(Dated: November 29, 2009)

We study the quasiparticle interference (QPI) patterns caused by scattering off nonmagnetic, magnetic point impurities, and edge impurities, separately, in a two dimensional helical liquid, which describes the surface states of a topological insulator. The unique features associated with hexagonal warping effects are identified in the QPI patterns of charge density with nonmagnetic impurities and spin density with magnetic impurities. The symmetry properties of the QPI patterns can be used to determine the symmetry of microscopic models. The Friedel oscillation is calculated for edge impurities and the decay of the oscillation is not universal, strongly depending on Fermi energy. Some discrepancies between our theoretical results and current experimental observations are discussed.

I. INTRODUCTION

Several recent theoretical\textsuperscript{1,2,3} and experimental\textsuperscript{4,5,6,7,8,9} works have focused on a new quantum state of matter, topological insulators in three dimensions, which exhibit bulk insulating gaps (mainly of spin-orbit origin) while possess time-reversal symmetry protected gapless surface states. One of intriguing properties in this new quantum state comes from those “protected” surface states, which provide a lab-realizable condensed-matter analog of two dimensional, massless Dirac theory with “odd” number of species (Dirac cones), in the surface Brillouin zone (SBZ)\textsuperscript{10}. The charge carriers on the surfaces here, the so-called (spin) helical Dirac fermions\textsuperscript{6,11}, behave like relativistic particles with a spin locked to its momentum leading to the breakdown of the spin SU(2) rotational symmetry. This feature is sharply in contrast to graphene, where the system not only possesses an even number of Dirac cones in its spectrum, but the role of the “locked” spin is also replaced by a pseudo-spin (sublattice symmetry) and hence each Dirac cone still has two-fold spin degeneracy\textsuperscript{12}.

As a useful surface probe, recent angle-resolved photoemission spectroscopy (ARPES) experiments successfully demonstrated the surface band structures with odd number of Dirac cones\textsuperscript{12} as well as the corresponding spin helical structures near a Dirac point\textsuperscript{5,6,8}. Although the confirmed nature of the bands by ARPES suggests the quantum state to be topologically insulating, the quest for new quantum phenomena uniquely associated with such topology-protected surface states remains urgent and necessary. The usual way in solid state physics to explore the nontrivial electronic properties of helical Dirac fermion systems would be the transport measurement on the surface of a topological insulator\textsuperscript{13}. However, such a measurement may not be practically straightforward, since (i) tuning the system to the topological transport regime where the charge density vanishes is tricky, and (ii) the presence of the n-type doping from vacancy (or anti-site defects) as well as the fact that the surface states surround the sample make the results difficult to be distinguished from the bulk and surface contributions\textsuperscript{7,13}.

Alternatively, the quasiparticle interference (QPI) caused by scattering off impurities on a surface can provide a way of revealing the topological nature of the surface states\textsuperscript{14,15,16,17}. The concept of QPI is elementary in quantum mechanics. For instance, due to impurity (elastic) scattering, the interference between the incoming and outgoing waves with momenta $\mathbf{k}_i$ and $\mathbf{k}_f$, respectively, can give rise to an amplitude modulation in the local density of states (LDOS) at wavevector $\mathbf{q} = \mathbf{k}_f - \mathbf{k}_i$. Such kind of interference pattern can be observed in Fourier transform scanning tunneling spectroscopy (FT-STS) nowadays and it has been proved useful in determining the pairing nature of high-$T_c$ cuprates\textsuperscript{18}. By measuring the QPI patterns and analyzing them through a convolution of ARPES data together with a spin-dependent scattering matrix element, Roushan and et al\textsuperscript{18} were able to demonstrate the absence of backscattering in the topological surface states of Bi$_{1-x}$Sb$_x$, a key property of helical spin liquid.

Most recently, based on symmetry analysis, a new hexagonal warping term, which is absent in Bi$_{1-x}$Sb$_x$, is suggested by Liang Fu\textsuperscript{19} to explain the evolution of the Fermi surface of the effective 2D helical Dirac model describing the surface band structure of a family of 3D topological insulators, Bi$_2$X$_3$ (X=Se or Te). As measured in ARPES experiments, the shape of the Fermi surface (FS) evolves gradually from a hexagram, a hexagon, to a circle of shrinking volume, and finally meets at the Dirac point when lowering the Fermi energy. The new term leads to strong density variation around Fermi surface and also modifies the spin helical configuration. As a result, the existence of the new term can strongly modify the QPI. In other words, the QPI can provide a direct evidence to justify the model.

In this paper we systematically investigate the interference effects of a point-impurity and an edge-impurity scattering, respectively, on the LDOS in a 2D helical Dirac fermion system. We use T-matrix approach to calculate QPI spectra at a few representative energies, for emphasizing the effects of the hexagonal warping term, in the presence of a nonmagnetic/magnetic impurity. We also investigate an edge impurity by using a method gen-
eralized from 1D scattering problems with a potential barrier. Several profound features are found in this study. In a nutshell, we observe: (i) the backward scattering by nonmagnetic point impurities is topologically suppressed, just as what has been shown in 1D with a simpler empirical analysis, and the dominant interference pattern becomes that of spatial period \( 2\pi/|q_{35}| \) when going away from the Dirac regime (see Fig. 4 for the definition of \( q_{35} \)); (ii) In the presence of magnetic impurity, the QPI of charge density is very weak while that of spin density becomes strong. Near the Dirac regime, spin moments of fermions are flipped when scattering wave vector crosses \(|q| = 2|k_F|\), as demonstrated in the (z-component) spin LDOS [see Fig. 3(b)]; (iii) the mirror symmetries of the spin LDOS in the presence of in-plane magnetic impurity with spin polarization fixed along \( x \) and \( y \) directions can be used to determine the symmetry of microscopic models and to verify the presence or absence of the warping term; (iv) In the case of 1D edge impurities, the Friedel oscillation has no universal decaying function. Depending on Fermi surface energy, we show that the oscillation decays as \( 1/\sqrt{|x|} \) if the FS shape is dominated by the warping term, and as \(|x|^{-3/2}\) if the warping term is negligible. These special quantum phenomena, sharply in contrast to conventional metals, are mainly associated with the 2D helical liquid.

