ABSTRACT

We present Very Long Baseline Array observations of the kinematics of the water masers associated with OH 12.8−0.9, the fourth member of the so-called water-fountain class of sources. We find that the masers occupy two distinct regions at the ends of a bipolar jetlike structure oriented north-south, with the blueshifted masers located to the north and the redshifted masers to the south. The masers are distributed along arclike structures 12−20 mas across that are oriented perpendicular to the separation axis with an angular separation of ~110 mas on the sky. Our multiepoch observations show the two maser arcs to be expanding away from each other along the axis of separation. The relative proper motions of the two maser regions is 2.7 mas yr\(^{-1}\) (~105 km s\(^{-1}\)) at the assumed distance of 8 kpc. The measured radial velocity difference between the northern blueshifted masers and the southern redshifted masers is 48.4 km s\(^{-1}\). The radial velocity, when combined with the proper motion, yields a three-dimensional expansion velocity of 58 km s\(^{-1}\) and an inclination angle of 24\(^\circ\) for the jet. By combining our radial velocities with historical values, we estimate the three-dimensional acceleration of the masers to be ~0.63 km s\(^{-1}\) yr\(^{-1}\) and a dynamical age for the collimated outflow of ~90 yr.

Subject headings: circumstellar matter — masers — stars: AGB and post-AGB — stars: individual (OH 12.8−0.9) — stars: mass loss

1. INTRODUCTION

In the study of stars and stellar evolution, certain stages in the stellar life cycle remain a mystery simply because of their transitory nature. The evolutionary stage between the end of the asymptotic giant branch (AGB) and the planetary nebula (PN) phase is one such example. As stars evolve up the AGB, they lose mass at an increasing rate and spherically symmetric circumstellar envelopes (CSEs) are formed. Despite the spherical symmetry of the mass-loss process, a large fraction (~75%) of planetary nebulae (PNs) show aspherical (i.e., elliptical, bipolar, quadrupolar) morphologies (Manchado et al. 2000). The shaping of asymmetrical PNs must therefore occur over the relatively short time period of 10\(^3\)−10\(^4\) yr that the star spends in a post-AGB or proto–planetary nebula (PPN) phase (Kwok 1993). On the basis of comparative studies of compact and extended PNs, Aaquist & Kwok (1996) find that the lack of difference in the morphologies between the two groups suggests that PN morphologies are primarily inherited from the AGB evolutionary stage. Sahai & Trauger (1998) surveyed a number of young PNs with the Hubble Space Telescope Wide Field Planetary Camera 2 and found that the majority of them were characterized by multipolar bubbles distributed in a point-symmetric fashion about the central star. They also found collimated radial structures and bright equatorial structures indicating the presence of jets and disks/tori in some objects. These observations led Sahai & Trauger (1998) to propose a mechanism in which high-speed collimated outflows operate during the late AGB or early PPN stages of stellar evolution. During this phase, the jetlike outflows carve out an imprint in the spherical AGB wind, and it is this imprint that provides the morphological signature necessary for the development of aspherical PNs.

There is a small number of evolved objects that have been shown to exhibit the types of collimated jetlike outflows described above. These objects, dubbed “water-fountain” nebulae, are thought to be stars entering the post-AGB or PPN evolutionary stages. They exhibit both H\(_2\)O and OH maser emission; however, the relative characteristics of the two maser species differ from those of the typical AGB star. These differences are apparent in both the spectral profiles of the two types of masers and in the unique spatial morphologies of the masers as measured by radio interferometry. Prior to our study of OH 12.8−0.9 (Boboltz & Marvel 2005), there were three confirmed water-fountain sources: IRAS 16342−3814 (Sahai et al. 1999; Morris et al. 2003), IRAS 19134+2131 (Imai et al. 2004), and W43A (Imai et al. 2002).

Spectrally, these water-fountain sources exhibit double-peaked OH and H\(_2\)O maser profiles with the peaks symmetrically distributed about the radial velocity of the star. However, unlike the typical evolved star, the H\(_2\)O maser peaks have a greater spread in velocity than the corresponding OH masers. For IRAS 16342−3814, IRAS 19134+2131, and W43A, these velocity ranges for the H\(_2\)O masers are 259, 132, and 180 km s\(^{-1}\), respectively (Likkel et al. 1992). In addition, the expansion velocities (>60 km s\(^{-1}\)) implied by the maser spectra are much greater than the expansion velocity for the circumstellar wind of a typical AGB star (5−30 km s\(^{-1}\)).

