ABSTRACT

Context. Transitional disks are circumstellar disks with dust gaps thought to be related in some cases with planet formation. They can shed light on the planet formation process by the analysis of their gas and dust properties. T Cha is a young star surrounded by a transitional disk with signatures of planet formation.

Aims. The aim of this work is to study the outer disk around T Cha and to derive its main properties.

Methods. We have obtained high-resolution and high-sensitivity ALMA observations in the CO(3–2), 13CO(3–2), and CS(7–6) emission lines to reveal the spatial distribution of the gaseous disk around the star. In order to study the dust within the disk we have also obtained continuum images at 850 µm from the line-free channels.

Results. We have spatially resolved the outer disk around T Cha. Using the CO(3–2) emission we derive a radius of ∼230 AU. We also report the detection of the 13CO(3–2) and the CS(7–8) molecular emissions, which show smaller radii than the CO(3–2) detection. The continuum observations at 850 µm allow the spatial resolution of the dusty disk, which shows two emission humps separated by ∼40 AU, consistent with the presence of a dust gap in the inner regions of the disk, and an outer radius of ∼80 AU. Therefore, T Cha is surrounded by a compact dusty disk and a larger and more diffuse gaseous disk, as previously observed in other young stars. The continuum intensity profiles are different at both sides of the disk suggesting possible dust asymmetries. We derive an inclination of i = 67 ± 5, and a position angle of PA = 113 ± 6, for both the gas and dust disks. The comparison of the ALMA data with radiative transfer models shows that the gas and dust components can only be simultaneously reproduced when we include a tapered edge prescription for the surface density profile. The best model suggests that most of the disk mass is placed within a radius of R < 50 AU. Finally, we derive a dynamical mass for the central object of M = 1.5 ± 0.2 M⊙, comparable to the one estimated with evolutionary models for an age of ∼10 Myr.

1. Introduction

T Chamaeleontis (T Cha) is a young (∼7 ± 5 Myr) nearby (108 pc) T Tauri star in the ε-Cha association, surrounded by a transition disk (Alcalá et al. 1993; Brown et al. 2007; Torres et al. 2008; Murphy et al. 2013). There is evidence of a dust gap within the disk, and a yet unconfirmed substellar companion inside the gap (see Huélamo et al. 2011; Olofsson et al. 2013). If confirmed, the disk around T Cha can give us important clues about the physical conditions for substellar formation at early evolutionary phases.

T Cha is surrounded by a very narrow inner disk that extends from 0.13 to 0.17 AU (Olofsson et al. 2013), and an outer disk whose main properties have been inferred from the modeling of its spectral energy distribution (SED, e.g. Brown et al. 2007). Cieza et al. (2011) showed that the models are highly degenerate and can fit the SED of T Cha equally well either with a very compact outer dust disk (a few AU wide) or a much larger but more ‘tenuous’ disk, with a very steep surface density profile. Both family of models suggest a very peculiar outer disk with little or no dust beyond ∼40 AU. On the other hand, the cold gas in the T Cha outer disk has been studied by Sacco et al. (2014). Their spatially unresolved observations suggest the presence of a gaseous disk with an outer radius of RCO ∼ 80 AU in Keplerian rotation.

Overall, the disk around T Cha shows properties similar to the so-called ‘faint’ disks, characterized by weak millimeter continuum emission that can be result of different properties or processes (e.g. Piétu et al. 2014). In the case of T Cha there is evidence of dust clearing, grain growth, and a high disk inclination (Brown et al. 2007; Pascucci & Sterzik 2009).

In this work we present high quality observations of T Cha obtained with the Atacama Large Millimeter Array (ALMA), which have allowed us to spatially resolve the outer disk around T Cha for the first time. ALMA has allowed us to derive basic parameters of the outer disk, to break the degeneracy of radiative
transfer models based on SED fitting, and to understand if it is peculiar in comparison with other circumstellar disks.

2. Observations

The observations were performed on 2012 July 01, 26 and November 03 at Band 7, as part of the ALMA Cycle 0 program 2011.0.000921.S. The field of view was ∼ 18′. A total of three data sets were collected, using between 18 and 23 antennas of 12 m diameter and accounting for 6 hours of total integration time including overheads and calibration. Weather conditions were good and stable, with an average precipitable water vapor of 0.7 mm. The system temperature varied from 150 to 250 K.

The correlator was set to four spectral windows in dual polarization mode, centered at 345.796 GHz (CO(3–2)), 342.883 GHz (CS(7–6)), 332.505 GHz (SO2(4,3–1–3,2,2)), and 330.588 GHz (13CO(3–2)). The effective bandwidth used was 468.75 MHz, providing a velocity resolution of ∼ 0.11 km s⁻¹ after Hanning smoothing.

