Objective
To systematically review the literature on the prognostic value of lymphovascular invasion (LVI) and embryonal carcinoma (EC) for occult metastatic disease in clinical stage I nonseminomatous germ cell tumour (CS I NSGCT).

Materials and methods
The PubMed, Embase (OVID) and SCOPUS databases were searched up to March 2019. Studies reporting on the association between LVI and/or EC and occult metastatic disease were considered for inclusion. The quality and risk of bias were evaluated by the Quality in Prognosis Studies tool.

Results
We screened 5287 abstracts and 207 full-text articles. We included 35 studies in the narrative synthesis and 24 studies in a meta-analysis. LVI showed the strongest effect. Pooled rates of occult metastasis were 47.5% and 16.9% for LVI-positive and LVI-negative patients, respectively (odds ratio [OR] 4.33, 95% confidence interval [CI] 3.55–5.30; P < 0.001). Pooled rates of occult metastasis were 33.2% for EC presence and 16.2% for EC absence (OR 2.49, 95% CI 1.64–3.77; P < 0.001). Pooled rates of occult metastasis were 40.0% for EC >50% and 20.0% for EC <50% (OR 2.62, 95% CI 1.93–3.56; P < 0.001).

Conclusions
LVI is the strongest risk factor for relapse. The prognostic value of EC is high, but there is no common agreement on how to define this risk factor. Both EC presence and EC >50% have similar ORs for occult metastasis. This shows that the assessment of EC presence is sufficient for the classification of EC.

Introduction
Approximately 30% of patients with nonseminomatous germ cell tumour (NSGCT) presenting with clinical stage I (CS I) have occult metastatic disease in their retroperitoneal lymph nodes [1]. These patients will relapse if treated with active surveillance (AS).

Several management strategies for CS I NSGCT exist. Primary retroperitoneal lymph node dissection (RPLND) is still a standard approach in the USA [2]. In Europe, its role is largely diminished, as it is associated with high morbidity and European follow-up is generally well organised [3]. Various guideline statements acknowledge non-risk-adapted AS as a preferred management strategy [3,4]. This approach limits overtreatment, and most relapsed patients can still be cured with salvage chemotherapy. However, salvage treatment consists of multiple cycles of bleomycin, etoposide, and cisplatin (BEP) chemotherapy and is associated with an
increased risk of secondary malignancy [5] and cardiovascular disease [6].

The high survival rate and the long life-expectancy of patients have shifted focus to minimisation of treatment-related morbidity. This includes a reduction of treatment-associated long-term toxicities caused by salvage therapy. Early identification of patients who have a high risk of relapse enables adjuvant treatment at an early stage. This prevents relapse, thereby avoiding the necessity of salvage treatment and reducing toxicity [7,8].

In order to select these high-risk patients, several risk-adapted strategies have been developed [7,9]. Patient selection is largely based on two histopathological features in the primary tumour: presence of lymphovascular invasion (LVI) and presence or predominance of the tumour subtype embryonal carcinoma (EC) [3,7,8,10,11]. High-risk patients can be offered treatment with one course of BEP [3]. This reduces the relapse risk by 90–95%, regardless of risk classification [7]. In a prospective study by the Swedish and Norwegian Testicular Cancer Group (SWENOTECA), the relapse risk after one course of BEP was 3.2% and 1.6% for patients with and without LVI, respectively [7].

As the presence of LVI and EC are important factors that aid clinical decision-making on adjuvant treatment in patients with CS I NSGCT, their prognostic value needs to be clarified. Several studies have investigated the association between these predictors and occult metastatic disease. However, a systematic review with meta-analysis is necessary to quantify the strength of these predictors more precisely. The aim of the present study was to systematically review the literature to establish the prognostic value of LVI and EC in CS I NSGCT.

Materials and methods

Search strategy

This review was performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) statement and the recommendations of the Meta-analysis Of Observational Studies in Epidemiology (MOOSE) group [12,13]. The review protocol has been published in the International Prospective Register of Systematic Reviews (PROSPERO) database (registration number CRD42018107698).

A systematic PubMed, Embase (OVID) and SCOPUS literature search was conducted up to March 2019. An information scientist (E.W.) was involved in the design of the search strategy. The full search strategy is available in Appendix S1. Relevant references from selected studies were also considered. Two reviewers (J.B. and I.P.) independently screened all abstracts and full-text articles. Disagreement was resolved by discussion.