Spatially, the H\(_2\)O masers associated with these sources are known to trace bipolar jetlike outflows; hence the “water fountain” name. In the first very long baseline interferometry (VLBI) study of the H\(_2\)O masers toward W43A, Imai et al. (2002) showed that the water masers are formed in a collimated precessing jet with an estimated three-dimensional (3D) outflow velocity of 145 km s\(^{-1}\). Interferometric studies of IRAS 16342−3814 (Morris et al. 2003; Claussen et al. 2004) and IRAS 19134+2131 (Imai et al. 2004) also found the H\(_2\)O masers to exhibit bipolar distributions. The 3D outflow velocities for IRAS 16342−3814 and IRAS 19134+2131 are 185 and 130 km s\(^{-1}\), respectively. The bipolar jets traced by the H\(_2\)O masers, presumably along the polar
axis of the star, may represent the onset of the axisymmetric morphologies that typify PNs. The dynamical ages of the jets for IRAS 19134+2131 and W43A are estimated to be ~50 and ~40 yr, respectively (Imai et al. 2002, 2004). That for IRAS 16342−3814 is estimated to be ~150 yr (Claussen et al. 2004).

The enigmatic source OH 12.8−0.9 was first classified by Baud et al. (1979) as a type II OH/IR star on the basis of its characteristic double-peaked 1612 MHz OH maser profile. The distance to the source is unknown, although Baud et al. (1985) included it in a sample of OH/IR stars associated with the Galactic center. OH 12.8−0.9 has been linked to the infrared source IRAS 18139−1816, which is ~26° away (te Lintel Hekkert et al. 1989). The SIMBAD astronomical database, however, still lists two separate entries for the source, one for each identifier. Classification of IRAS 18139−1816 based on IRAS Low Resolution Spectrometer (8−23 μm) data was performed by Kwok et al. (1997), who placed the source in category I, a group with noisy or incomplete spectra. Kwok et al. (1997) also noted that IRAS 18139−1816 is a "25 μm peaker": a source whose IRAS flux density at 25 μm is greater than its flux density at both 12 and 60 μm. Other 25 μm peakers include young PNs and carbon stars with circumstellar silicate emission features (Kwok et al. 1997). OH 12.8−0.9 has been also observed with the PHT-S (2.5−11.6 μm) spectrophotometer on board the Infrared Space Observatory (ISO). From the spectra, Hodge et al. (2004) classify the source in the 4/5.SA category. Sources in the 4/5 group peak longward of the 11.6 μm limit of the PHT-S. Objects in the 4/5.SA subgroup additionally exhibit a deep 10 μm absorption feature and absorption features from H$_2$O at 3 and 6 μm, CO at ~4.3 μm, and CO at ~4.6 μm (Hodge et al. 2004).

H$_2$O maser emission from OH 12.8−0.9 was first detected by Engels et al. (1986), who noted the fact that the H$_2$O emission peaks are outside the range of the OH maser emission. Gómez et al. (1994) used the Very Large Array (VLA) to show that the "anomalous" H$_2$O and OH maser emission was spatially coincident to within 1" and therefore belonged to the same source. Gómez et al. (1994) also found double-peaked profiles for both the OH and the H$_2$O, with the peaks of the OH separated by ~23 km s$^{-1}$ and the H$_2$O peaks separated by nearly twice this amount, ~42 km s$^{-1}$. Although the velocity range for the H$_2$O is not as wide as the other water-fountain sources, Engels (2002) found that the shape and variations in the spectra were consistent with the water-fountain class and compatible with an axisymmetric wind.

In Boboltz & Marvel (2005) we reported on our initial Very Long Baseline Array (VLBA) observations of the H$_2$O masers associated with OH 12.8−0.9. We found that the H$_2$O masers trace the bipolar morphology typical of the water-fountain class. This bipolar structure combined with the spectral characteristics of the H$_2$O and OH maser emission led us to propose that OH 12.8−0.9 is a fourth member of the rare water-fountain class of objects. In this article, we present additional multiepoch observations made with the VLBA with the goal of measuring the kinematics of the H$_2$O masers that trace the jet of OH 12.8−0.9.

2. OBSERVATIONS

We observed the 22.2 GHz H$_2$O maser emission from OH 12.8−0.9 ($\alpha = 18^h16^m49.23^s$, $\delta = −18°15′01.8″$) using the 10 stations of the VLBA. The VLBA is operated by the National Radio Astronomy Observatory (NRAO).¹ VLBA spectral line observations occurred on 2004 June 21, 2005 July 21, 2005 November 2, and 2006 February 24. Each observing run was approximately 5 hr in length. A reference frequency of 22.23508 GHz was used for the H$_2$O maser transition. Data were recorded in dual circular polarization using two 8 MHz (112.6 km s$^{-1}$) bands centered on the local standard of rest (LSR) velocity of −58.0 km s$^{-1}$.