The ALMA calibration includes simultaneous observations of the 183 GHz water line with water vapor radiometers, which measure the water column in the antenna beam, later used to reduce the atmospheric phase noise. Amplitude calibration was done using Juno and Titan, and quasars J1256–057 and J1147–6753 were used to calibrate the bandpass and the complex gain fluctuations respectively. Data reduction was performed using version 4.1 of the Common Astronomy Software Applications package (CASA). We applied self-calibration using the continuum and we used the task CLEAN for imaging the self-calibrated visibilities. The continuum image was produced by combining all of the line-free channels using uniform weighting (synthesized beam 0.52′′ × 0.34′′, P.A. ~29°; rms = 0.7 mJy beam⁻¹). For the CO(3–2) line we used Briggs weighting (beam 0.64′′ × 0.48′′, P.A. ~31°; rms per channel = 9 mJy beam⁻¹), and for the rest of the lines we used natural weighting, providing a synthesized beam ~0.8′′ × 0.6′′, P.A. ~25° and an rms per channel of 11 mJy beam⁻¹ for the 13CO and 7 mJy beam⁻¹ for the CS and the SO2.

3. Results and discussion

3.1. Molecular emission line detections

Molecular line emission is detected for the transitions CO(3–2), 13CO(3–2), and CS(7–6). All of them are spatially resolved for the first time for T Cha. No detection was found for SO2(4,3–1–3,2,2), with a 3σ upper limit of 20 mJy.

Figure 1 shows the integrated emission maps of the three detected molecules while Figure 2 displays the intensity-weighted velocity profiles at both sides of the disk, together with the average profile, including only datapoints above 5σ. As in the case of the gas molecules, they have been computed using slices along the semi-major axis of the disk (dashed white line in Fig. 1, left) in the gas emission maps. We do not see a significant difference of the profiles at both sides of the disk (NE and SW) suggesting a symmetric distribution of the gas.

Gas emission from CS(7–6) is also spatially resolved and shows a deconvolved radius of RCS ~ 100 AU. The integrated intensity emission above 3σ is 0.54 ± 0.08 Jy km s⁻¹. To our knowledge, this is the first time that such a high transition of the CS molecule is spatially resolved in a disk around a late-type star (the first detection in a Herbig star has been recently reported by van der Plas et al. 2014).

3.2. Continuum emission at 850 μm

Continuum emission at 850 μm is detected centered at the position R.A.(J2000) = 11°57′13″42, Dec(J2000) = -79°21′31″696. The flux density integrated over the disk structure above 5σ is Sₘₜₜ = 198 ± 4 mJy.

Figure 1 shows the dusty outer disk around T Cha represented by black contours. The disk is spatially resolved in its major axis with a projected diameter of 1.50″ (measured at the 5σ contour level), which corresponds to an outer dust disk radius of Rₘₜₜ ~ 80 AU after deconvolution with the synthesized beam, and adopting a distance of 108 pc. Two local peaks are observed at a projected separation of 0.37″ (40 AU at 108 pc), which is close to the beam size, and suggest the presence of a gap in the inner regions of the disk as predicted by SED modeling.

In Figure 3 we have represented the continuum radial intensity profiles at both sides of the disk, together with the average profile, including only datapoints above 5σ. As in the case of the gas molecules, they have been computed using slices along the semi-major axis of the disk (dashed white line in Fig. 1, left) in the gas emission maps. We do not see a significant difference of the profiles at both sides of the disk (NE and SW) suggesting a symmetric distribution of the gas.
Fig. 1. Integrated emission maps of the CO(3–2), $^{13}$CO(3–2), and the CS(7–6) transitions (from left to right). The black contours represent the continuum emission at 850 $\mu$m at 5, 15, 30, 45, 60, 75, 90, and 110 $\sigma$ where 1 $\sigma$ is 0.7 mJy beam$^{-1}$. We detect two emission bumps separated by 40 AU and an outer dust radius of 79 AU. The white ellipses are the synthesized beams for the spectral emission lines and the green ellipse is the synthesized beam for the continuum map. The white dashed line in the left panel represents the axis where the position-velocity diagram in Figure 4 has been obtained.

Fig. 2. Intensity-weighted mean velocity maps (first-order moment, 2$\sigma$ cut for CO(3–2) and $^{13}$CO(3–2), and 1.5$\sigma$ cut for CS(7–6)).

panel) in the continuum emission maps. We can see a significant difference between the profiles at both sides, with the NW side being slightly larger than the SE one, suggesting asymmetries within the dusty disk. Finally, the $i$ and PA values that we derive using the continuum emission at 850 $\mu$m are similar to those estimated with the CO(3–2) observations.

