface with the nickelate. These experimental results are thus in qualitative agreement with the theoretical results of Fig. 2a.

To detect possible changes in the Ni valence near the interface, we conducted valence band HXPS of a LNO/GTO bilayer at 0.2° and 10° incidence angles. Here, the relative contribution of interfacial Ni planes to the overall signal is slightly higher at 10°
than at 0.2\textsuperscript{\textdegree}. In the spectra shown in Fig. 2g, two peaks (labelled ‘a’ and ‘b’) are visible at \(\approx 1.4\) eV and \(\approx 0.2\) eV. In single LNO films, they are ascribed to \(t_{2g}\) and \(e_{g}\) peaks, respectively\textsuperscript{21}. Their intensity is weaker than in thicker LNO films, consistent with earlier results on ultrathin films\textsuperscript{23}. Whereas peak ‘a’ is larger at 10\textsuperscript{\textdegree}, peak ‘b’ is more intense in grazing incidence (see also the intensity difference plotted in Fig. 2h). This is surprising because, in grazing incidence, both peaks are usually depressed in LNO single films. The black rectangle highlights the Ni L\textsubscript{2,3} edge for a GTO film (purple), LNO/GTO (red), NNO/GTO (orange), SNO/GTO (green) and a STO crystal (blue). The black rectangle highlights the second peak of the Ti L\textsubscript{2,3} edge used for the analysis.

Detailed view of the experimental XAS (symbols) at the second peak of the Ti L\textsubscript{2,3} edge. In parallel, we looked for variations in the Ti valence by analysing the overlap of the La M\textsubscript{4,5} signal (see Supplementary Information). In Ni oxides, the spectral shape of the Ni L\textsubscript{2,3} edge strongly varies with the Ni oxidation state\textsuperscript{24} and we thus use it to gain insight into the Ni valence in our samples. As visible in Fig. 3b, the shape of the spectra in our bilayers clearly deviates from that of a reference NiO film (top panel), which readily indicates a different formal Ni oxidation state. The changes in the spectral shape, and in particular the sharpening of the low-energy feature (labelled ‘a’) is reminiscent of the signature of Ni\textsuperscript{2+} in the NiO reference\textsuperscript{24} (bottom panel, Fig. 3b). We analyse the valence change in the different bilayers by comparing the relative intensity of the two features (‘a’ and ‘b’). Figure 3c summarizes these results and suggests that the Ni valence is reduced towards 2\textsuperscript{+} for the three samples, with a stronger change for the NNO/GTO and SNO/GTO samples. This behaviour is further confirmed by our DFT calculations on a set of different RTO/RNO superlattices (Fig. 3d and Supplementary Information), revealing a strong effect of the sole rare earth in the nickelate on the amount of transferred electrons.

In parallel, we looked for variations in the Ti valence by analysing the XAS at the Ti L\textsubscript{2,3} edge, see Fig. 3e. Literature on XAS in rare-earth titanates is scarce\textsuperscript{25}, especially for strongly distorted compounds such as GTO, and direct comparison with bulk spectra is not possible. Trends in the XAS spectra can, however, be inferred from the electronic structure of perovskite titanates\textsuperscript{26}. There are...
Figure 4 | Covalence versus ionicity. a, b, Experimental XAS signal (thick line) at the Ni L₃ edge for a LNO film and a LNO/GTO bilayer (a) and a SNO film and a SNO/GTO (b). All spectra were fitted with two peaks (thin lines) and shifted in energy to align the first component at 853.5 eV. The arrows indicate the position of the second peak. c, Energy difference between the two components in a, b and for a NNO film and a NNO/GTO bilayer analysed similarly (not shown). GNO is GdNiO₂ and YNO is YNiO₂. d, Covalence extracted from first-principles calculations of density of states in nickelate films strained on LAO (open symbols) and bulk (solid symbols). e, O K-edge for reference thin films of SNO (violet) and GTO alone (blue), along with the same bilayers. In the bilayers data the integrated areas for the Ni and Ti pre-peaks are shaded in purple and blue, respectively. f, Relative integrated area for the different bilayers. g, FWHM of the Ni and Ti pre-peaks. h–j, Schematic representation of the interfacial charge transfer and the rehybridization processes in the covalent bond represented as two independent bands ([3d⁷] and [3d⁸L]) for decreasing rare-earth size (from left to right). The upper panels represent the two parts of the heterostructure before contact and the lower panels depict the resulting electronic state after charge transfer and rehybridization.