Study eligibility

Studies reporting on the individual association of LVI and/or EC with occult metastatic disease in patients with CS I NSGCT treated with AS or primary RPLND were eligible for inclusion. Studies reporting on patients treated with adjuvant therapy or with a risk-adapted protocol were not included. Studies reporting on patients with pure seminoma, paediatric GCT, or bilateral testicular tumours were also not included. Reviews, case reports, conference papers, editorials, commentaries, and studies not in the English language were excluded. If multiple studies reported on the same patient cohort and reported the same outcome measures, only the most recent publication was included. If multiple studies possibly included the same patients (but not the same cohort), we included both studies in the narrative synthesis but included only the most recent study in the meta-analysis.

Studies making a distinction between vascular and lymphatic invasion were also included in the narrative synthesis but not in the meta-analysis. If it was not explicitly stated whether LVI or strictly vascular invasion (VI) was meant, the corresponding author was contacted.

Outcome measures of interest were relapse during AS or positive nodes on primary RPLND. LVI and EC were evaluated as dichotomous variables (presence vs absence). The percentage of EC was evaluated either as a continuous variable or as a categorical variable using different cut-off points. Studies reporting raw data were included in the meta-analysis. If relapse rates were reported, these were converted to number of patients. AS studies with a median follow-up of <24 months were included in the narrative synthesis but not in the meta-analysis.

Risk of bias assessment

Two reviewers (J.B. and I.P.) independently assessed the quality and risk of bias in the included studies using the Quality in Prognosis Studies (QUIPS) tool for six domains: study participation, study attrition, prognostic factor measurement, outcome measurement, study confounding, and statistical analysis and reporting [14]. Disagreement was resolved by discussion. The highest score on one of the domains was taken as the overall grade of bias. In addition, the sources of funding for the included studies were evaluated. Publication bias was assessed using a funnel plot.

Data extraction and statistical analysis

Data from the articles were extracted independently by two reviewers (J.B. and I.P.). Baseline characteristics were summarised using descriptive statistics. Cochrane’s Review
Manager (version 5.3) was used for the meta-analysis and construction of the Forest plots in collaboration with a biostatistician (K.J.). Statistical heterogeneity was evaluated by calculating $I^2$.

**Results**

Our search identified 9314 manuscripts (March 2019). After removal of duplicates, 5287 studies were screened. Of these, 207 studies were selected for full-text evaluation. A total of 35 studies, reporting on 7113 patients were included in the systematic review [1,10,15–47] (Fig. 1, Table 1, Appendix S2); 26 studies reported on patients treated with AS [1,15–38,46] and nine reported on patients treated with primary RPLND [10,39–45,47]. Of these studies, 14 included >150 patients [1,10,15,17,19,20,22,25,28,32,37,39,42,43]. The median age of the patients at time of diagnosis ranged from 25 to 31 years. In the primary RPLND studies, the percentage of patients with pathological Stage II was between 18.6% and 41.3%. In the AS studies, overall relapse rates varied between 17.1% and 36.3%. Reported median follow-up durations ranged from 18 to 180 months.

A total of 24 studies could be included in a meta-analysis.[1,10,15–17,21,22,24–31,34,39–43,45–47]. In these studies, the rate of occult metastatic disease ranged from 18.6% to 41.3%. The median follow-up for the 16 AS studies in the meta-analysis varied between 38 and 180 months.

In one study with an accrual period from 1982 to 1992, patients in the first 2 years underwent explorative laparotomy in conjunction with orchidectomy [28]. If no palpable lymph nodes were found during surgery, the lymph nodes were not resected and the patients were classified as CS I and treated with AS.

The overall risk of bias was moderate to high for all studies (Table S1). Symmetry shown in the funnel plots for studies on LVI and EC predominance indicates that there was a low risk of publication bias (Fig. S1). The funnel plot for studies on EC presence showed asymmetry, which suggests that there may be some unpublished negative studies.