For an unknown reason, the observations made on 2005 July 21 did not detect the H$_2$O masers from OH 12.8−0.9. Following this nondetection, we requested a short (5 minute) observation of OH 12.8−0.9 with the Green Bank Telescope (GBT) in order to decide whether the masers would still be detectable in the pending two epochs of VLBA observations. On 2005 September 13 the GBT observed the H$_2$O maser spectrum and found masers at levels of 2−3 Jy. We therefore continued with remaining two scheduled VLBA epochs and subsequently managed to detect and image the masers. The remainder of this article relates only to the three epochs in which the maser observations were successful, hereafter denoted as epoch 1 (2004 June 21), epoch 2 (2005 November 2), and epoch 3 (2006 February 24).

The data were correlated at the VLBA correlator operated by NRAO in Socorro, NM. Auto- and cross-correlation spectra consisting of 512 channels with channel spacings of 15.63 kHz (~0.22 km s$^{-1}$) were produced by the correlator. Calibration of each of the three epochs was performed in accordance with standard VLBA spectral line procedures using the Astronomical Image Processing System (AIPS) maintained by NRAO. The calibration of epoch 1 is described in Boboltz & Marvel (2005), and the two subsequent epochs were calibrated in a similar manner. For each epoch, residual delays due to the instrumentation were corrected by performing a fringe fit on the continuum calibrator (J1751+0939) scans. Residual group delays for each antenna were determined and applied to the target data.

The bandpass response was determined from scans on J1751+0939 and was used to correct the OH 12.8−0.9 data. The time-dependent gains of all antennas relative to a reference antenna were determined by fitting a total power spectrum (from the reference antenna with the target source at a high elevation) to the total power spectrum of each antenna. The absolute flux density scale was established by scaling these gains by the system temperature and gain of the reference antenna. Errors in the gain and pointing of the reference antenna and atmospheric opacity variations contribute to the error in the absolute amplitude calibration, which is accurate to about 15%−20%.

Residual fringe rates were obtained by fringe-fitting a strong reference feature in the spectrum of OH 12.8−0.9. For each epoch we used the same strong feature at channel velocity $V_{LSR} = −81.6$ km s$^{-1}$. The resulting fringe-rate solutions were applied to all channels in the spectrum. An iterative self-calibration and imaging procedure was then performed to map the emission in the reference channel for each epoch. The resulting residual phase and amplitude corrections from the reference channel were then applied to all channels in the 8 MHz band. All of the above calibrations were then applied to the data prior to imaging.

Imaging of the epoch 1 data is discussed in Boboltz & Marvel (2005), and a similar methodology was employed for the two subsequent epochs. For epochs 2 and 3, full-resolution images of 2048 × 2048 pixels (~160 × 160 mas) were generated using synthesized beam sizes of 1.08 × 0.39 mas for epoch 2 and 0.88 × 0.33 mas for epoch 3. Images were produced for all spectral channels from ~88.3 km s$^{-1}$ to ~25.1 km s$^{-1}$, forming an image cube of 301 image planes. Since peak maser flux densities were on the order of 1 Jy, channel images are noise-limited and do not suffer from dynamic range limitations, as is often the case in maser

¹ The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.
observations. Typical 1σ off-source noise estimates for individual image planes were 8–10 mJy beam⁻¹ for epoch 2 and 10–12 mJy beam⁻¹ for epoch 3. The analysis and extraction of relevant information from the image cubes is described below.

3. RESULTS

In order to identify and extract maser component parameters, two-dimensional Gaussian functions were fitted to the emission in the image plane of each spectral (velocity) channel using the AIPS task SAD. Image quality was assessed using the off-source rms noise in the image. A cutoff flux density was set at 5 times the rms noise in the image plane containing the emission. Emission features with flux densities greater than the cutoff were fitted with Gaussians to determine maser component parameters. The errors in right ascension and declination of the Gaussian fits to the identified components were computed by the AIPS task SAD following the method outlined by Condon (1997). These position errors ranged from 5 μas for features with high signal-to-noise ratios to 110 μas for features with lower signal-to-noise ratios.

Figures 1 and 2 show the spectral (upper subpanels) and spatial (lower subpanels) distributions of the H₂O masers toward OH 12.8–0.9 from the analysis of our VLBA images for epoch 2 (Fig. 1) and epoch 3 (Fig. 2). A similar plot for epoch 1 was presented in Boboltz & Marvel (2005). In the figures, panel a shows all H₂O maser components from our VLBA observations. A dashed line represents the axis of separation between the centers of the blue- and redshifted masers at a position angle of 2.6° east of north. The cross represents the midpoint of the bipolar distribution. Panels b and c show enlarged views of the blue- and redshifted maser features, respectively. Errors in the positions of the features are smaller than the data points for all panels.