3.3. Comparison with radiative transfer models

Our ALMA observations reveal that T Cha is surrounded by a compact dusty disk with a sharp outer edge at $\sim$80 AU and a larger gaseous disk with an outer radius of $\sim$230 AU. This trend, a compact dust disk with a larger and more diffuse gaseous disk, has already been observed in a significant number of circumstellar disks (e.g. Isella et al. 2007; Hughes et al. 2008; Andrews et al. 2012; de Gregorio-Monsalvo et al. 2013; Piétu et al. 2014).

Cieza et al. (2011) used the radiative transfer code MCFOST (Pinte et al. 2006, 2009) to model the SED of T Cha. They showed that there are two families of dust disk models that can reproduce equally well the SED: very small disks (a few AU width) or much larger ($R_{\text{out}} \sim$300 AU) but with a very steep surface density profile (with an exponent of $\alpha \leq -2$, for a power-law prescription). The large degeneracy between these two disk parameters, $R_{\text{out}}$ and $\alpha$, did not allow them to choose between these two scenarios. Olofsson et al. (2013) used MCFOST to fit the SED together with near-IR interferometric data. They fixed $R_{\text{out}} = 25$ AU, and $\alpha = -1$, and found a best fit model with a narrow dust outer disk ($R_{\text{in}} = 12 \pm 2$ AU).

Our ALMA data shows that models with a power-law surface density, like the ones used in these two works, cannot reproduce both the CO and continuum data. We nevertheless first consider this type of models to discuss the ALMA data in the context of previous results.

We have modeled the SED of T Cha with MCFOST, being the starting point the model grid presented by Cieza et al. (2011) and refined by Olofsson et al. (2013). Basically, the disk is composed of 2 sub-disks: an inner and an outer disk with a density structure defined by a power law surface density profile with exponent $\alpha$, $\Sigma(r) = \Sigma_0 (r/r_0)^\alpha$, and a scale height of $h(r) = h_0 (r/r_0)^\beta$, with $\beta$ being the disk flaring index, and $h_0$ the scale height at a reference radius $r_0 = 50$ AU. Each disk extends from an inner radius, $R_{\text{in}}$, to an outer radius, $R_{\text{out}}$. The grain size distribution in each disk is defined by $dn(a) \propto a^p da$, be-
two parameters obtained from the ALMA data, measuring the disk is in pure Keplerian rotation. The temperature profiles and the radiation field estimated by the Monte Carlo simulation are used to calculate level populations for the CO molecule and to produce the SED, continuum images, and line emission surface brightness profiles, as well as kinematics with a ray-tracing method. The kinematics are calculated assuming the Mie theory. Finally, the total gas mass in the disk (including all grain sizes) is represented by \( M_{\text{dust}} \).

To calculate the CO channel maps and surface brightness distribution, we assume a constant gas-to-dust mass ratio of 100 throughout the disk (both radially and vertically). We adopted a standard CO abundance with respect to H\(_2\) (10\(^{-4}\)), set constant through the disk where \( T_{\text{dust}} > 20\) K and equal to zero where \( T_{\text{dust}} < 20\) K to mimic the effect of CO freeze out. The \(^{12}\)CO/\(^{13}\)CO ratio is set to 76. The level populations are calculated assuming \( T_{\text{gas}} = T_{\text{dust}} \) at each point in the disk. The radial and vertical temperature profiles and the radiation field estimated by the Monte Carlo simulation are used to calculate level populations for the CO molecule and to produce the SED, continuum images, and line emission surface brightness profiles, as well as kinematics with a ray-tracing method. The kinematics are calculated assuming the disk is in pure Keplerian rotation.

We have adopted the inner disk parameters from Olofsson et al. (2013). For the outer disk, we have fixed two parameters obtained from the ALMA data, \( R_{\text{in}} \) and \( i \), selecting the grid values closer to the ALMA measurements (80 AU and 68\(^\circ\), respectively). We have explored \( R_{\text{in}} \), \( \beta \), \( h @ 50\) AU, \( \alpha \) and \( M_{\text{dust}} \), using the same parameter range shown in Cieza et al. (2011). For the SED, we have fitted the same observational dataset displayed in that work. The adopted stellar parameters are \( T_{\text{eff}} = 5400\) K, \( A_i = 1.5 \), and \( d = 108\) pc (Torres et al. 2008; Schisano et al. 2009). The best disk model, that is, the one with the minimum \( \chi^2 \), provides parameters of \( \alpha = -2.5, \beta = 1.07, R_{\text{in}} @ 50\) AU = 19 AU, \( \alpha_{\text{max}} = 1000 \), and a disk dust mass of \( M_{\text{dust}} \sim 1 \times 10^{-5} \) M\(_{\odot}\).