several important differences in the Ti 3d levels of a Ti³⁺ perovskite compared to those of a Ti⁴⁺ perovskite, including the finite d level occupancy and the splitting of both t₂g and e_g levels due to Jahn–Teller and orthorhombic GdFeO₃ distortions for Ti³⁺ (ref. 26). As a result, the spectral shape and width of the absorption peaks are expected to be broader in rare-earth titanates than in Ti⁴⁺ perovskites such as SrTiO₃ (STO), see refs 25,27. In Fig. 3f, we plot the high-energy Ti L₃ peak for LNO/GTO, NNO/GTO and SNO/GTO bilayers, along with those of a GTO single film and a STO crystal. Whereas the peak for STO can be well fitted by a single component, two components are needed for the GTO film and the three bilayers. The total width of the experimental peak as well as the energy splitting between both components decreases on going from the GTO film through the bilayers series (see Fig. 3g). Because the structural parameters of GTO in the different bilayers are the same, this variation is unlikely to be associated with changes in the crystal field splitting. Rather, this finding suggests a mixed Ti³⁺/⁴⁺ character for the bilayers, with an increase of the Ti valence towards ⁴⁺ for smaller rare-earths in the nickelate. Again, this behaviour is reproduced by our first-principles calculations (Fig. 3h). Remarkably, the trend is opposite and complementary to that of the Ni valence inferred from Fig. 3a–h, strongly suggesting that the transfer of electrons from the titanate to the nickelate is controlled by the sole rare earth in the nickelate, in agreement with the calculations (see Supplementary Information). Here, because XAS probes the whole nickelate and titanate thickness, the valence changes that we deduce correspond to weighted averages within each layer. In line with recent results on LaTiO₃/LaFeO₃ interfaces28, the total charge transferred from the GTO to the nickelate is thus large, particularly for the NNO/GTO and SNO/GTO samples. For LNO/GTO, however, charge transfer is thwarted by strong covalence effects, as we shall see in the following.

We now turn to investigate how the transferred charge is distributed in the hybridized bands of the nickelate. As shown by Van Veenvendaal et al.29, changes in the multiplet splitting of the Ni L₃ absorption edge can be used to estimate the level of covalence. This splitting corresponds to the energy separation between t₂g and e_g levels resulting from the interplay between hybridization and Coulomb repulsion, which are both stronger for e_g levels6. Previous studies in bulk samples have shown that progressing in the nickelate series (decreasing the rare-earth ionic radius) results in a larger splitting of the L₃ peaks, analysed in terms of a decrease in covalence29–31. We have analysed and fitted the XAS at the Ni L₃ edge for LNO, NNO and SNO reference films as well as for LNO/GTO, NNO/GTO and SNO/GTO bilayers. Results for LNO and LNO/GTO, as well as for SNO and SNO/GTO, are shown in Fig. 4a,b, respectively. The energy splittings between both components of the fit are plotted in Fig. 4c. The peak splitting increases on going from LNO/GTO to NNO/GTO to SNO/GTO, reflecting a decrease in covalence, as found in bulk nickelates with...
decreasing rare-earth size\(^\text{29,31}\). In addition, we also find that the splitting values are similar between the bilayers and reference single films (fully strained on LAO). This indicates that the relative weights in the hybridized states \(|\Psi\rangle = a|3d^\alpha\rangle + b|3d^\beta\rangle\) are comparable in films and in bilayers, suggesting that, for a given rare-earth nickelate, the proportion \(\beta^2/(\alpha^2 + \alpha^2)\) is characteristic of the chemical Ni\(^{1+}\) state. To reinforce this interpretation, we performed simulations of the electronic structure of single films of nickelates (bulk and strained on LAO). The evolution of the computed covalence (estimated from the number of oxygen \(p\) electrons, \(N_p\), and the number of electrons, \(N_e\), near the Fermi level, see Supplementary Information) as a function of the rare-earth nickelate presented in Fig. 4d is in close agreement with what is observed experimentally. This confirms the idea that covalence is mostly a local and intrinsic property of the Ni–O–Ni bond (with strain playing a minor role in the low-strain limit of larger rare-earth nickelates on LAO).