Fig. 1.—H₂O maser emission toward OH 12.8–0.9 from epoch 2 (2005 November 2). In (a), (b), and (c), the upper subpanels show the spectra formed by plotting maser component flux density vs. LSR velocity, color-coded according to maser velocity. A dark solid line in each upper subpanel represents the scalar-averaged cross-power spectrum on the Los Alamos–Pie Town VLBA baseline. A dotted line in the upper subpanel of (a) represents the scalar-averaged cross-power spectrum of the OH masers (with the flux density scaled by a factor of 0.5) from the Los Alamos–Pie Town baseline. The lower subpanels in (a), (b), and (c) plot the spatial distribution of the H₂O masers, with point color representing the corresponding velocity bin in the spectrum and point size proportional to the logarithm of the maser flux density. (a) All H₂O maser components from our VLBA observations. A dashed line represents the axis of separation between the centers of the blue- and redshifted masers at a position angle of 2.6° east of north. The cross represents the midpoint of the bipolar distribution. (b) and (c) Expanded views of the blue- and redshifted maser features, respectively. Errors in the positions of the features are smaller than the data points for all panels.
the velocities of the blue- and redshifted OH peaks to be \(-68.0\) and \(-43.7\) km s\(^{-1}\), respectively, with a velocity resolution of \(0.18\) km s\(^{-1}\). By comparison, the velocities of the two peaks reported in Gómez et al. (1994) are essentially the same at \(-67.4\) and \(-44.0\) km s\(^{-1}\), to within the velocity resolution of their VLA observations (1.1 km s\(^{-1}\)). As in epoch 1, the H\(_2\)O masers form a double-peaked profile with a velocity extent greater than that of the double-peaked OH maser profile. On the blueshifted side of the emission, the peak flux density of epoch 2 remained the same as that for epoch 1 at 1.3 Jy beam\(^{-1}\) and decreased slightly in epoch 3 to 0.97 Jy beam\(^{-1}\). For the redshifted emission, the peak flux density steadily decreased from 1.0 Jy beam\(^{-1}\) in epoch 1 to 0.6 Jy beam\(^{-1}\) in epoch 2 to 0.2 Jy beam\(^{-1}\) in epoch 3. The velocity distributions for the masers in epochs 2 and 3 are very similar to those in epoch 1 and will be discussed in detail in §3.2.

The lower subpanels of Figures 1\(a\) and 2\(a\) show the entire spatial extent of the H\(_2\)O masers for epochs 2 and 3, respectively. Enlarged views of the north and south regions are also shown in panels \(b\) and \(c\) of each figure. We find that in epochs 2 and 3 the overall spatial structure of the H\(_2\)O masers has remained essentially unchanged from that in epoch 1. There are two distinct regions oriented roughly north-south on the sky that are separated by \(\sim 110\) mas. The position angle of the axis of separation between the mean position centers of the northern and southern maser regions is \(\sim 2.6^\circ\) east of north. The masers in the two regions are arranged in arclike structures oriented roughly east-west, with the exception of the feature located near (15.0, \(-10.0\)) in Figures 1\(b\) and 2\(b\). This feature, although apparent in the epoch 1 image cube, did not meet all of the component selection criteria in our initial analysis of the data (Boboltz & Marvel 2005). The feature is discussed further in §3.1 below. The blue- and redshifted arcs of masers are approximately 20 and 12 mas across, respectively, with corresponding opening angles for the jet of 13\(^\circ\)–20\(^\circ\).

### 3.1. Maser Proper Motions

In Figures 1 and 2, we plotted the maser emission identified in every spectral channel; thus, an individual maser feature will appear in multiple spectral channels and will consist of multiple points in the spatial distributions shown in the figures. In order to track and estimate the motions of the maser features, it is necessary to determine average values in right ascension, declination, and velocity for each feature. These average values were computed using a flux-density–squared weighted average for emission identified in two or more channels and spatially coincident to within 1 mas. The flux assigned to the maser feature was simply
the peak flux in the channels spanned by the feature. Characteristics of the masers for the three epochs are presented in Tables 1–3.

Since we did not use the technique of phase-referencing for our three VLBA epochs, the absolute position of the phase center in each image cube is unknown. However, in the reduction and analysis of each epoch of observations, we used what we believe to be the same maser feature as a phase reference. This feature was the strongest feature in each of the three epochs. In addition, it maintained the same velocity and spatial location relative to the other three northern blueshifted masers common to all three epochs. The averaging of the maser identifications over several epochs resulted in slight (<0.1 mas) position shifts for the reference feature in each of the three epochs. The coordinate frames for all three epochs were therefore realigned such that the reference feature (the third blueshifted feature in Table 1 and the second blueshifted feature in Tables 2 and 3) coincided with the origin.