\section*{II. THE MODEL AND T-MATRIX FORMALISM}

We now briefly introduce our used formalism below. The explicit model we study here is written as

\[
H(k) = v(k_x \sigma_y - k_y \sigma_x) + \frac{k^2}{2m^*} + \frac{\lambda}{2} (k_+^3 + k_3^3) \sigma_z, \tag{1}
\]

where \( k_\pm \equiv k_y \pm ik_x \). \( v \) and \( \lambda \) denote Fermi velocity and hexagonal warping parameter, respectively. The Pauli matrices, \( \sigma_i \), act on spin space of fermionic quasiparticles. The form of \( H(k) \) is suitable for describing the [111] surface band structure near \( \Gamma \) point in SBZ of a 3D topological insulator Bi\(_3\)X\(_3\), and is fixed under general symmetry considerations, namely, time reversal and \( C_{3v} \) symmetries\(^{19}\). Notice that we have chosen \( x \) direction to be along \( \Gamma M \) in SBZ. The \( k \)-linear term, \( H_0 = v(k_x \sigma_y - k_y \sigma_x) \), describes an isotropic 2D helical Dirac fermions, and the \( k \)-square term causes particle-hole asymmetry. More importantly, the \( k \)-cube warping term, \( H_w = \frac{\lambda}{2} (k_+^3 + k_3^3) \sigma_z \), leads to hexagonal distortion of the Fermi surface. The resulting two energy bands now touch at the Dirac point (i.e., \( \Gamma \) point in SBZ) with dispersion relation,

\[
\epsilon_\pm(k) = \frac{k^2}{2m^*} \pm \sqrt{v^2k^2 + \frac{\lambda^2}{4}(k_+^3 + k_3^3)^2}. \tag{2}
\]

Defining the characteristic length scale \( b \equiv \sqrt{\lambda/v} \) and energy \( E^* \equiv v/b \) introduced by the hexagonal warping parameter, we draw the contours of constant energy (CCE) in momentum space in units of \( 1/b \) and single-particle density of states (DOS) of \( H(k) \), respectively, in Figs. 4 and 2.

![FIG. 2: Density of states based on the model in Eq. (1).](image)

In the numerical evaluation, we have taken \( b \equiv 1 \), \( v = 0.25 \), and \( \lambda = 0.25 \) such that the Fermi surface in 0.67\% Sn-doped Bi\(_3\)Te\(_3\) can be qualitatively reproduced, where the measured \( v = 2.55eV \cdot \AA \) and \( E_F = 1.2E^* \approx 0.3eV \). Unless otherwise stated, we will assume particle-hole symmetry, \( i.e., m^* \rightarrow \infty \). As shown in Figs. 4 and 2 when \( \omega \ll 0.2 \) the DOS is almost linear in \( \omega \) with more circular FS, while when \( \omega \gg 0.2 \) the DOS behaves like \( \omega^{-1/3} \) with hexagram-like FS.

In addition to the CCE, we also present the spin-resolved FS with two representative energies used through out this paper, \( E_D = 0.05eV \) (0.2\( E^* \)) and \( E_W = 0.3eV \) (1.2\( E^* \)) in Fig. 3. They clearly demonstrate the “spin-helical” nature of the 2D fermions, which is indeed essential when analyzing the QPI spectra later. In particular, as \( \omega = E_W \), non-vanishing spin moments along \( z \) direction (out of surface plane) are present mainly due to \( \sigma_z \) in the warping term, which is directly proportional to electron’s spin. Notice that the spin moment
must be in-plane along $\Gamma M$ (i.e., at each sharp vertex of the FS), which is a consequence of the odd parity of $\sigma_z$ under the mirror operation $y \to -y$.

![Figure 3: Spin textures around the Fermi surface at $\omega = 0.3$eV in (a) and at $\omega = 0.05$eV (b).](image)

Next, we consider the quasiparticle scattering problem within the $T$-matrix approach\[20\]. For a general $N$-impurity problem, the impurity-induced electronic Green's function is given by

$$
\delta G(\mathbf{r}, \mathbf{r}', \omega) = \sum_{i,j=1}^{N} G_{0}(\mathbf{r}, \mathbf{r}_i, \omega)T(\mathbf{r}_i, \mathbf{r}_j, \omega)G_{0}(\mathbf{r}_j, \mathbf{r}', \omega),
$$

(3)

where the $T$-matrix obeys the Bethe-Salpeter equation

$$
T(\mathbf{r}_i, \mathbf{r}_j, \omega) = V_{r_i} \delta_{r_i, r_j} + V_{r_i} \sum_{k=1}^{N} G_{0}(\mathbf{r}_i, \mathbf{r}_k, \omega)T(\mathbf{r}_k, \mathbf{r}_j, \omega),
$$

(4)

and the Green's function (in momentum space) of the clean system is

$$
G_{0}(\mathbf{k}, \omega) = [\omega + i\eta - H(\mathbf{k})]^{-1}.
$$

(5)

In the case of a single point nonmagnetic (magnetic) impurity located at the origin, the scattering potential is simply $V_r = \delta_{r,0}V_{NI}\sigma_0$ ($\delta_{r,0}V_{MI}\sigma$), where $\sigma_0$ is a $2 \times 2$ identity matrix. Taking the advantages of the translational symmetry of the clean system and momentum independence of the scattering potential (for instance, $V_{\mathbf{k},\mathbf{k}'} = V_{NI}\sigma_0/N \equiv \hat{V}$ in the nonmagnetic case), one can simplify the formula as

$$
T(\omega) = [1 - \hat{V} \int_{\epsilon_{\text{r}}(\mathbf{k}) < \Lambda} \frac{d^2k}{(2\pi)^2} G_{0}(\mathbf{k}, \omega)]^{-1},
$$