In Fig. 4e, we plot the spectra for the three bilayers and two reference samples (purple: SNO single film, blue: GTO single film). Bilayers exhibit two pre-peaks at 529 eV and 531 eV, associated with oxygen hybridization with Ni and Ti, respectively. On going from LNO/GTO to NNO/GTO and SNO/GTO, the Ni pre-peak intensity decreases globally whereas that of the Ti pre-peak increases (see Fig. 4f). This latter trend is a direct confirmation of the change in the Ti valence discussed in connection with Fig. 3c.g. The decrease in the Ni pre-peak intensity as the rare earth is varied from La to Sm is much stronger than that found in bulk RNiO\(_3\) (ref. 32), and thus cannot be attributed to a simple decrease in the covalence.

To understand this variation, it is helpful to consider that charge transfer from GTO causes a change from Ni\(^{3+}\) = \(\alpha|3d^\alpha\rangle + \beta|3d^\beta\rangle\) towards a Ni\(^{1+}\) \(\approx \alpha|3d^\alpha\rangle\). In the bilayers, nickel can thus be described as a mixture of Ni\(^{3+}\) and Ni\(^{1+}\) —that is, \(\alpha|3d^\alpha\rangle + \beta|3d^\beta\rangle + \gamma|3d^\gamma\rangle\), now with \(\alpha^2 + \beta^2 + \gamma^2 = 1\). Charge transfer from GTO increases \(\alpha^2\), thereby reducing \(\alpha^2 + \beta^2\), and in fact both \(\alpha^2\) and \(\beta^2\), because, as discussed above, the ratio \(\beta^2/(\alpha^2 + \beta^2)\) is fixed for a given nickelate (see Fig. 3c). This rehybridization process\(^3\) requires a redistribution of electrons between the \(|3d^\alpha\rangle\) and the \(|3d^\beta\rangle\) states, which occurs at an energy cost \(|\Delta|\) for each electron transferred between \(|3d^\alpha\rangle\) and \(|3d^\beta\rangle\). Their relative proportion is \(\beta^2\); thus the resulting energy cost is proportional to \(\beta^2|\Delta|\).

Figure 4g also presents the full-width at half-maximum (FWHM) of both pre-peaks\(^4\), characterizing the hole bandwidths for Ti—which increases as the Ti 3d band is depleted—and for Ni—which decreases as the Ni hybridized states are filled. This observation definitely confirms the transfer of charge from the GTO to the nickelate, controlled by the rare-earth size.

We summarize these ideas in Fig. 4h–j. The top panels correspond to a schematic representation of the electronic structure of ‘bulk’ GTO (left) and nickelate (decomposed into \(\alpha|3d^\alpha\rangle + \beta|3d^\beta\rangle\) states, right). The rare-earth size decreases from (h) to (i) to (j), causing a progressive decrease of the bandwidth of the \(3d^\gamma\) state and a reduction of the covalent character (decrease of \(\beta^2\)). When an interface is built between GTO and the nickelate (bottom panels), the system attempts to transfer electrons to align...
the electrochemical potentials, leading to the rehybridization process discussed above. For large rare-earth size (Fig. 4h), the nickelate has a strong covalent character, which increases the cost of rehybridization. This mechanism competes with the energy gain associated with the difference in electron affinity, thereby limiting the amount of charge that can be transferred across the interface. This scenario can also be viewed as a decrease of the effective $\delta \phi$ for larger rare-earth radii.