Relevant maser characteristics determined from the analysis are plotted in Figures 3 and 4. Figure 3 shows the blueshifted H$_2$O masers in the north of OH 12.8–0.9. In this figure, the alignment of the reference features for the three epochs at the origin is apparent. Also common to all three epochs are features near (−2.0, 0.5), (8.0, 0.2), and (15.0, −10.0). As mentioned earlier, the feature near (15.0, −10.0) did not appear in Boboltz & Marvel (2005) because it did not meet all of the selection criteria at the time. However, with the additional data from epochs 2 and 3 and some reprocessing of the epoch 1 image cube, we were able to extract the relevant parameters for this feature. From Figure 3 it is apparent that any position differences between the three epochs are small, thus indicating little motion of the northern features relative to the reference feature over the course of the three epochs. This, however, is not the case for the southern maser features. Figure 4 shows the redshifted H$_2$O masers in the south of OH 12.8–0.9. Here there are five features that are common to all three epochs. Clearly there is a consistent proper motion of all of the features of nearly due south relative to the blueshifted reference feature. The average angular separations of the north and south masers are 107, 110, and 111 mas for epochs 1, 2, and 3, respectively. As discussed in Boboltz & Marvel (2005), the distance to OH 12.8–0.9 is not well known. Best estimates place the object near the Galactic center at $d \approx 8$ kpc (Baud et al. 1985). If we assume this distance, then the linear separations between the blue- and redshifted masers are approximately 860, 880, and 890 AU, respectively.

In order to better characterize the net expansion of the masers, we computed the separations between pairwise combinations of components. This technique has previously been used to

characterize OH (Chapman et al. 1991; Bloemhof et al. 1992; Kemball 1992), H$_2$O (Marvel 1996), and SiO (Boboltz et al. 1997; Chen et al. 2006) maser motions and has no dependence on the alignment of the maps or a priori assumptions about the velocity field. The procedure involves computing the angular separation ($\theta$) between two features at one epoch (epoch A) and the separation between the corresponding two features at a second epoch (epoch B). The difference between the two values of $\theta$ is the pairwise separation and can be written as

$$\Delta \theta_B - \Delta \theta_A = |r_i - r_j|_B - |r_i - r_j|_A, \quad i = 1, n; \quad j = i + 1, n,$$

where $r_i = (x_i, y_i)$, and $(x_i, y_i)$ are the relative offsets in right ascension and declination, respectively. The procedure is repeated for all possible pair combinations, and the separations can be plotted as a histogram (e.g., Fig. 5). The inclusion of all possible pair combinations often results in a bimodal distribution with one of the peaks biased toward zero. This is because some of the separations involve pairs of closely spaced maser components on the same side of the distribution (i.e., the northern or southern regions for OH 12.8–0.9) that have little motion relative to one another. For the sake of clarity, and to determine representative values for the angular shifts due to the expansion, we have included only those pairs separated by more than 80 mas in the histograms shown in Figure 5. Figure 5 plots the pairwise separations over time intervals of (a) 613, (b) 500, and (c) 114 days, respectively. All three histograms have centroids that are biased toward positive values indicative of expansion. The mean (median) differences between the north and south masers are

Fig. 3.—Northern blueshifted masers associated with OH 12.8–0.9 for all three epochs (2004 June 21, 2005 November 2, and 2006 February 24). Masers are color-coded according to velocity, and point size is proportional to the logarithm of the maser flux density. There are four maser features common to all three epochs, including the reference feature at (0, 0). The masers show little motion relative to this stationary reference feature.

Fig. 4.—Southern redshifted masers associated with OH 12.8–0.9 for all three epochs (2004 June 21, 2005 November 2, and 2006 February 24), demonstrating the motions of the masers over time relative to the reference feature in Fig. 3. Masers are again color-coded according to velocity, and point size is proportional to the logarithm of the maser flux density. All five features are common to all three epochs.
erages we computed the spectral separation standard deviations for each set of components. From these averages identified in Tables 1 this, we averaged the velocities of the blue- and redshifted maser features representing the peaks in our spectrum with peak combinations of northern and southern maser pairs for (a) epochs 3 and 1, (b) epochs 2 and 1, and (c) epochs 3 and 2. Listed in each panel is the lapsed time between epochs in units of days.

4.64 (4.69) mas, 3.88 (3.89) mas, and 0.77 (0.80) mas for 613, 500, and 114 days, respectively. The 1σ standard deviations are 0.28, 0.21, and 0.13 mas, respectively. The equivalent mean angular velocities are 2.76 ± 0.16, 2.83 ± 0.15, and 2.47 ± 0.41 mas yr⁻¹. To within the errors, the three velocities are consistent, and it is impossible to determine whether there is any acceleration of the masers in the outflow.