(6)

and hence around the impurity, spatial oscillations of the local density of states are induced. To see the interference effects due to impurity scattering, it is more convenient to compute the Fourier-transformed (induced) local density of states (FT-LDOS),

$$
\int d^2r e^{i\mathbf{q} \cdot \mathbf{r}}\delta\rho(\mathbf{r}, \omega) \sim \delta\rho(\mathbf{q}, \omega)
$$

$$
= \frac{i}{2\pi} \int_{\epsilon_{\text{r}}(\mathbf{k}) < \Lambda} \frac{d^2k}{(2\pi)^2} g(\mathbf{k}, \mathbf{q}, \omega),
$$

(7)

where $g(\mathbf{k}, \mathbf{q}, \omega) = \sum_{i=1}^{Z} \delta G_{ii}(\mathbf{k} + \mathbf{q}, \omega) - \delta G^{*}_{ii}(\mathbf{k} + \mathbf{q}, \omega)$. In general, $\rho(\mathbf{q}, \omega)$ is a complex number. If we separately define the symmetric and antisymmetric parts of the LDOS as

$$
\rho^{\pm}(x, y, \omega) = \frac{\rho(x, y, \omega) + \rho(-x, -y, \omega)}{2}
$$

and

$$
\rho^{\pm}(x, y, \omega) = \frac{\rho(x, y, \omega) - \rho(-x, -y, \omega)}{2},
$$

the real and imaginary parts of $\rho(\mathbf{q}, \omega)$ simply describe the symmetric and antisymmetric parts of the LDOS respectively. In the following discussion of the effects of nonmagnetic impurities, since the real part is at least two orders of magnitude larger than the imaginary part, we focus on the former. In our calculation, we have introduced an energy cutoff $\Lambda = 4E_{\text{F}}$ when integrating over momentum. Our main results do not sensitively depend on the chosen $\Lambda$ as long as $\Lambda$ is much greater than the impurity scattering strength. Moreover, the spin-resolved FT-LDOS can be obtained if we separate each component $i$ when evaluating function $g(\mathbf{k}, \mathbf{q}, \omega)$, i.e., $i = 1$ for spin-up and $i = 2$ for spin-down.

In principle, for the case of an edge-impurity scattering, one can use Eqs. (3-5) to compute the LDOS from $\delta\rho(\mathbf{r}, \omega) = -\text{Im} \sum_{\mathbf{r}} \delta G_{ii}(\mathbf{r}, \mathbf{r}, \omega)/\tau$ in a straightforward manner. However, it is more convenient, without loss of generality, to treat this scattering problem by using an analogy of the elementary scattering problem with a barrier potential in one dimension, which is directly based on the wave function point of view. Our method is briefly sketched in section III C.

### III. NUMERICAL RESULTS

We compute the induced LDOS at selected $\omega$, $\delta\rho(\mathbf{q}, \omega)$, for the nonmagnetic/magnetic impurity case, and $\rho(\mathbf{q}, \omega)$, for the edge impurity case. Our numerical results are reported for a representative potential scattering strength, $V_{NI} = V_{MI} = V_0 = 0.05$eV. The chosen imaginary part of the energy $\eta = 10$meV has been checked to be insensitive to the observed main features.
Also, in our analysis a 400 × 400 momentum grid is used in (−π, π) × (−π, π) k space and 200 discrete points are displayed within (−π, π) along each direction in q space. Note that the relevant range of SBZ in experiments would correspond to about 5.5 times larger than 2π.

A. Nonmagnetic point impurity

We first consider the interference patterns in a 2D helical liquid with a nonmagnetic point impurity. Starting with ω = EW = 0.3eV far away from the Dirac point (ω = 0), the shape of the FS is now like a hexagon. This is just the energy range where experiment may achieve without subtle chemical tuning near the surface of a 3D topological insulator. As we will see later, such energy range indeed provide a better chance to reveal the topological nature of the helical Fermion system. In Fig. 4 the spectral function, \( A(\mathbf{k}, \omega) = -\frac{i}{2} \text{Im} \text{Tr} G_0(\mathbf{k}, \omega) \) at ω = 0.3eV, are plotted with scattering vectors on top, which are expected to associate with high joint DOS on a constant-energy contour.

As shown in Fig. 5 (a), the interference pattern includes six sharp peaks along ΓK outside a complicated, hexagon-shaped pattern centered at Γ and other six weaker peaks along ΓM slightly inside the hexagon. These two sets of peaks simply correspond to \((±q_{13}, ±q_{25}, ±q_{35})\) and \((±q_{12}, ±q_{21}, ±q_{34})\), respectively, as indicated in Fig. 4. However, the most prominent feature we observed here is that those expected peaks, which correspond to the \((±q_{14}, ±q_{25}, ±q_{36})\), are entirely absent. This apparent puzzle can be understood by the absence of backscattering between two time reversal connected partners, as shown in (14). Suppose in our scattering problem, |\(\mathbf{k}, \uparrow\rangle\rangle is the incoming state, while its time-reversal partner, |\(-\mathbf{k}, \downarrow\rangle\rangle \propto \mathcal{T}\langle\mathbf{k}, \downarrow\rangle\rangle, is the outgoing state. \(\mathcal{T}\) is the time-reversal operator with the property \(\mathcal{T}^2 = -1\). For any time-reversal invariant and hermitian operator \(\hat{V}\) (such as our nonmagnetic scattering potential), we have

\[
\langle -\mathbf{k}, \downarrow | \hat{V} | \mathbf{k}, \uparrow \rangle = \langle \mathcal{T} \langle \mathbf{k}, \uparrow | \hat{V} | \mathbf{k}, \downarrow \rangle \rangle = \langle \mathcal{T} \hat{V} | \mathbf{k}, \uparrow \rangle \rangle | \mathcal{T}^2 | \mathbf{k}, \uparrow \rangle \rangle
\]

\[
= -\langle -\mathbf{k}, \uparrow | \hat{V} \mathcal{T} | \mathbf{k}, \downarrow \rangle \rangle = -\langle -\mathbf{k}, \uparrow | \hat{V} \mathcal{T} | \mathbf{k}, \downarrow \rangle \rangle^* \]

\[
= -\langle -\mathbf{k}, \uparrow | \mathcal{T} \hat{V} | \mathbf{k}, \downarrow \rangle \rangle = -\langle -\mathbf{k}, \uparrow | \mathcal{T} \hat{V} | \mathbf{k}, \downarrow \rangle \rangle^* \]

\[
= -\langle -\mathbf{k}, \downarrow | \hat{V} | \mathbf{k}, \uparrow \rangle \rangle = 0. \quad (8)
\]

