Abstract

**Background and Objectives:** The predictive value of plaque characteristics assessed by virtual histology-intravascular ultrasound (VH-IVUS) including fibrous tissue (FT), fibrofatty (FF), necrotic core (NC) and dense calcium (DC) in identifying distal embolization after percutaneous coronary intervention (PCI) is still controversial. We performed a systematic review and meta-analysis to summarize the association of pre-PCI plaque composition and post-PCI distal embolization in acute coronary syndrome patients.

**Methods:** Studies were identified in PubMed, OVID, EMBASE, the Cochrane Library, the Current Controlled Trials Register, reviews, and reference lists of relevant articles. A meta-analysis using both fixed and random effects models with assessment of study heterogeneity and publication bias was performed.

**Results:** Of the 388 articles screened, 10 studies with a total of 872 subjects (199 with distal embolization and 673 with normal flow) met the eligibility of our study. Compared with normal flow groups, significant higher absolute volume of NC [weighted mean differences (WMD): 5.79 mm³, 95% CI: 3.02 to 8.55 mm³; p < 0.001] and DC (WMD: 2.55 mm³, 95% CI: 0.22 to 4.88 mm³; p = 0.03) were found in acute coronary syndrome patients with distal embolization. Further subgroup analysis demonstrated that the predictive value of tissue characteristics in determining distal embolization was correlated to clinical scenario of the patients, definition of distal embolization, and whether the percutaneous aspiration thrombectomy was applied.

**Conclusion:** Our study that pooled current evidence showed that plaque components were closely related to the distal embolization after PCI, especially the absolute volume of NC and DC, supporting further studies with larger sample size and high-methodological quality.

Introduction

**Rationale**

Distal embolization (DE) is a common complication after percutaneous coronary intervention (PCI), particularly in the setting of acute coronary syndrome (ACS) or vein graft intervention, which may result in microvascular obstruction and no-reflow phenomenon [1,2]. This undesirable side effect of PCI has been confirmed to be associated with increased post-procedural myocardial infarction, in-hospital mortality, and long-term adverse events [3–5]. However, there is no effective strategy for prediction and prevention of DE, which is an important issue for interventional cardiology.
Although several studies using grayscale intravascular ultrasound (IVUS) have indicated that plaque characteristics identified by pre-interventional IVUS (i.e., a large plaque burden, a lipid-pool-like image, and positive remodeling) maybe associated with the angiographic no-reflow phenomenon in ACS patients [6–10], gray-scale IVUS is dependent on the simple interpretation of acoustic reflections and of limited value for identifying specific plaque components [11]. Recently, some new methods able to assess both plaque morphology and tissue characteristics, such as virtual histology-IVUS (VH-IVUS), have become clinically available. VH-IVUS is based on spectral and amplitude analysis of IVUS backscattered radiofrequency that allows for characterization of in-vivo atherosclerotic plaque into four types: fibrous (FT), fibrofatty (FF), necrotic core (NC), and dense calcium (DC) [12–23]. However, whether pre-PCI plaque characteristics of culprit lesion assessed by VH-IVUS could predict post-PCI angiographic DE, and which plaque components are associated with no-reflow phenomenon remain debated. We therefore performed a systematic review that pooled current evidence to investigate the relationship between pre-PCI plaque composition characteristics assessed by VH-IVUS and post-PCI DE phenomenon in ACS patients.

Methods

Search strategy
PubMed, Ovid, EMBASE, and the Cochrane Library databases were searched in their entirety from January 2002 to April 2013. Complex search strategies were formulated using the following MESH terms and text words: intravascular ultrasound, virtual histology, IVUS, VH-IVUS, plaque component, plaque composition, plaque characteristic, no reflow, DE, microembolization, and obstruction. In order to identify any studies missed by the literature searches, we had searched reference lists of all eligible studies and relevant review articles. In addition, we searched from published and ongoing trials in clinical trial registries (Clinical-Trials.gov, Controlled-trials.com and the WHO International Clinical Trials Registry Platform). Searches were not restricted by language, time published, or publication status. Duplicate reports were eliminated (Appendix S1).

Study selection
We included studies when the following criteria were met: (1) Plaque characteristics were assessed by VH-IVUS; (2) VH-IVUS was performed before coronary intervention in ACS patients; and (3) DE was defined according to angiographic evidence or clinical relevancy. Studies without normal flow (NF) group were excluded from our analysis.

Data extraction
Two reviewers (D. S. and P. J.) assessed the eligibility of studies using a standardized form developed for this purpose in duplicate and independently. Disagreements were adjudicated by review by consensus. Data extraction was completed by the same observers using a standardized data extraction form developed for this study. The following information was extracted from each study: sample size, mean age, gender distribution, risk factors, clinical scenario, definition of DE, and the volume (mm³) and percentage of each tissue component of plaque (including FT, FF, NC, and DC). Several studies met our inclusion criteria but were...

missing data vital to our analysis; in these cases, we contacted the authors to obtain raw data whenever possible.