If 8 kpc is again assumed to be the distance to OH 12.8–0.9, the linear proper motions of the masers can be computed for the angular velocities above. The resulting average linear separation velocities are 105 ± 6, 107 ± 6, and 94 ± 16 km s⁻¹ for the 613, 500, and 114 day intervals, respectively. If we assume that the north and south masers are moving outward at equal speeds (i.e., at half the computed separation velocity), then the outflow velocity in the plane of the sky would be ~53 km s⁻¹ for the 613 day interval. This velocity is slightly more than double the outflow velocity determined for OH 12.8–0.9 in Boboltz & Marvel (2005), which was based solely on the radial velocities. In the following section (§ 3.2) we update the radial velocities of the masers and combine them with the proper motions in order to estimate the full 3D kinematics of the masers in the jet.

### 3.2. Three-dimensional Maser Outflow

In Boboltz & Marvel (2005) we compared the spectral separation of the blue- and redshifted peaks in our spectrum with peak separations from previous single-dish and VLA observations (i.e., Engels et al. 1986; Gómez et al. 1994; Engels 2002). Here we wish to compare our spectral separations computed from the component averages with these previous results; however, only Engels (2002) tabulates parameters for individual spectral features. Engels (2002) categorizes components A–H of his Table 4 into the blueshifted group and components M–Q of his Table 5 into the redshifted group, with the remaining components, I–L, listed as intermediate. From this information, we computed average velocities for the blue- and redshifted spectral features and values for Δv in a manner similar to that performed for our own VLBA data. The resulting values of Δv and the corresponding errors for the Engels (2002) data are listed in Table 4. The only drawback to the Engels data as compared to our VLBA data is the fact that there is no spatial information; thus, the degree to which spectral blending is a factor is unknown. It should be noted that the spectral resolution of the Engels measurements is slightly better than our VLBA resolution at 0.16 km s⁻¹.

In Boboltz & Marvel (2005) we treated the radial velocity of OH 12.8–0.9 by simply determining the velocity separation of the blue- and redshifted maser features representing the peaks in the spectral distribution. This was an improvement over previous single-dish and VLA studies that contained limited spatial information and likely suffered from blending of features in the spectral domain. In light of the two new epochs of VLBA data, we felt that the more rigorous approach of computing spectral separations (Δv) from multiple features was more appropriate. To do this, we averaged the velocities of the blue- and redshifted masers identified in Tables 1–3 separately. We also computed the standard deviations for each set of components. From these averages we computed the spectral separation Δv at each epoch.

The error in Δv is simply the standard deviations added in quadrature. Using this method, we find mean values for Δv of 48.7 ± 1.6, 48.3 ± 1.3, and 48.2 ± 1.3 km s⁻¹ for epochs 1, 2, and 3, respectively. These values are also listed in Table 4.

In Boboltz & Marvel (2005) we compared the spectral separation of the blue- and redshifted peaks in our spectrum with peak separations from previous single-dish and VLA observations (i.e., Engels et al. 1986; Gómez et al. 1994; Engels 2002). Here we wish to compare our spectral separations computed from the component averages with these previous results; however, only Engels (2002) tabulates parameters for individual spectral features. Engels (2002) categorizes components A–H of his Table 4 into the blueshifted group and components M–Q of his Table 5 into the redshifted group, with the remaining components, I–L, listed as intermediate. From this information, we computed average velocities for the blue- and redshifted spectral features and values for Δv in a manner similar to that performed for our own VLBA data. The resulting values of Δv and the corresponding errors for the Engels (2002) data are listed in Table 4. The only drawback to the Engels data as compared to our VLBA data is the fact that there is no spatial information; thus, the degree to which spectral blending is a factor is unknown. It should be noted that the spectral resolution of the Engels measurements is slightly better than our VLBA resolution at 0.16 km s⁻¹.