In other words, the backward scattering between time-reversal partners is not allowed. This naturally explains the absence of the interference peaks, corresponding to \(q_{36}\) (and of the same type). Such a behavior sharply distinguishes the 2D helical Fermion system from a conventional metal. In addition, it might be worth mentioning here that the angles of our observed interference peaks, \(q_{35}\), appear different from the experiment done by Zhang et al. (10), where there exhibits six peaks along ΓM, instead of ΓK as displayed in Fig. 5 (a). We would like to postpone this issue to the discussion section.

When further increasing the Fermi level, the vertices become sharper and the joint DOS at fixed \(q_{35}\), however, is suppressed. As a result, the six peaks seen in Fig. 5 (a) diminish and the replaced feature turns out to
be the other six peaks at fixed $q'\xi$, corresponding to the scattering vectors connecting between second neighbor of the convex parts of the FS (see Fig. 6), which were observed in recent experiments\textsuperscript{12}. On the other hand, when the Fermi level gets closer to the Dirac point, for instance, $\omega = 0.05eV$, the interference pattern becomes almost isotropic with obvious stronger weight within a circular region, as shown in Fig. 6(b). The size of the region can be estimated to be a disk with twice longer radius of the corresponding circular FS of the system. This is basically consistent with our CCE picture (see Fig. 1), where no finite, specific $q$ vectors can be picked out when $\omega$ approaches to the Dirac point.

![Image](image1.png)

**FIG. 6:** The real part of the Fourier transform of local density of states in the case of single nonmagnetic point impurity at $\omega = 0.375eV$.

**B. Classical magnetic point impurity**

Next, we study the QPI induced by a time-reversal symmetry breaker, a magnetic impurity\textsuperscript{21}. We focus on the effects of a classical magnetic impurity so that the Kondo physics is ignored. In the following, after describing general features of the QPI with a magnetic impurity, we will discuss the cases separately when the impurity moment is fixed along $x$, $y$, and $z$ directions.

Different from nonmagnetic impurities, a weak magnetic impurity has very little effect on the charge density of the system, namely, instead of having $\delta\rho_\uparrow(q, \omega) = \delta\rho_\downarrow(q, \omega)$ as in the nonmagnetic impurity case, we have $\delta\rho_\uparrow(q, \omega) \approx -\delta\rho_\downarrow(q, \omega)$ . This effect can be easily understood. Suppose we are considering an impurity moment along the $z$-direction, then the spin-up electrons and spin-down electrons see two scattering potentials of opposite signs. In the lowest order of perturbation theory, the scattering amplitude of the spin-up and spin-down electrons thus differ by a minus sign so that the total interference pattern of the charge density vanishes almost everywhere. The same argument no longer holds if higher orders of perturbation are included. For the model considered here, we can explicitly prove the above statement. Assuming $V \ll \omega$, the approximation $T(\omega) \approx V$ becomes sufficiently accurate. In this case (impurity moment along $z$-direction), we have

\begin{align}
\text{Tr}[\delta G(q, \omega)] &\approx \int \frac{d^2k}{(2\pi)^2} \text{Tr}[G_0(k, \omega)\hat{V}G_0(k + q, \omega)] \\
&= V \int \frac{d^2k}{(2\pi)^2} \text{Tr}[(\omega\sigma_0 - k_y\sigma_x + k_z\sigma_y + \frac{3}{2}(k_x^2 + k_y^2))\sigma_z(\omega\sigma_0 - (k_y + q_y)\sigma_x + (k_x + q_x)\sigma_y + \frac{3}{2}((k + q)^2 + (k + q)^2)\sigma_z)] \\
&= V \int \frac{d^2k}{(2\pi)^2} \frac{(k_x^2 + k_y^2 + (k + q)^2 + (k + q)^2 + ik_y(k_x + q_x) - ik_x(k_y + q_y))}{((\omega + i\eta)^2 - \epsilon^2_+(k))(\omega + i\eta)^2 - \epsilon^2_+(k + q))} \\
&= 0.
\end{align}

(9)
The last equality is achieved by shifting the origin to \((q_x, q_y)\), changing the integrated variables \(k \rightarrow -k\), and taking the advantage that \(\epsilon_+ (k) = \epsilon_+ (-k)\). Similar derivations hold for the impurity moment along \(x\) and \(y\)-directions. If the second order term \(O(V^2)\) is included in the \(T\)-matrix, the cancellation becomes no longer valid, and there is indeed small but finite charge LDOS pattern in the system. In Fig. 6, we plot the numerical results of \(\delta \rho(\mathbf{q}, \omega)\) at \(\omega = 0.05, 0.3\). It is clear that The amplitude of charge density variation by magnetic impurities in Fig. 7 is two orders of magnitude smaller than that shown in Fig. 4 by nonmagnetic impurities.

Therefore, for the magnetic impurity case, we should choose a time-reversal breaking observable to study the interference, and a natural choice is the spin local density of states (SLDOS), defined by

\[
\tilde{S}(\mathbf{r}, \omega) = -\frac{1}{\pi} \text{Im} \left[ \int dt \theta(t) \langle \psi_\alpha (\mathbf{r}, t) \sigma^\alpha \beta \psi^\dagger_\beta (\mathbf{r}, 0) \rangle e^{i\omega t} \right],
\]

where \(c^\dagger_\beta (\mathbf{r}, t)\) creates an electron with spin polarization \(\alpha\) at position \(\mathbf{r}\) and time \(t\). From now on we will only focus on the FT of the \(z\)-component SLDOS.

\[
\mathbf{q} = (q_x, q_y)
\]

**FIG. 8:** The real part of the Fourier transform of spin local density of states in the case of single magnetic point impurity with its spin polarized along the \(z\)-axis at \(\omega = 0.3\) eV, and \(\omega = 0.05\) eV.