We now turn to the magnetic properties of the heterostructures. Magnetism in transition metal insulators such as nickelates and titanates is ruled by super-exchange interactions. Strongly distorted rare-earth titanates such as GTO are ferromagnetic. Nickelates are antiferromagnets at low temperatures, although ferromagnetic and antiferromagnetic exchange paths alternate in the [111] direction in a way determined by the ionic (antiferromagnetic) or covalent nature (ferromagnetic) of the bonds. At the interface between GTO and a nickelate there is a Ti$^{3+}$–O–Ni antiferromagnetic super-exchange path mediated by $\delta \phi$ electrons, which will locally induce a ferromagnetic-like moment in the nickelate. This path will be interrupted for the non-magnetic Ti$^{4+}$ if charge transfer occurs at the interface. Thus, looking at the magnetic interactions in the nickelate provides further information about covalence and charge transfer.

In Fig. 5, we present XAS, XRMS and XMCD measured at low temperature and a field of 5 T in a NNO/GTO bilayer. A magnetic signal is detected at the Gd M$_{4,5}$ (we estimate $M_{\text{Gd}} = 5.8 \mu_B$) and Ti L$_{2,3}$ edges, consistent with the ferromagnetic character of GTO. Interestingly, although bulk NNO is antiferromagnetic, a sizeable

dichroic signal is measured at the Ni L$_{3,2}$ edge (sum rules lead to a value of about $\Delta E = 0.1 - 0.2 \mu eV$ averaged over the whole 7 u.c. thickness).

The magnetic field dependence of the dichroic response at the Ni L$_{3}$ edge for this sample is shown in Fig. 6a–h. Figure 6a–f shows XRM spectra measured at different fields ramping the field down from 3 T (darker graphs) and up from 3 T (lighter graphs). A first observation is that at high magnetic field the spectra for both sweep directions are virtually superimposed (Fig. 6a,f), whereas they are different at low magnetic field (see for instance Fig. 6d,e). This indicates hysteresis and a ferromagnetic-like behaviour. Second, the shape of the signal changes with the magnetic field. Although this could reflect a magnetic-field-induced change of the electronic and magnetic structure, such as a spin-state transition, the plausible explanation is that several magnetic components are present in the sample, and that they respond differently to the magnetic field. The detailed analysis of this peculiar behaviour, however, lies beyond the scope of this paper and here we report only the field dependence of the main component. As visible in Fig. 6g, it shows a hysteresis loop that is open at low positive fields, and shifted both horizontally and vertically. Such horizontal and vertical loop shifts—sometimes persisting up to several teslas—are reminiscent of the phenomenon of exchange bias which occurs at interfaces between a ferromagnet and an antiferromagnet. For instance, we note that exchange bias has been observed in nickelate/manganite multilayers.

To explore the influence of interfacial charge transfer on magnetism in the nickelate, we compare XMCD at the Ni L$_{3}$ edge for the three bilayers after normalization at the L$_{3}$ peak of the respective XAS spectra, see Fig. 6i–k. As visible in Fig. 6i, a large XMCD signal is observed for all samples. In Fig. 6j, we highlight the signal at the Ni L$_{3}$ edge. As in the XAS (see Fig. 3b), the spectral shape varies with the rare earth, suggesting an influence of the Ni valence change on its magnetic response. The intensity of the low-energy feature (a) increases when going from LNO/GTO to SNO/GTO, as summarized in Fig. 6k. The parallel between Fig. 3c and Fig. 6k indicates that Ni$^{2+}$ ions strongly contribute to the overall magnetic signal, which provides further evidence of the role played by covalence in this system. Further work is needed to ascertain the exact nature of the exchange paths at play at this complex interface, but one may speculate that coherent exchange, proposed as the source of ferromagnetism in Li$_2$Ni$_{2}$O$_3$ (ref. 42), is an important ingredient to produce the observed Ni dichroism.