Since SED modeling is highly degenerate, the best-fit model is unlikely to be a unique solution. Therefore, we have performed a Bayesian analysis to estimate the validity range for each of the explored parameters (Press et al. 1992; Pinte et al. 2007). The result is displayed in Figure 5 where we show the Bayesian probability distributions for the different disk parameters. While \( M_{\text{dust}}, R_{\text{in}} \) and \( h_0 \) seem well constrained, this is not the case for \( \alpha \): it shows a local peak at \( \alpha \sim -2.5 \) but a relatively flat distribution. We conclude that, even fixing \( R_{\text{out}} \), \( \alpha \) remains unconstrained by the SED modeling.

With our ALMA observations we have partially broken the \((\alpha, R_{\text{out}})\) degeneracy commonly encountered with SED fitting by measuring \( R_{\text{out}} \). The resolution reached by our observations does not allow us to constrain accurately the surface density profile. But with \( R_{\text{in}} \sim 20\) AU and a disk width of \(~60\) AU, we exclude surface density profile shallower than -1. According to the observed \( R_{\text{out}} \), we can also discard the family of models with very narrow dusty rings, and the extreme case of a very large disk (\( R_{\text{out}} \sim 300\) AU) with \( \alpha \sim -3 \).

If we take the gas emission into account, the model fails to fit simultaneously the gas and dust profiles (see Figure 3), as already observed in other spatially resolved circumstellar disks (e.g. Hughes et al. 2008). As discussed by the authors, a power law density profile cannot reproduce the different extent of the gas and dust emission observed in circumstellar disks while a tapered edge model, in which the surface density falls o

\[
\Sigma(r) = \Sigma_0(r/r_0)^{-\gamma} \exp \left( -\left( r/r_0 \right)^{2-\gamma} \right).
\]
have sampled a range of dust mass to
for the outer disk. We have fixed the disk inclination to 68°
ners from Olofsson et al. (2013), and varied only the prescription
outer disk radius and the disk inclination. The result is displayed in Figure 3 where we show the best
model that can fit simultaneously the two disk components and the observedSED. The model shows $\gamma = 0.5$ and $R_c = 50$ AU
for both the gas and the dust. We also derive these parameters: $R_o =
20$ AU, $h_o@50$ AU = 4 AU, and $\beta = 1.0$. This model is consistent with having the gas and the dust well mixed and mainly
located at a radius smaller than 50 AU, as suggested by Cieza et al. (2011) based on the steep drop of the SED at sub-mm wave-
lenghts.

Figure 3 shows that our best model does not perfectly fit the CO line profiles, which can be related either with the underlying
chemistry (we assumed ISM abundances and very simple CO freeze-out) or with the model prescriptions. In fact, tapered-
edge models sometimes fail to reproduce simultaneously the observed gas and dust profiles obtained from very high spatial resolution and sensitivity observations (see Andrews et al. 2012 and de Gregorio-Monsalvo et al. 2013), and suggests that other processes like e.g. grain growth and radial migration should be taken into account. Given that the disk is barely resolved in our observations, we expect future, higher spatial resolution observations to provide stronger constraints on the relative location of the gas and dust, and the departure from point-symmetry.

4. Conclusions

High spatial resolution and high sensitivity ALMA observations have allowed us to spatially resolve the outer disk around the young and isolated object T Cha. The target is surrounded by a compact dusty disk and a ~3 times larger gaseous disk. Our main results can be summarized as follows:

- We have spatially resolved the gaseous disk of T Cha in three different molecular emission lines: CO(3–2), $^{13}$CO(3–2) and CS(7–8). Using the CO(3–2) image we derive an outer radius of $R_{gas,\text{out}} \sim 230$ AU, an inclination of $i(\text{CO}) = 67±5$, and a position angle of $PA(\text{CO}) = 113±6$. The line intensity profiles are similar at both sides of the disk in the CO molecules, consistent with a uniform distribution of the gas.
- The disk around T Cha is in Keplerian rotation, and the estimated dynamical mass of the central object, $M_*=1.5±0.2 M_{\odot}$, is in good agreement with previous estimations based on evolutionary tracks.
- The dusty disk is resolved in the continuum observations at 850 µm and it shows a similar $i$ and $PA$ to the gaseous disk. The continuum intensity profile displays two emission bumps separated by 40 AU, suggesting the presence of an inner dust gap as predicted by SED modeling, and an outer radius of ~80 AU. The profiles are different at both sides of the disk, which points towards asymmetries in the dust distribution. These data allows us to rule out both the very small and large $R_{disk}$ families of SED models.
- Radiative transfer models including a truncated power law prescription for the surface density profile cannot reproduce simultaneously the gas and dust profiles. We can fit both components simultaneously using a tapered-edge model prescription for the surface density. The best model provides values of $\gamma = 0.5$, and $R_c = 50$ AU, which is consistent with having most of the disk mass within the inner 50 AU.