In the case of nonmagnetic impurity, we have demonstrated the absence of interference between \(|\mathbf{k}, \uparrow\rangle\) and \(|-\mathbf{k}, \downarrow\rangle\), which form a time-reversal pair. Physically, a time-reversal breaker such as a magnetic impurity can lift this ban on the backscattering. Similar to Eq. (8), it is easy to show that \(\langle -\mathbf{k}, \downarrow | \hat{V} | \mathbf{k}, \uparrow \rangle \neq 0\) due to \(T \sigma_1 T^{-1} = -\sigma_1\). This feature is universal in all of our figures for magnetic impurity. Taking Fig. 8(a) as an example, we can compare it with Fig. 5(a) and notice that although they have common features, the points in the FT-SLDOS that associate with the \(2k_F\) backscattering scattering vectors is only present \((\pm \mathbf{q}_{14}, \pm \mathbf{q}_{25}, \pm \mathbf{q}_{36})\) (see Fig. 4) in the magnetic scattering. We can also compare Fig. 8(b) for magnetic scattering with Fig. 5(b) for nonmagnetic scattering when \(\omega = 0.05\) eV. In the latter case, the interference strength universally decays quickly after reaching the boundary of the circle; while in the former case, the interference strength reaches a negative peak across the boundary, indicating a scattering that flips spin moments of the quasiparticles.

**FIG. 9:** The (a) real part and the (b) imaginary part of the Fourier transform of spin local density of states in the case of single magnetic point impurity with its spin polarized along the \(y\)-axis at \(\omega = 0.3\) eV.

Now, we discuss the QPI by magnetic impurities with in-plane magnetic moments. In this case, a unique feature rises in the FT-SLDOS. As shown in Fig. 9 and in Fig. 10, at \(\omega = 0.3\) we plot two figures, which correspond to the real and imaginary parts of the FT-SLDOS separately. Similar to the LDOS, the real and imaginary parts correspond to the symmetric and antisymmetric parts of \(S_z(x, y, t)\) respectively. For magnetic impurity with magnetic moment along \(z\) axis, the symmetric part dominates and the antisymmetric part is either vanishing or orders of magnitude smaller than the symmetric part. However, here as shown in Fig. 9 the antisymmetric part is about three times larger than the symmetric part.
can be understood as follows. An inversion transformation in a two dimensional plane, i.e. $(x, y) \rightarrow (-x, -y)$ takes $\hat{\sigma}_z(x, y, t) \rightarrow \hat{\sigma}_z(-x, -y, t)$ and $\hat{\sigma}_{x,y}(x, y, t) \rightarrow -\hat{\sigma}_{x,y}(-x, -y, t)$. Therefore, under this transformation, the Hamiltonian without the warping term in the presence of magnetic impurities with in-plane magnetic moments transforms as $H(V_0) \rightarrow H(-V_0)$, where $V_0$ is the coupling strength of magnetic impurity. Thus, from this symmetry, if we consider $S_z(x,y,t)$ as function of $V_0$ as well, we have $S_z(x,y,t,V_0) = S_z(-x,-y,t,-V_0)$. Therefore, the first order correction from the scattering potential vanishes for the symmetry part. In the presence of the warping term, there is no such an exact symmetry argument. Nevertheless, the symmetric part is still much smaller than the antisymmetric part. In the following, we will first focus on the antisymmetric part.

Fig. 10(b) shows the (antisymmetric) FT-interference pattern for the impurity moment along the $y$-axis at $\omega = 0.3$ eV. We find that the strongest interference appears at wave vector $\pm q_{z1}$ in Fig. 10(b) ($q_{ij}$ is defined in Fig. 10). Moreover, $q_{13}$ and $q_{35}$ do not present as strong peaks, in contrast with the cases of the nonmagnetic impurity and the magnetic impurity spin along $z$-axis. In addition, a remarkable feature in the interference pattern is that $S_z^A(q,\omega)$ is zero on the line $q_y = 0$. This is caused by an exact symmetry of the system which dictates $S_z(x,y,t) = -S_z(x,-y,t)$. This point will be discussed later in length. Fig. 10(b) shows the (antisymmetric) FT-interference pattern for the impurity spin along the $x$-axis at $\omega = 0.3$ eV. We can see that the strongest interference is associated with the vertex-to-vertex wave vectors $q_{13}$ and $q_{35}$. The strong peak at $q_{z1}$ does not appear and we have $S_z^A(0,q_y,\omega)$ vanishing. This result stems from an approximate equality $S_z(x,y,t) \approx S_z(x,-y,t)$, a point of which will be discussed next.

We can understand above detailed features in the SL-DOS from the symmetry analysis of the model. The model obviously has the time-reversal symmetry and the three-fold rotation symmetry. Moreover, the model also preserves the $y \rightarrow -y$ mirror symmetry ($m_y$) but breaks the $x \rightarrow -x$ mirror symmetry ($m_x$), as can be seen in the warping term. Explicitly, the $m_x$ operator takes $k_z$ to $k_\mp$ and $\sigma_z$ to $-\sigma_z$, which changes the sign of the warping term. Now, let us consider the system in the presence of a magnetic impurity with its spin along $y$-axis. Since $s_y \rightarrow s_y$ under $m_y$, the whole system still preserves the mirror symmetry $m_y$. This symmetry directly leads to

$$S_z(x, y, \omega) = -S_z(-x, -y, \omega). \quad (11)$$

This symmetry property is clearly demonstrated in Figs. 10(a) and (b). On the other hand, if the impurity spin is fixed along the $x$-direction, the system does NOT have $m_x$ symmetry and we have $S_z(x,y,\omega) \neq -S_z(-x,-y,\omega)$. This feature is also demonstrated in Fig. 10(a). If we had $S_z(x,y,\omega) = -S_z(-x,-y,\omega)$, we should have $S_z^A(q_x,q_y,\omega) = -S_z^A(-q_x,q_y,\omega)$ or $S_z(x,y,\omega) = S_z(-x,y,\omega) = 0$. However, in Fig. 10(a), it is clear that $S_z^A(q_x,q_y,\omega) = S_z^A(-q_x,q_y,\omega) \neq 0$.