In summary, we have discovered that, at interfaces between strongly correlated oxides, the covalent character of the transition metal/oxygen bonds plays a key role in determining the amount of charge transferred across the interface, and the resulting charge density in the different available bands. The situation is thus very different from that found at weakly correlated interfaces, where, conventionally, differences in electron affinity and possible polar discontinuities control the interfacial doping. Our results suggest novel strategies to engineer two-dimensional states in correlated oxides by adjusting both the electron affinity mismatch and the level of covalence. In bulk nickelates, the latter can be adjusted by changing the rare-earth size, but any mechanism altering the electron bandwidth should play the same role. For instance, strain engineering in the large-strain limit seems fairly promising as an additional means to tailor interfacial properties. Another means of tuning covalence could be to move from oxygen to other ligands, such as S or Se. In combination, these different controls may allow one to finely tune the orbital hierarchy as well as the $p$ and $d$ hole density, in the search for artificial cuprate-like superconductivity.

Methods

Growth of the heterostructures. The LaAlO$_3$ substrates were cleaned in acetone and propanol and annealed before deposition. All targets were pre-ablated in the growth conditions for 15 min. The GTO was then deposited by pulsed laser deposition at $P_{\text{O}_2}=2 \times 10^{-4}$ mbar and $T_{\text{dep}} \approx 700^\circ$C. The growth was monitored by in situ RHEED and stopped after 7 u.c. Then the temperature was slowly decreased in the titanate growth pressure to the growth temperature for the nickелates (600–650 °C). While the temperature was reduced, we monitored the evolution of the titanate with RHEED and no structural modification was observed. Immediately after deposition the samples were annealed in situ for 30 min at 500 °C and 300 mbar of oxygen.

TEM and EELS analysis. Cross-sectional specimens for electron microscopy were prepared by conventional methods: grinding and Ar ion milling. STEM–EELS observations were carried out in a Nion UltraSTEM200 dedicated STEM equipped with a fifth-order aberration corrector and a Gatan Enfinium spectrometer. On occasion, principal component analysis was used to remove random noise from EELS data sets. EELS maps have been produced both by integrating the signal under the edges of interest after background subtraction using a power law or by using a multiple linear least squares fit routine.

X-ray absorption spectroscopy. The experiments were performed at the electron storage ring of the Helmholtz-Zentrum Berlin (HZB) by using the 70kOE high-field end station located at the UE46-PGM1 beamline. Spectra were obtained across the Ti and Ni $L_\alpha$ edges as well as across the O K and Gd and Nd $M_{\alpha}$ edges. A magnetic field of 30kOe was applied perpendicularly to the sample surface during measurements. Absorption experiments (XAS) were performed at normal incidence by means of total electron yield detection. The escape depth of the secondary photoelectrons guarantees that the measured signal arises from the whole GTO and RNO thickness. Reflection experiments—that is, XRMS and XRMS asymmetry—were done in a $\vartheta/2\vartheta$ geometry for which the sample was placed at an incidence angle of $\vartheta=19^\circ$ with respect to the incoming propagation direction. The XMCD data were taken at 5 K at normal incidence by means of total electron yield detection. XMCD was obtained experimentally as the difference between two absorption spectra measured with right ($\mu_+$) and left ($\mu_-$) circular polarized radiation, whereas $A_{\text{XMCD}}$ is defined as the difference of the two reflection curves ($R_+\text{ and } R_-$) normalized by their sum. Errors bars in Figs 3, 4 and 6 are extracted from the fitting procedure. The Ni $L_\alpha$, XAS spectra were background corrected at the pre-edge of the L-edge (far from the overlapping La M$_\alpha$ signal) and then renormalized at the post-edge. To suppress the La signal we corrected the XAS measured at the Ni L-edge in the bilayers using the XAS measured in the same conditions and same temperature from a reference LAO/GTO(7 u.c.) sample deposited on LAO. For the analysis of the Ni $L_\alpha$ of the LNO reference sample, we subtracted a Lorentzian function from the data as in ref. 30. The Ti L-edge signal was corrected by subtracting a linear background at the pre-edge and renormalizing it to the post-edge. For the sake of clarity, the spectra for reference samples were then shifted to align the second peak at the $L_{\alpha}$ edge to be at the same energy. The O K-edge signal was also background corrected at the pre-edge and renormalized at its post-edge (550 eV).