Plotted in Figure 6 are the results of our computation of Δv from the blue- and redshifted component averages. The values from the 11 epochs of Engels (2002) are plotted as filled triangles, and those from our three epochs of VLBA data are plotted as filled circles. The data clearly show an increase in Δv as a function of time. To these data, we performed a linear least-squares fit weighted by the squares of the errors. This fit is plotted as the line in Figure 6, with a slope of 0.53 ± 0.04 km s⁻¹ yr⁻¹ corresponding to the relative acceleration of the blue- and redshifted masers in the radial direction. This is slightly lower than the value of 0.68 ± 0.06 km s⁻¹ yr⁻¹ reported in Boboltz & Marvel (2005). With the new procedure of averaging over multiple spectral features, we have attempted to remove the error involved in computing the velocity separation from single peaks on the blue- and redshifted sides of the spectrum that are likely unrelated over periods greater than the lifetime of the components, <3 yr (Engels 2002). Engels also discusses ~1 km s⁻¹ velocity shifts that were observed for some components in the spectra of OH 12.8–0.9 and the likelihood of these shifts being caused by intensity changes.
The outflow velocity in the radial direction is away from each other along the line of sight to the observer, then masers to be \( v_{\text{out}} \). Separations computed from single spectral peaks, as was done in within blended features. Such shifts could affect the velocity acceleration of \( 0.53 \text{ km s}^{-1} \) yr\(^{-1} \). The 3D outflow velocity of the masers may be estimated by combining the radial motion with the plane of the sky determined in Fig. 6. Measured velocity separation \( (\Delta v) \) of the blue- and redshifted water maser features as a function of time, from values listed in Table 4. The line represents a weighted linear least-squares fit to the data and indicates a constant acceleration of \( 0.53 \text{ km s}^{-1} \) yr\(^{-1} \).

Within blended features. Such shifts could affect the velocity separations computed from single spectral peaks, as was done in Boboltz & Marvel (2005).

If we assume an average over our three VLBA epochs, \( \Delta v \approx 48 \text{ km s}^{-1} \), as the speed at which the masers are moving away from each other along the line of sight to the observer, then the outflow velocity in the radial direction is \( \sim 24 \text{ km s}^{-1} \). The 3D outflow velocity of the masers may be estimated by combining the radial motion with the plane of the sky determined in \( \S \) 3.1. We find the 3D outflow velocity of the masers to be \( \sim 58 \text{ km s}^{-1} \), with an inclination angle for the jet of \( \sim 24^\circ \) with respect to the plane of the sky. The 3D outflow acceleration, assuming this inclination angle and the radial acceleration above, is \( \sim 0.63 \text{ km s}^{-1} \) yr\(^{-1} \). The outflow acceleration in the plane of the sky would be \( \sim 0.58 \text{ km s}^{-1} \) yr\(^{-1} \) under this assumption. Thus, over the 613 days between epochs 1 and 3, we could expect a change in the velocity of the blueshifted masers relative to the redshifted masers of \( 1.93 \text{ km s}^{-1} \) or 0.05 mas yr\(^{-1} \), which is undetectable in our present observations.

From the above information and two additional assumptions, namely, that the dynamical center of the outflow is the midpoint along the axis of separation between the two maser regions and that the masers have zero initial velocity, an upper limit to the dynamical age of the outflow can be computed. We find this dynamical age to be \( \sim 90 \) yr. This value is roughly consistent with the age determined in Boboltz & Marvel (2005), which was estimated with no knowledge of the maser motions in the plane of the sky or the inclination angle of the outflow. If one assumes that the acceleration has and will remain constant at the above value of \( 0.63 \text{ km s}^{-1} \) yr\(^{-1} \), then the total time to reach an outflow velocity comparable to the other water-fountain sources \( (\Delta v \approx 150 \text{ km s}^{-1}) \) is only about \( \sim 240 \) yr, roughly 2.5 times the current dynamical age of OH 12.8–0.9.

In order to compare the characteristics of OH 12.8–0.9 to those of the other water-fountain sources, we have summarized the relevant properties of all four sources in Table 5. From the table we see that the assumed distance to OH 12.8–0.9 is intermediate among the four sources. The peak flux density is shown as a range measured over multiple epochs by Engels (2002) for OH 12.8–0.9 and by Likkel et al. (1992) for the other three sources. The peak flux range for OH 12.8–0.9 is similar to that of the other distant source IRAS 19134+2131 and weaker than those of W43A and IRAS 16342–3814. The angular extent of the outflow on the plane of the sky is also similar to that of IRAS 19134+2131. The linear extent of OH 12.8–0.9, however, is much less than those of any of the other water-fountain sources. An increase in the assumed distance to the source would serve to bring this value in line with the other sources. For the collimation of the OH 12.8–0.9 jet, we have used an average of the northern and southern arcs and find that the collimation is slightly larger.

**TABLE 5**

| Characteristic       | OH 12.8–0.9 | W43A | IRAS 19134+2131 | IRAS 16342–3814 |
|----------------------|-------------|------|-----------------|-----------------|
| Distance (kpc)       | 8           | 2.6  | 16              | 2               |
| \( S_{\text{peak}} \) (Jy) | 1.4–13.0    | 11.5–56.6 | 1.2–6.0         | 16.0–67.7       |

than that for the other three water-fountain sources. If we use only the southern arc, or if we disregard the one northern feature at $(15.0, -10.0)$, then the collimation is $\sim 10^\circ$, which is consistent with the other water-fountain sources. The estimated inclination angle of the outflow is also comparable with values estimated for the other three objects.