**LVI as a risk factor for recurrence**

All but one study reported the effect of LVI (Table 2) [1,10,15–44,46,47]. Six studies analysed VI and lymphatic
| Study                        | Inclusion period | Country                          | Inclusion criteria for AS                                      | Patients, n | Age, years, median (range) | Follow-up, months, median (range) | Overall metastatic rate, % | Central pathology review | Overall risk of bias |

Note: LVI = Liver Vein Invasion; N = Number of Patients; P = Probability; OR = Odds Ratio; HR = Hazard Ratio; RR = Relative Risk; LVI: P = Probability; VI: P = Probability; 2-year LVI = LVI at 2 years; VI: LVI = LVI at VI years; RFR = Risk Factor Ratio; NR = Not Reported; NS = Not Significant; LI: = Liver Invasion.
invasion separately or mentioned only VI [28,32,36–38,44]. The proportion of patients with LVI ranged from 16.4% to 61.4%.

Studies with central pathology review reported a higher rate of LVI. The weighted average percentage of LVI-positive patients was 23.5% for studies without pathology review and 36.6% for studies with central pathology review.

The relapse rate for LVI-positive patients varied between 26.1% and 60.6%, and was <40% in four of 28 studies that reported on it [18,21,34,39]. The relapse rate for LVI-negative patients ranged from 10.9% to 37.0%. In the RPLND studies, the rate of N+ was 25.8–65.3% and 11.9–25.8% for patients with and without LVI, respectively. In all studies, the metastatic rate was higher for LVI-positive patients.

A total of 21 studies reported the univariable analysis of LVI [10,15–18,21,23–27,29,30,33,35,39–43,47], and this was statistically significant in 18 studies [10,15–17,23–27,30,33,35,39–43,47].

In all, 18 studies reported raw data and were eligible for inclusion in the meta-analysis (Fig. 2A) [1,10,16,21,24–27,29,30,34,39–43,46,47]. These studies reported on 3009 patients, of which 894 (29.7%) were LVI positive. The pooled rate of occult metastatic disease for LVI-positive patients was 47.5%, compared to 16.9% for LVI-negative patients (odds ratio [OR] 4.33, 95% CI 3.55–5.30; P < 0.001).

EC as a risk factor for recurrence

A total of 27 studies analysed the association between EC and relapse (Table 3) [10,15–24,26–31,33–35,40–43,45–47]. In 12 studies, EC was analysed as present vs absent. The percentage of EC was analysed in several studies, but mostly as a categorical variable with different cut-off values. Two studies analysed EC percentage as a continuous variable [15,47].

The percentage of EC-positive patients ranged from 69.7% to 87.1%. Rates of occult metastatic disease were 22.0–34.6% and 0–38.5% for EC-positive and -negative patients, respectively.

A total of 10 studies reported raw data on the analysis of EC present vs absent and were included in the meta-analysis (Fig. 2B) [15,21,22,27,28,31,34,40,42,46]. These studies reported on 1346 patients of whom 1049 (77.9%) were EC positive. The pooled rates of occult metastasis were 33.2% and 16.2% for EC-positive and -negative patients, respectively (OR 2.49, 95% CI 1.64–3.77; P < 0.001).

One study analysed the prognostic value of pure EC and found that it was significantly associated with recurrence (hazard ratio [HR] 1.74, 95% CI 1.10–2.74; P = 0.02) [19]. Patients classified as high risk, based on the presence of pure EC and/or LVI, had a 52% risk of relapse, compared to 15.8% of patients classified as low risk.
### A: LVI presence

Studies reporting on the predictive value of percentage of EC were of heterogeneous design. Four studies divided the study population into more than two categories, all using different cut-off values [15,24,29,45]. The association between percentage of EC and relapse was significant on univariable analysis in three studies.

Six studies analysed EC percentage as a binary variable [10,16,20,23,41,47]. The cut-off value was 50% in five studies [10,16,20,23,47]. Three studies found no significant difference in occult metastasis between EC ≥50% and EC <50% [10,16,41] and two studies did not report on it, but showed a significant difference when we re-calculated the ORs [20,47].

Alexandre et al. [23] used 40% as a cut-off value and reported a significant difference in relapse-free survival on univariable analysis. The relative risk (RR) for patients with EC >40% in comparison to patients with EC ≤40 was 3.5 (95% CI 1.4–8.7; P = 0.008), but this was not statistically significant on multivariable analysis.

Three of the four studies that divided EC percentage into more than two categories found a significant difference in occult metastatic disease occurrence [15,24,29]. Two studies included EC percentage in a multivariable model, and this was significant only in the study by Gilbert et al. [15]. However, the cut-off values in this study (<25%; 26–99%; 100%) were data-driven and not based on previous reports.