**Statistical analysis**

Statistical analysis in this study was carried out using RevMan software version 5.2 (The Cochrane Collaboration). Results were summarized as weighted mean differences (WMD) with their associated 95% confidence intervals (CI) using both fixed and random effects models, the latter was more conservative where heterogeneity beyond that expected by chance alone was encountered. In addition, the odds ratio (OR) was calculated for baseline comorbidities. Heterogeneity between studies was analyzed by the Q statistic and the I² statistic. A p value of the Q statistic <0.1 was defined as an indicator of heterogeneity, and an I² <50% indicated that the magnitude of the heterogeneity might not be significant. Funnel plots were plotted to investigate possible small study effects/publication bias by using Revman 5.2. Planned subgroup analyses were conducted based on the clinical scenario, definition of DE, and whether percutaneous aspiration thrombectomy was applied.

**Quality assessment**

Methodological quality was assessed independently by 2 reviewers (D. S. and P. J.) using the Newcastle-Ottawa Scale.

**Results**

**Search result**

After initial literature search, we identified 388 potential studies, of which 357 studies were excluded based on the title and abstracts, because they were unrelated papers, reviews, editorials, letters, case reports or animal studies. The remaining 31 articles were considered of interest and examined in full-text. Of these, 19 studies those were not IVUS-based were excluded. Of the remainder, 2 studies without DE data were excluded [12,13]. Therefore, 10 observational studies were included in our final meta-analysis [14–23]. Figure 1 shows the study selection process.

**Characteristics of included studies**

Table 1 and 2 summarize the main features of the included studies. A total of 872 patients (199 patients in DE group and 673 patients in NF group) were enrolled in the 10 studies, and the sample sizes were 44–190 in each study. Among the included studies, 5 studies involved AMI patients [14,18–21] (4 of them only involved STEMI patients), 3 studies enrolled unstable angina (UA) patients [16,22,23], and the remaining 2 studies involved ACS (including both AMI and UA) patients [15,17]. Percutaneous aspiration thrombectomy was performed before IVUS examinations in 7 studies [14,15,18–21,23]. There were no significant differences between DE and NF groups in age and gender of patients. Moreover, there was no significant difference in the incidence of hypertension (OR: 1.36, 95% CI: 0.95 to 1.95, \( p = 0.10 \)), diabetes (OR: 1.36, 95% CI: 0.94 to 1.96, \( p = 0.10 \)) and hyperlipidaemia (OR: 1.44, 95% CI: 0.89 to 2.31, \( p = 0.13 \)) between the two groups. A Funnel plot for NC volume outcome data was used to assess any potential small study effects or publication bias (Figure 2). The Funnel plot was roughly symmetrical as to the mean-effect size line.

Moreover, we evaluated the quality of primary studies using the Newcastle–Ottawa Scale, a validated technique for assessing the quality of observational and non randomized studies. As shown in Table 3, all observational studies were intermediate to low intermediate bias risk as assessed by the Newcastle-Ottawa Scale for quality assessment risk evaluation of adequacy of selection, comparability of study groups, and assessment of outcome or exposure.

**Relationship between coronary plaque characteristics and DE**

As shown in Table 4, Figure 3 and 4, the absolute volume and percentage of four different plaque compositions through the entire culprit lesion were assessed. Compared with NF group, the overall pooled results with random-effects analysis showed DE group had significant higher absolute volume of NC (WMD: 5.79 mm³; 95% CI: 3.02 to 8.55 mm³; \( p < 0.001 \)) and DC (WMD: \( p < 0.001 \)).
2.55 mm$^3$, 95% CI: 0.22 to 4.88 mm$^3$; $p = 0.03$). The difference between the two groups was not statistically significant with respect to percentage of NC (WMD: 4.35%, 95% CI: −1.44% to 10.15%; $p = 0.14$) and DC (WMD: 0.81%, 95% CI: −1.20% to 2.82%; $p = 0.43$). In addition, there were no significant differences in absolute volume and percentage of FT and FF at the entire culprit lesions between the two groups. Substantial statistical heterogeneity was detected in all of the comparisons among these trials, except for the absolute volume of FT ($I^2 = 0\%$).

Subgroup analysis

Planned subgroup analyses were conducted based on the different clinical scenario, definition of DE, and whether percutaneous aspiration thrombectomy was applied (Table 5 and 6). Subgroup analysis by different clinical scenario showed that patients with DE had significantly higher absolute volume and percentage of NC (WMD: 6.61 mm$^3$, 95% CI: 4.11 to 9.12 mm$^3$; $p < 0.001$ and WMD: 8.64%, 95% CI: 5.29% to 11.99%; $p < 0.001$) in subgroup of UA patients.

In order to assess the impact of the definition of DE in determining DE on our analyses, subgroup analysis by angiographic or clinical relevance definition was performed. The results showed that there was significantly higher absolute volume of NC (WMD: 7.13 mm$^3$, 95% CI: 4.40 to 9.87 mm$^3$; $p = 0.04$) in subgroup of DE in clinical relevance definition.