Hard X-ray photoemission spectroscopy. We conducted hard x-ray photoemission spectroscopy (HXPS) experiments at the GALAXIES beamline (Synchrotron SOLEIL, France; ref. 45). The photon energy was set at 2,300 eV and the binding energy scale was calibrated using the Fermi edge of the sample at 2,295 eV. The overall resolution was better than 250 meV and all measurements were done at room temperature. A Shirley background was subtracted from every core-level spectrum. The angle versus depth photon field magnitude was computed using YRXO software46, taking into account the experimental geometry and the bilayer optical properties at 2,300 eV for linearly polarized light. The modelling of the photon field as a function of the photon incidence angle is based on Chiam et al.’s methodology48 using the depletion model of Tanaka and colleagues48.

First-principles calculations. First-principles calculations were performed using density functional theory (DFT) calculations with the VASP package49,50. We used the PBEsol (ref. 51) + $U$ framework, as implemented by Lichtenstein’s method52. The Hubbard $U$ correction on titanium and nickel atoms was chosen to reproduce their bulk ground state properties. A value of $U_{\text{Ni}}=3$ eV previously yields correct ground state properties in strongly correlated RTiO$_3$ compounds53. The case of nickelates is more difficult to address, and there is a debate on whether a small or large value of $U$ is required to reproduce the ground state properties. We have chosen a $U_{\text{Ni}}=2$ eV, yielding the correct ground state properties regarding the complex antiferromagnetic (AFM) structure (T-type AFM or S-type AFM) and the band gap values on a large range of nickelates ($R=Y, \text{Gd, Sm, Nd and Pr}$). We emphasize here that LaNiO$_3$ was not considered in our DFT study, as it requires its own parameters to reproduce the bulk ground state (the ideal case would be $U_{\text{Ni}}=0$ eV, as discussed in ref. 41). Geometry optimizations on a set of (GdTiO$_3$)$_n/(\text{GdNiO}_3)$ ($n \leq 7$) were performed until forces were lower than 0.01 eV Å$^{-1}$ and energy was converged to $1 \times 10^{-6}$ eV. All possible lattice distortions were considered in the calculations, including the breathing of the oxygen cage. The plane-wave cutoff was set to 500 eV and we used a $k$-point mesh of $5 \times 5 \times 1$ for superlattices with $n \geq 3$ ($5 \times 5 \times 3$ for $n=1$). We worked at the collinear level and only a ferromagnetic solution was used in all our simulations of superlattices. PAW pseudo-potentials54 were used in the calculations with the following electron configurations: 4$s^2$3$d^3$(Ti), 4$s^2$3$d^8$(Ni), 2$s^2$2$p^6$(O), 4$p^6$5$s^2$4$d^4$(Pr, Nd, Sm), 4$p^6$5$s^2$/4$(\text{Gd})$ and 4$p^6$5$s^2$/4$d^4$(Y). We note that f electrons were not treated explicitly in our calculations and were included in the pseudo-potential. Results of charge transfer as a function of the rare earth in nickelates were obtained in a set of (RTiO$_3$)$_n/(\text{RNiO}_3)$ superlattices ($R=Y, \text{Gd, Sm, Nd, Pr and Ce}$). This is justified by the fact that the charge transfer seems to appear mostly interfacial and is controlled only by the sole rare earth in the nickelate (see Supplementary Information). It also avoids any built-in polarization altering the charge transfer.