Aside from the difference in linear extent, the primary difference between OH 12.8–0.9 and the other water-fountain sources is in the kinematics. Both the radial ($v_{\text{rad}}$) and tangential ($v_{\text{tan}}$) outflow velocities are less than half the values for the other sources. It is possible that the tangential velocity could be closer to that of the other sources if the distance to the source turns out to be greater than 8 kpc. An increased distance would not increase the radial velocity estimate, but would instead result in a decreased estimate for the inclination angle of the jet. Another major difference between OH 12.8–0.9 and the three other water-fountain sources is that OH 12.8–0.9 appears to be the only object with a measurable acceleration ($a_{\text{rad}}$) of the masers along the line of sight. Likkel et al. (1992) observed the H$_2$O maser spectra of the three other water-fountain sources over the course of a few years and found no evidence for systematic velocity drifts in spectral features that would suggest acceleration of the masers. The acceleration in combination with the smaller extent of the masers toward OH 12.8–0.9 might suggest that it is younger than the other three objects. This is not, however, confirmed by the computed dynamical age of the jet, which is intermediate among the four sources at 90 yr.

One characteristic that is not shown in the tables is the morphology of the masers relative to the central star and the jet direction. From the images of OH 12.8–0.9 presented here, we find that the masers are arranged in point-symmetric fashion along arcs perpendicular to the direction of the outflow, suggesting that the outflow is impacting a denser surrounding medium. This bow shock structure is also observed for the H$_2$O masers toward IRAS 16342–3814, at least for the blueshifted side of the jet (Claussen et al. 2004). These two sources are in contrast to W43A, where the masers are arranged along the direction of the outflow. The structure of the W43A masers is well represented by a precessing jet model (Imai et al. 2002, 2005). The remaining water-fountain source, IRAS 19134+2131, shows the point-symmetric morphology of the three other sources, but the relationship between the masers and the outflow is less clear. From the two epochs of VLBI observations reported in Imai et al. (2004), the masers on the eastern redshifted side appear to be roughly aligned with the line connecting them to the western blueshifted masers. The motions of the masers, however, do not appear to be along this line, but rather perpendicular to this in a primarily north-south direction.

Similar to the W43A outflow, precession is indicated for IRAS 16342–3814, but not as a result of the available H$_2$O maser data. Instead, it was the Keck adaptive optics images in the near-infrared (Sahai et al. 2005) that showed a corkscrew structure inscribed on the walls of the observed lobes. The combined radio/infrared observations demonstrate that both bow shock morphologies and precession can take place in the same object. Since no such high-resolution optical/infrared imaging is available for OH 12.8–0.9, it is unknown whether precession occurs in the object; however, it is clearly not suggested by the structure or kinematics of the H$_2$O masers.

### 4. Conclusions

Using the VLBA, we have shown that, like the spatial morphology, the kinematics of the H$_2$O masers toward OH 12.8–0.9 indicate that the object is a member of the rare “water-fountain” class of sources. We find that the masers continue to be located in two distinct regions at the ends of a bipolar jet-like structure having a north-south orientation on the sky. The masers in the two regions are distributed along arclike structures $\sim 12$–20 mas across that are oriented roughly perpendicular to the separation axis. The angular separation of the two regions is roughly 110 mas, with the blueshifted masers located to the north and the redshifted masers to the south. The arclike arrangements of the masers are suggestive of bow shocks formed by a collimated axisymmetric wind impinging on the ambient medium surrounding the star.

The two additional epochs of VLBA observations beyond our first epoch in 2004 have allowed us to track the projected spatial motions of individual features over the course of $\sim 600$ days. We find that the two maser regions maintain their arclike appearance as they expand away from each other along the axis of separation. The observed proper motion of the southern masers relative to the northern masers is $2.76$ mas yr$^{-1}$ ($\sim 105$ km s$^{-1}$ at the assumed distance of 8 kpc). The masers maintain collimation during this expansion, with little motion perpendicular to the north-south axis. Combining the proper motions with the measured radial velocities yields a three-dimensional (3D) expansion velocity of $58$ km s$^{-1}$ relative to the dynamical center of the distribution. The inclination angle of the jet is estimated to be $\sim 24^\circ$. A simple linear fit to the historical radial velocity data combined with our own measurements yields an estimate for the 3D acceleration of $\sim 0.63$ km s$^{-1}$ yr$^{-1}$ and a corresponding dynamical age for the outflow of $\sim 90$ yr. Long-term VLBA monitoring of the H$_2$O masers should enable the determination of the tangential acceleration of the masers and the true 3D acceleration of the outflow associated with OH 12.8–0.9.