Gilbert et al. [15] also analysed EC percentage as a continuous variable. In their model, which also included LVI, the OR for EC percentage was 1.011 (95% CI 1.002–1.019; P = 0.012). As mentioned before, Albers et al. [47] also found a significant correlation between EC as a continuous variable and occult metastatic disease, but LVI and tumour proliferation rate were better predictors.

We included nine studies, reporting on 932 patients, in the meta-analysis comparing EC >50% with EC <50% (Fig. 2C) [10,16,20,24,29,41,45–47]. Four studies used 50% as a cut-off value in their own statistical analysis [10,16,41,47]. The other studies reported sufficient raw data that it was possible to construct 2 × 2 tables and include them in the analysis. Pooled rates of occult metastasis were 40.0% and 20.0% for patients with EC >50% and EC <50%, respectively (OR 2.62, 95% CI 1.93–3.56; P < 0.001).

## Multivariable analyses

A total of 21 studies reported multivariable analysis, but with various levels of quality. Most studies used the Cox proportional hazards model, and six studies used logistic regression analysis [10,16,24,28,42,44]. Three studies reported HRs instead of ORs [15,17,19].

The presence of LVI was the most studied predictor and showed the strongest effect. The largest cohort, by Daugaard

### Table 3 (continued)

| Author | Patients with EC, N | Patients per category, % | Method of EC reporting | Method of multivariable analysis | Reported univariable analysis | Reported multivariable analysis | Pooled rates of occult metastasis, % | Description |
|--------|---------------------|--------------------------|------------------------|---------------------------------|-------------------------------|---------------------------------|-------------------------------------|-------------|
| Nicolai and Pizzocaro 1995 [29] | 81 | <50%: 4.7 | 3 categories: | Not reported | Not reported | Cox prop. hazards model | 49.4 | 3 categories: |
| Albers et al. 1995 [45] | 90 | 0 | 4 categories: | NS | NR | Cox prop. hazards model | 38.9 | 4 categories: |
| Sturgeon et al. 2011 [19] | 371 | 0 | Pure EC | NR | NR | Cox prop. hazards model | 15.1 | Pure EC |
| Sweeney et al. 2000 [43] | 292 | 0 | Predominant vs not predominant | NR | NR | Cox prop. hazards model | 46.4 | Predominant vs not predominant |
| Ondrus and Hornak 1994 [30] | 80 | <50%: 50.6 | 4 categories: | NR | NR | Cox prop. hazards model | 5.0 | 4 categories: |

EC, embryonal carcinoma; NR, not reported; NS, not significant; RFR, relapse-free rate.
et al. [17] (n = 1226), found an HR of 1.57 (95% CI 1.22–2.02; P < 0.001) for LVI alone. The Princess Margaret Cancer Center reported on a series of 371 patients treated between 1981 and 2005 [19]. LVI, regardless of other prognostic factors, was an independent predictor of relapse (HR 3.22, 95% CI 2.17–4.78; P < 0.001) in this cohort. Albers et al. [10] calculated the negative (NPVs) and positive predictive values (PPVs) for various combinations of histopathological risk factors. The best prediction of a low-risk group was a combination of absent LVI and low proliferation rate. This resulted in a NPV of 86.5%. Patients with a combination of LVI presence, high proliferation rate, and EC ≥50% were the best predicted high-risk group (PPV 63.6%).

The independent predictive value of EC was analysed in several studies, but different definitions were used. Sturgeon et al. [19] was the only study to include the presence of pure EC in a multivariable analysis and found a significant association (HR 1.74, 95% CI 1.10–2.74; P = 0.02). The cohort by Daugaard et al. [17] analysed EC presence as a single risk factor and also found a significant association (HR 2.73, 95% CI 1.94–3.85; P < 0.001). In a Turkish study of 138 patients, the presence of EC led to a 3.7-fold increase of the relapse risk [21]. Three studies reported no significant association between presence of EC and relapse [28,31,42].