The above symmetry is a very important property of the model. In fact, to simply account for the shape of FS, we may also artificially make the Fermi velocity strongly angle dependent while keeping the same spin texture where all spins on the FS are in-plane without tilting. For instance, we can write

$$\hat{H}(k) = v(k)(k_x\sigma_y - k_y\sigma_x) + \frac{k^2}{2m^*}, \quad (12)$$

where $v(k) = \sqrt{v^2 + \lambda^2 k^4 \sin^2(3\theta)}$, with $\theta$ being the azimuthal angle with respect to $x$ axis $(\Gamma M)$. This model (the in-plane model) has the same dispersion as the model in Eq. 4 but has only in-plane spin texture. The symmetries of the SL-DOS here can help us distinguish these two models. For example, one can check these two equations experimentally: $S_z(x,y,\omega) = -S_z(-x,-y,\omega)$ for impurity spin polarized along $y$ axis and $S_z(x,y,\omega) = -S_z(-x,-y,\omega)$ for impurity spin polarized along $x$ axis. If both are held, then the in-plane model suffices; but if only one is held, we may need an out of plane spin (warping) term. In Table 1 we list the property of SL-DOS in the two models, Eq. 4 and Eq. 12, in the presence of different types of impurities and under basic symmetry operations.
Table I: The symmetry of \( S_z(x, y, t) \) under symmetry operations of mirror-x (\( m_x \)), mirror-y (\( m_y \)) and three-fold rotation about z-axis (\( C_3 \)) with impurity spin along three axes. (a) is for the model in Eq.(11) and (b) the model in Eq.(12). ’1’ means symmetric; ’-1’ means antisymmetric and ’\( \times \)’ means neither of the above. The ’\( \approx \)’ means it is symmetric (antisymmetric) in the weak impurity strength approximation.

C. Nonmagnetic edge impurity

Step atomic roughness on a surface may be locally idealized into an edge impurity, that is, an infinite line with different but uniform potential on two sides. An edge impurity in a 2D conventional Fermi gas is known to give rise to Friedel oscillation at fixed energy in the LDOS. This oscillation can simply be understood as an interference pattern between the incoming plane wave and the reflected wave by the 1D edge. The major contribution comes from the two opposite reflected waves by the 1D edge. The major contribution comes from the two opposite \( k \)-points on the constant energy contour, \( \pm k_F \), and the oscillation has the wavenumber \( 2|k_F| \) while decaying as a form \( 1/\sqrt{d} \) where \( d \) is the distance from the edge impurity. The same picture is no longer valid if the state at \( k \) and \(-k\) do not scatter with each other, a case for the surface states of a 3D topological insulator where the backscattering is forbidden by the time-reversal symmetry. Therefore the oscillation is expected to decay much faster and thus practically absent in an STM experiment. The ’absence’ of the Friedel oscillation is considered as a sign of (spin) helical Dirac Fermion systems. However, the oscillation has been observed in STM experiments. The apparent discrepancy between theory and experiment was soon claimed to be superficial and explained by the hexagon-shape of the FS. In this subsection an exact calculation is performed to test this physical picture.

We consider that the edge impurity is fixed along y axis and the system has zero potential for \( x < 0 \) and uniform potential \( V \) for \( x > 0 \). A general quantum state on the left hand side (LHS) takes the form

\[
\psi(k_x, k_y; x, y) = \frac{\phi_0(k_x, k_y; x, y) + r\phi_0(-k_x, k_y; x, y)}{\sqrt{1 + |r|^2}},
\]

and the LDOS is

\[
\rho(x, \omega) = \int_{k_x > 0} \frac{d^2k}{(2\pi)^2} |\psi(k_x, k_y; x, y)|^2 \delta(\omega - \epsilon_+(k_x, k_y)).
\]

The reflection amplitude \( r \) can be obtained together with the transmission amplitude \( t \) by matching the boundary condition at the edge, namely,

\[
\phi_0(k_x, k_y; 0, y) + r\phi_0(-k_x, k_y; 0, y) = t\phi_0(k''_x, k_y; 0, y),
\]

where \( k''_x \) is fixed by the energy conservation \( \epsilon(k_x, k_y) = \epsilon(k''_x, k_y) - V \).

Fig. 11(a) shows the FT-LDOS for the LHS of the edge impurity at \( \omega = 0.5 \). We can clearly identify the two peaks in the interference associated with \( q_x = 2k_2 \) and \( q_x = 2k_3 \), defined in Fig. 11(b). No feature is present at \( q_x = 2k_1 \), reflecting the absence of backscattering. The spatial dependence of the oscillation, a real space LDOS, is given in Fig. 12(a). A clear beating pattern can be seen with spatial period \( \sim (k_3 - k_2)^{-1} \). The oscillation decays like \( 1/|x|^{\alpha} \) where \( \alpha \sim 0.46 \), qualitatively matching the theoretical prediction in the large \( |x| \) limit. When \( |x| \) is large enough, the stationary points approximation tells us that, if the edge impurity is along the y-axis, the interference pattern is dominated by the \( k \)-points where \( k_x \) reaches local minimum or maximum. In our model, \( k_{3(3)} \) are the points corresponding to the minimum (maximum) of \( k_x \) on the contour of constant energy. However, the existence of such extrema depends on \( \omega \). If \( \omega \) is small enough, the extrema \( k_{2,3} \) disappear and we are left with only \( k_1 \). Since \( k_1 \) is not allowed to scatter with its time-reversal partner, the decaying of Friedel oscillation becomes \( |x|^{-3/2} \) at large \( |x| \) [see Fig. 12(b)]. Therefore, there is no universal function for the oscillation decay.