In order to investigate whether percutaneous aspiration thrombectomy would affect the outcomes, trials were divided into two subgroups according to whether thrombectomy was applied. The results showed that in the subgroup without thrombectomy, patients with DE had significantly higher absolute volume and percentage of NC (WMD: 7.47 mm$^3$, 95% CI: 4.25 to 10.69 mm$^3$; $p < 0.001$ and WMD: −7.45%, 95% CI: 4.38% to 10.53%; $p < 0.001$), and significantly lower absolute volume of FF (WMD: −7.38 mm$^3$, 95% CI: −9.86 to −4.90 mm$^3$; $p < 0.001$).

Discussion

The present meta-analysis that pooled all currently available published data indicated that, among four phenotypes of coronary plaque composition assessed by VH-IVUS, absolute volume of NC components was closely related to the DE after PCI in ACS patients. Besides, absolute volume of DC component might also be related to the DE after PCI. Further subgroup analysis revealed that the predictive value of VH-IVUS plaque characteristics in determining DE was correlated to the clinical scenario of the patients, the definition of DE, and whether percutaneous aspiration thrombectomy was applied.

Two recent review/meta-analyses [24,25] that investigated the relationship between plaque characteristics and DE after PCI have also reported that the extent of NC was larger in patients with DE. The meta-analysis by Jang et al. [24] evaluated the effect of plaque characteristics on embolization after PCI by grayscale-IVUS and VH-IVUS, and found that the morphologic characteristics of plaque derived from grayscale-IVUS (i.e., eccentric plaque, ruptured plaque, and attenuated plaque) and the NC component derived from VH-IVUS are closely related to the DE phenomenon after PCI. The systematic review by Claessen et al. [25] summarized the published data on the use of plaque composition assessment by VH-IVUS to predict the occurrence of DE, and found that the NC component was associated with DE in all but 2 of the 11 reviewed studies. In the present study, we performed a systematic review that pooled all the currently available published data investigating the relationship between pre-PCI plaque composition characteristics assessed by VH-IVUS and post-PCI
Table 4. Composition of plaque by VH-IVUS.

| Study         | Absolute volume (mm³) | Percentage (%) |

Data are presented as mean (SD)

FT, fibrous tissue; FF, fibrofatty; NC, necrotic core; DC, dense calcium.

doi:10.1371/journal.pone.0106583.t004
DE phenomenon in ACS patients, and we updated the meta-analysis by adding two VH-IVUS studies [22,23] that did not include in the previous meta-analysis by Jang et al. [24]. We found that absolute volume of NC component, but not percentage of NC component, was closely related to the DE after PCI in ACS patients, confirming the findings of previous review/meta-analyses. In addition, our analysis that pooled all current evidence found that besides NC volume, absolute DC volume was also closely related to the DE phenomenon after PCI. There is some evidence which indicated that DC might be related to DE. For example, pathologic studies revealed that coronary calcification is related to the total plaque burden, NC component, plaque erosion or rupture that is responsible for coronary thrombosis [26–29]. In addition, some studies have also reported that coronary calcium

There is some evidence which indicated that DC might be related to DE. For example, pathologic studies revealed that coronary calcification is related to the total plaque burden, NC component, plaque erosion or rupture that is responsible for coronary thrombosis [26–29]. In addition, some studies have also reported that coronary calcium
was associated with coronary event including myocardial infarction or death in symptomatic/asymptomatic persons [30–33].

In our analysis, we noted a considerable degree of heterogeneity among the included trials. Thus, we performed further subgroup analyses and tried to appraise the possible sources of differences and heterogeneity among trials. Our results suggested that the clinical scenario of the patients, the definition of DE and the use of thrombectomy may influence the correlation between tissue characteristics of coronary plaque and DE. When analyzed in the context of clinical scenario, increased absolute volume of NC was found in DE group in studies including UA patients, but not in those including AMI patients. This phenomenon might be

doi:10.1371/journal.pone.0106583.t006
explained by the rupture and migration of NC plaque in AMI patients. In addition, VH-IVUS is limited to detecting thrombus (in fact, thrombus appears as either fibrotic or fibrofatty plaque depending on the age of the thrombus) [34]. Moreover, large amount of NC may have migrated into the distal coronary bed before or during primary PCI in AMI patients [14]. An unexpected finding in our analysis was that no association was found between plaque components and DE in the subgroup of angiographically defined DE. Although angiography has been commonly used as a gold standard for assessing DE, TIMI flow grade is a subjective method to assess epicardial blood flow. As suggested by published literatures, the qualitative nature of TIMI grade renders it somewhat dependent on the technical skill of the observer, and significant differences were found in inter-observer variabilities among different reports, particularly for TIMI 2 grade. Therefore further studies with larger sample size and high-methodological quality are needed.

(2012) In vivo characterization of coronary plaques: novel findings from comparing greyscale lumen and site over the whole lesion, these measurements were not usually reported uniformly in the individual studies involved in our study. Thirdly, although our pooled analysis found that besides NC volume, absolute DC volume was also closely related to the DE phenomenon after PCI, more evidence should be obtained to confirm this finding because only two of the studies included in our meta-analysis reported statistically significant association between DC component and post-PCI DE. Finally, all of the involved trials were non-randomized studies and of small sample sizes, which might have brought some bias. Therefore further studies with larger sample size and high-methodological quality are needed.