EC ≥50% was included in a multivariable analysis in two studies, with contradictory results [10,26]. Sogani et al. [26] found that it was a significant predictor (OR 2.6; P = 0.016), but it was not significant in the study by Albers et al. [10] (P = 0.080). Gilbert et al. [15] analysed the predictive value of EC in various ways. LVI and EC, either as a continuous variable or split into the three previously mentioned categories (≤25%; 26–99%; ≥100%), were independent predictors of relapse. Only when EC was analysed as a binary variable (present/absent), the molecular marker C-X-C motif chemokine 12 (CXCL12), but not EC, was a significant negative predictor. As mentioned before, Albers et al. [47] also found a significant correlation between EC as a continuous variable and occult metastatic disease, but LVI and tumour proliferation rate were better predictors.

**Discussion**

Our present study confirms that the presence of LVI is the strongest predictor of occult metastatic disease in CS I NSGCT. The prognostic value of this parameter is affirmed by several large cohort studies and our present meta-analysis.

EC is an additionally useful risk prognosticator but agreement about the definition to be used is necessary. Our meta-analysis showed that the ORs for EC presence and EC ≥50% are quite similar (2.49 vs 2.62) and the relapse rates are approximately equal (33.2% vs 40.0%). This small difference in prognostic value between EC presence and EC ≥50% suggests that the assessment of EC presence may be sufficient to identify high-risk patients.

A continuous correlation between EC and occult metastatic disease was found in both studies that investigated it [15,47]. The clinically most relevant cut-off value, however, is still up for debate. It is likely that the risk of occult metastatic disease is already high in the presence of only a small amount of EC and any further increase in EC percentage does not involve a relevant increase in clinical risk.

A meta-analysis from 2002 by Vergouwe et al. [48] also investigated the predictive value of LVI and EC. The results of that study are very much in line with our present findings. LVI had the strongest predictive value (OR 4.7) and EC presence and EC >50% showed similar ORs for metastasis (OR 2.9 and 2.8, respectively).

Risk stratification of CS I NSGCT is important for patient counselling and when adjuvant treatment is considered. Several stratifications have been proposed. Since 1995, the SWENOTECa has identified high-risk patients on the basis of LVI presence or absence [7]. Lago-Hernandez et al. [9] developed a 0, 1, and 2 scoring system to stratify patients according to LVI presence and EC predominance (defined as EC presence at a larger level than any other histological type). Relapse rates were 25%, 41%, and 77% for 0, 1, and 2 risk factors, respectively. Daugaard et al. [17] also explored the combination of different risk factors and found that 5-year relapse risk was highest for patients with EC + LVI + rete testis invasion (50%, HR 5.65). Risk for patients with LVI alone was 18% (HR 1.57) and 41% for patients with EC + LVI (HR 4.29).

The proportion of high-risk patients based on LVI and/or EC differed between the included studies. This may be due to selected patient groups and is not necessarily a reflection of differences between study populations. More specifically, not all AS studies reported on truly unselected AS populations. In both studies by Sturgeon et al., [19,33] AS was offered as the preferred management method for all men with CS I NSGCT, but patients were allowed to choose. This may have introduced bias, which is illustrated by the differences in proportion of LVI-positive patients and relapse rates between the two studies by Kollmannsberger et al. [1,20]. The data included in Kollmannsberger et al. [1] is pooled from several institutions and almost half of the cohort comes from centres where patients can choose between AS and adjuvant therapy (SWENOTECa). Both the relapse rate (19.4%) and the proportion of LVI-positive patients (16.4%) in that study were low. In an earlier study by the same author [20], which reports on some of the same patients as the 2015 study and is also not a strictly AS population, the relapse rate and LVI percentage were higher (26.5% and 29.1%, respectively).
We compared the weighted average of strictly AS studies with studies that reported no strict AS in a subgroup analysis. Weighted average relapse rates were 30.2% and 25.0% for strictly AS and non-strictly AS studies, respectively. The weighted rate of LVI-positive patients was slightly higher for strictly AS patients (27.4% vs 25.0%). Thus, studies that did not explicitly state that a strict AS protocol was followed, often reported on a selected population. This can give contradictory results.

The difference in rate of high-risk patients could also be due to a lack of reproducibility of LVI assessment by pathologists. This is reflected by the difference in rate of LVI between reports with and without central pathology review. In a series of 221 patients by Harari et al. [49], reporting of LVI changed in 22% of cases after central pathology review. Purushouse et al. [50] reported that in 7.2% of patients with NSGCT the tumour prognostic factors were changed after central pathology review. In a series of 221 patients by Harari et al. [49], reporting of LVI changed in 22% of cases after central pathology review. Purushouse et al. [50] reported that in 7.2% of patients with NSGCT the tumour prognostic factors were changed after central pathology review (5% for LVI status, 2.2% for EC). This discrepancy emphasises the need for pathology review by an expert genitourinary pathologist.