![Figure 11](image-url)
The decay depends on the values of parameters. There are two inherent length scales in the model: \( b = \sqrt{\lambda/v} \) and \( b' = v/\omega \). If \( b > 1.48b' \), the energy contour is a hexagram and an \( 1/\sqrt{|x|} \) decay of the oscillation appears, while if \( b \ll b' \), we have a nearly circular FS and the decay of oscillation takes the form \( \rho(x) \sim |x|^{-3/2} \). In the intermediate range, the oscillation varies. For example, at \( b = 1.2b' \) (\( \omega = 0.3 \)), the oscillation decays exponentially for \( |x| < 100b \) but close to \( |x|^{-3/2} \) for \( |x| > 200b \).

FIG. 12: The real space interference pattern for the edge impurity (\( V = -0.1 \)) at (a) \( \omega = 0.5eV \) and (b) \( \omega = 0.05eV \). The density fluctuation \( \delta\rho \) is defined as \( \delta\rho = \rho - \rho_0 = \rho - 1 \). The position \( x \) is in units of \( b \).

FIG. 13: Fitting the experimental data of Ref.16 using different oscillating functions. The experimental energy -62meV corresponds to \( \sim 0.25eV \) in our units. In the exponential fit, \( d = 107A \).

In experiments on topological insulators, the Fermi level of the sample in general is closer to the bottom of the conduction band and is far away from the Dirac point. Such a system with finite density of states may provide enough screening effect to Coulomb interaction between surface electrons. Moreover, attempting to tune the Fermi level lower by a metallic gate may also lead to the same phenomenon, turning interaction between electrons into irrelevant regime.

(ii) In real systems, there is no ’purely magnetic’ impurity. A magnetic impurity should also have a non-magnetic component. This fact does not change our results obtained for magnetic impurities. In the parameter region we choose, the weak impurity approximation is always valid (see a detailed discussion of this approximation in the Appendix), the non-magnetic impurity only leads to the charge density modulation and has little effect on the SLDOS. Namely, the magnetic part of impurity is solely responsible for the SLDOS.

(iii) As we noticed in section III A, the STM experiment done by Zhang et al15 on [111] surface of Bi\(_2\)Te\(_3\) exhibited six peaks in FT-LDOS for the case of nonmagnetic impurities. The experimental result differs from our results shown in Fig. 1(a) by a 30 degrees of rotation. However, this discrepancy can be understood by noticing that in the energy range where they observed the clear interference patterns (50meV~400meV), the surface density of states are mixed with bulk states along \( \Gamma M \). Consequently, due to the superposition of waves with various wavelengths the interference patterns are simply smeared out in these regions. Instead of a full FS we considered here, the dominant interference patterns are then from other unmixed parts of the FS, \( i.e. \), the parts along \( \Gamma K \).

(iv) In an STM experiment done by Alpichshev et al16 the decaying behavior of the Friedel oscillation was claimed to be \( 1/|x| \). However, in the case of 1D edge impurities, our calculation shows \( 1/|x|^{1/2} \) behavior if the FS shape is dominated by the warping term, and \( |x|^{-3/2} \) if the warping term is negligible. We believe there are two possible sources of the discrepancy. First, we notice that a simple fitting to the first several periods of oscil-
In conclusion, we have investigated the quasiparticle scattering in a 2D helical liquid in the presence of nonmagnetic/magnetic point impurity or an nonmagnetic edge impurity. The inclusion of the hexagonal warping term in our system not only inherits the nature of the k-linear helical liquid but also sharpens our features mentioned above by distorting the shape of the FS. More importantly, it requires an out of plane spin texture and can be distinguished from other systems with examination of the mirror symmetries when the magnetic point impurity with in-plane spin moment is present. The absence (presence) of spots in FT-LDOS (FT-SLDOS), corresponding to the backscattering interference, are the essential features to confirm the topological nature of the helical liquid. The results in our work, as may be detected by STM experiments, can be a useful quantum signature, which is uniquely associated with this new phase of matter, a 3D topological insulator.

Acknowledgments

APPENDIX A: THE WEAK IMPURITY STRENGTH APPROXIMATION

For the parameter we used throughout the paper, the scattering strength is relatively small (i.e., $V_0\rho(\omega) \ll 1$). In this limit the approximation $T(\omega) \approx V$ is considerably accurate (less than 3% error in our case), and many approximate equalities may be derived thereof. This subsection is devoted to explicitly deriving these relations.

First we prove that for a purely magnetic impurity, the induced (charge) LDOS is almost zero everywhere. We prove this by showing $\text{Tr}[\delta G(\mathbf{q}, \omega)] \approx 0$. Within the approximation, we have

\[
\text{Tr}[\delta G(\mathbf{q}, \omega)] \approx \int \frac{d^2k}{4\pi^2} \text{Tr}[\hat{G}(\mathbf{k})\hat{V}\hat{G}(\mathbf{k} + \mathbf{q}, \omega)]
= V_0 \int \frac{d^2k}{4\pi^2} \text{Tr}[\hat{G}(\mathbf{k}, \omega)\sigma_i \hat{G}(\mathbf{k} + \mathbf{q}, \omega)].
\]

(A1)

In the equation above we do not specify the spin polarization of the impurity and the result is general. Noticing that the system is invariant under time reversal operation ($C = i\sigma_y$), i.e., $CH(\mathbf{k})C^{-1} = HT(-\mathbf{k})$ and that a magnetic impurity changes sign under the same operation, i.e., $C\sigma_i C^{-1} = -\sigma_i^T$, we have

\[
\int \frac{d^2k}{4\pi^2} \text{Tr}[G_0(\mathbf{k}, \omega)\sigma_i G_0(\mathbf{k} + \mathbf{q}, \omega)]
= \frac{d^2k}{4\pi^2} \text{Tr}[CG_0(\mathbf{k}, \omega)\sigma_i G_0(\mathbf{k} + b\mathbf{q}, \omega)C^{-1}]
= -\int \frac{d^2k}{4\pi^2} \text{Tr}[\hat{G}_0^T(-\mathbf{k}, \omega)\sigma_i^T \hat{G}_0^T(-\mathbf{k} - \mathbf{q}, \omega)]
= -\int \frac{d^2k}{4\pi^2} \text{Tr}[G_0(-\mathbf{k} - \mathbf{q}, \omega)\sigma_i G_0(-\mathbf{k}, \omega)]
= 0. \quad (A2)
\]

The last equality may be understood after changing variables $\mathbf{k} \rightarrow -\mathbf{k} - \mathbf{q}$.

Next we show that the approximate symmetries listed in TableI(a) hold within the same approximation. According to the table, we have, for impurity spin (again it is a purely magnetic impurity) along the $z$-axis, the SLDOS $S_z(x, y, t) \approx S_z(-x, y, t)$, which is equivalent to $S_z(q_x, q_y, \omega) \approx S_z(-q_x, q_y, \omega)$. This may be derived in the following way:

\[
S_z(q_x, q_y, \omega) = \text{Tr}[\delta G(\mathbf{q}, \omega)\sigma_z] \approx \int \frac{d^2k}{(2\pi)^2} \text{Tr}[\hat{G}_0(\mathbf{k}, \omega)\hat{V}\hat{G}_0(\mathbf{k} + \mathbf{q}, \omega)\sigma_z]
= V \int \frac{d^2k}{(2\pi)^2} \text{Tr}[\hat{G}_0(\mathbf{k}, \omega)(\omega \sigma_0 - k_y \sigma_x + k_z \sigma_y + \frac{\lambda^2}{4}(k_x^2 + k_y^2))\sigma_z
\]
\[
\approx V \int \frac{d^2k}{(2\pi)^2} \frac{\omega^2 + k_y(k_y + q_y) + k_x(k_x + q_x) + \frac{\lambda^2}{4}(k_x^2 + k_y^2)}{(\omega + i\eta)^2 - \epsilon_\mathbf{k}^2(\mathbf{k} + \mathbf{q})^2} \approx S_z(-q_x, q_y, \omega). \quad (A3)
\]

In deriving the last equality, we notice that $\epsilon(k_x, k_y) = \epsilon(-k_x, k_y)$ and change variables as $k_x \rightarrow -k_x$. In the second column of TableI(a), we find $S_z(x, y, t) \approx S_z(x, -y, t)$ for the impurity spin in $x$ and $z$ directions. Since $\sigma_y H(k_x, k_y) = H(-k_x, -k_y)$, we have

\[
\sigma_y H(k_x, k_y) \approx H(k_x, -k_y), \quad \text{for } S_z(q_x, q_y, \omega)
\]

(A4)

A simple consequence of the weak impurity approximation is a linear combination of LDOS or SLDOS when
there is more than one impurity, or an impurity that has both magnetic and non-magnetic parts. In the latter case, one can simply add up the FT-LDOS and FT-SLDOS for each part to obtain the total configuration. But as discussed in the text, the magnetic part contributes very little to the LDOS, and the non-magnetic part does not contribute to the SLDOS (obvious from time-reversal symmetry), most of the results for the magnetic impurity part remain the same.

APPENDIX B: FRIEDEL OSCILLATION AT FIXED ENERGY IN A 2D DIRAC METAL BY AN EDGE IMPURITY

In the text, we stated that when the energy lies within the ‘Dirac regime’ (e.g., when $\omega = 0.05eV$), the decay of the Friedel oscillation takes the form $\rho(x, \omega) \propto |x|^{-3/2}$. In this subsection the asymptotic expression for the LDOS oscillation caused by an edge impurity in a 2D Dirac metal is derived. The Hamiltonian takes the form

$$H(k) = v k \cdot \sigma.$$  \hfill (B1)

This form is equivalent to the linear part in Eq(1) up to a global spin-SU(2) gauge. The Hamiltonian may be easily solved: (only positive energy solutions are listed)

$$\epsilon(k) = v k,$$

$$\psi(k) = (e^{i\phi/2}, e^{-i\phi/2})^T \sqrt{2},$$ \hfill (B2)

where $\phi$ being the polar angle. Now let us suppose that the space is divided in half at $x = 0$ (i.e., the edge impurity is along y-axis), and the right side has a uniform potential of $V = -V_0$ where $V_0 > 0$. The continuity of the wavefunction at $x = 0$ gives

$$\begin{pmatrix} e^{i\phi/2} \\ e^{-i\phi/2} \end{pmatrix} + r(\phi) \begin{pmatrix} e^{i\phi'/2} \\ e^{-i\phi'/2} \end{pmatrix} = t(\phi) \begin{pmatrix} e^{i\phi''/2} \\ e^{-i\phi''/2} \end{pmatrix}.$$ \hfill (B3)

For the refraction part, $\phi''$ is fixed by

$$\frac{vk + V_0}{v} \sin(\phi'') = k \sin(\phi).$$ \hfill (B4)

And for the reflection part, $\phi' = \pi - \phi$. Solving these equations, one has

$$r = -\frac{\sin(\frac{\pi - \phi''}{2})}{\cos(\frac{\phi + \phi''}{2})},$$ \hfill (B5)

$$t = \frac{\cos(\phi)}{\cos(\frac{\phi + \phi''}{2})}.$$

Using the stationary phase approximation, we know that after integrating all the $k$'s on the fixed energy contour $\omega = vk$ to obtain the LDOS, the contribution mainly comes from the $k$'s that have small polar angles. At small angles, the reflection index takes the form

$$r(\phi) \approx -\frac{V_0}{2(V_0 + vk)} \phi.$$ \hfill (B6)

Using Eq(14), we have

$$\rho(x, \omega) \approx \int_{-\pi/2}^{\pi/2} \frac{d\phi}{2\pi} \frac{V_0}{2V_0 + \omega} \phi^2 \sin(\frac{2\omega}{v} \cos(\phi)x)$$

$$\approx \int_{-\infty}^{\infty} \frac{d\phi}{2\pi} \frac{V_0}{V_0 + \omega} \text{Im}[\phi^2 e^{i2\omega \cos(\phi)x}]$$

$$\approx \frac{V_0}{V_0 + \omega} \sqrt{\pi} \frac{2\omega}{v} \frac{1}{4} \frac{2\omega}{v} (\frac{2\omega}{v} x)^{-3/2}.$$ \hfill (B7)