Most studies investigated other possible histopathological risk factors in addition to LVI and EC. Tumour size, an important prognostic factor in seminoma, was significantly associated with relapse in the study by Roeleveld et al. [24] (cut-off value 5 cm; \( P = 0.039 \)). Five other studies in our present study also assessed this factor, but none found a significant correlation with occult metastatic disease [16,28,35,36,38]. In a large series of 779 patients by Beck et al. [51] (not included in our review), primary tumour size was not predictive of occult metastatic disease (\( P = 0.167 \)).

Several studies reported on the tumour proliferation rate, which is one of the prognostic markers mentioned in the European Association of Urology (EAU) guidelines [3]. It is commonly expressed as rate of MIB-1-positive tumour cells and was an independent predictor of metastatic disease in a prospective trial by the German Testicular Cancer Study Group Trial [10]. In that study, MIB-1 scores were available for 152 patients. Using a cut-off value of 70%, the OR for metastatic disease was 2.75 (95% CI 1.28–5.91; \( P = 0.010 \)). However, the PPV was relatively low at 43.0%. In an earlier study by the same author (but in a different patient cohort), the pathological stage was correctly classified in 69% of cases (NPV 88%, PPV 55%) [47]. These findings are contradicted by a series of 149 specimens by Heidenreich et al. [52] in which the MIB-1 score was not useful in predicting the pathological stage. Gilbert et al. [15] used the same cut-off values as the German trial and found no evidence of any prognostic value. This could be explained by the fact that only five of 179 patients had MIB-1 staining ≥70% cells. When MIB-1 staining was dichotomized (weak vs high), it had some prognostic value on univariable analysis, but this was reduced after stratification for LVI (\( P = 0.045 \)). In the meta-analysis by Vergouwe et al. [48], patients with MIB-1 staining >70% were at higher risk of occult metastasis (OR 4.7). However, the authors noted that this analysis was based on a low number of patients (\( N = 212 \)), the 70% cut-off value was data-driven, and, therefore, additional research is necessary.

One of the limitations of our present study is the heterogeneity of included studies. Studies were heterogeneous in terms of study population, year of accrual, assessment of histopathological risk factors, and methodological quality. Although studies reporting on a risk-adapted protocol were excluded, some studies reported on selected populations. Furthermore, only a few studies performed central pathology review in the context of the study. Several single-centre and some larger studies reported pathology review by an expert pathologist as part of standard care. Especially in low-volume centres, however, the quality of risk factor assessment might be low. In addition, most studies did not report the definition for LVI and several studies did not report the definition for EC predominance.

Missing data of the histopathological features of interest were high in a number of studies. Some retrospective studies only included patients with complete data without reporting the total number of patients treated during the study period. Therefore, missing data were not assessable in these studies. Most studies that reported missing data excluded these patients from further analysis. Imputation of missing data was only performed in the study by Daugaard et al. [17], in which LVI status was unknown in 44% of the cohort.

In the present study, we were only able to analyse LVI and EC separately. It would be interesting to evaluate the predictive value of both factors together. For example, it was not possible to assess the difference in relapse risk between LVI-positive patients with EC >50% and LVI-positive patients without EC >50%. This requires an individual patient data meta-analysis of the series included in this review.

The major strength of our present review is the systematic approach that was applied. Our methodology is in line with the Cochrane reporting standards, such as the PRISMA statement and the QUIPS tool for risk-of-bias assessment. Furthermore, a high number of participants have been included in our meta-analysis and we payed special attention to avoid the inclusion of overlapping populations. Even though methodological heterogeneity might exist, statistical heterogeneity \( \chi^2 \) was low for all meta-analyses.

Conclusions

Our present review and meta-analysis show that LVI is the strongest predictor of occult metastatic disease in CS I NSGCT. The prognostic value of EC is high, but consensus on how to use this risk factor is necessary. A cut-off value of
50% is reported in only a few studies, with contradicting results. Both EC presence and EC >50% show similar ORs for occult metastasis. This suggests that the assessment of EC presence is sufficient for the classification of EC.
