It has recently been proposed that fluctuating “pulled” fronts propagating into an unstable state should not be in the standard KPZ universality class for rough interface growth. We introduce an effective field equation for this class of problems, and show on the basis of it that noisy pulled fronts in \(d+1\) bulk dimensions should be in the universality class of the \((d+1)+1\) D KPZ equation rather than of the \((d+1)\) D KPZ equation. Our scenario ties together a number of heretofore unexplained observations in the literature, and is supported by previous numerical results.

\textbf{Consider spatio-temporal systems in which the important dynamics is governed by the propagation of fronts or interfacial zones separating two domains whose bulk dynamics is relatively trivial or uninteresting. In the presence of fluctuations, the theory of the stochastic behavior of such fronts or interfaces is well-developed\textsuperscript{[8,9,10]}. In particular it is known that many such fluctuating \(d\)-dimensional interfaces in \(d+1\) bulk dimensions are described by the KPZ equation\textsuperscript{[8]} for their height \(h\),

\[ \frac{\partial h}{\partial t} = \nu \nabla^2 h + \lambda (\nabla h)^2 + \eta, \] (1)

with \(\eta\) a random gaussian noise with correlations

\[ \langle \eta(r_\perp, t) \rangle = 0, \] (2)
\[ \langle \eta(r_\perp, t) \eta(r_\perp', t') \rangle = 2 \epsilon \delta^d(r_\perp - r_\perp') \delta(t - t'). \] (3)

We will follow common practice to refer to this equation as the \(d+1\)D\(=\)dimensional KPZ equation, where the \(d\) refers to the dimension of the interface and the +1 to the time dimension; \(r_\perp\) denotes the coordinates perpendicular to the direction of propagation of the interface.

The fact that the scaling behavior of so many stochastic interfaces fall in the \(d+1\)D universality class, is due to the fact that \((1)\) this equation contains all the terms in a gradient expansion which are relevant in a RG sense; and \((2)\) that the long wavelength deterministic dynamics of many interfaces is local \textit{in space and time}, i.e., of the form \(v_n = v_n(\nabla h, \nabla^2 h, \cdots)\), expressing that the normal velocity \(v_n\) becomes essentially a function of the instantaneous slope (angle) and curvature of the interface only. Upon expanding in the gradients, adding noise, and retaining only relevant terms, one then arrives at \((2)\).

The starting point of such an argument, the fact that one can integrate out the internal structure of the interface and on long length and time scales think of it as a mathematically sharp boundary with effective dynamics expressed by a boundary condition \(v_n = v_n(\nabla h, \nabla^2 h, \cdots)\) which is local in space and time, is appealing and usually correct. Intuitively, one associates it with the interfacial zone being sufficiently sharp on a spatial scale. Nevertheless, there have been scattered observations in the literature which indicate that there is more to it: \((a)\) Some continuum reaction-diffusion equations have propagating planar interfaces of finite width which are stable, but which become weakly unstable for discrete particle model equivalents\textsuperscript{[8]}; \((b)\) The empirical relation observed for the distribution of DLA fingers in a channel and the interface shape of a viscous finger could not be understood from the standard continuum model until the innocuously looking reaction term was regularized\textsuperscript{[8]}; on hindsight, this was because the standard mean-field DLA equations do not give the appropriate “local” boundary conditions of the type \(v_n = -\mu \nabla n p\).

\((c)\) In a simple stochastic particle model with fluctuating fronts, non-KPZ scaling was observed\textsuperscript{[8]} contrary to what one would naively have expected.

It turns out that these observations all have one common denominator\textsuperscript{[8,9,10]}, in that they are related to the existence of two classes of fronts, “pushed” and “pulled” fronts. \textit{Pushed} fronts are the usual ones: their dynamics is determined by the behavior in the interfacial zone, a region of finite thickness, and their response to the bulk fields is local in space and time\textsuperscript{[8,9,10]}. \textit{Pulled} fronts, on the other hand, propagate into a linearly \textit{un}stable state. Although they do not differ noticeably from pushed fronts in their appearance, their dynamics is driven by the growth and spreading of perturbations about the unstable state in the semi-infinite region \textit{ahead} of the front\textsuperscript{[8]}; hence they are particularly sensitive to slight changes in the dynamics there\textsuperscript{[1,14,15,33,35]}. These important differences led two of us\textsuperscript{[8]} to propose recently that fluctuating variants of \(d\)-dimensional pulled fronts in \(d+1\) bulk dimensions would indeed \textit{not} be in the \((d+1)\) D KPZ universality class, even though pushed fronts do effectively give local boundary conditions on long length and...
time scales, and hence do give rise to $d+1$D KPZ scaling in the absence of coupling to a diffusion or laplace field in the bulk \[12\]. Simulations of a simple stochastic lattice model were consistent with these arguments, and with the earlier observations of \[1\].

In this paper, we will argue that fluctuating pulled fronts are indeed in a different universality class from the earlier observations of \[6\]. Indeed, we will show that the semi-infinite fronts are indeed in a different universality class from the earlier observations of \[6\]. Simulations of a simple stochastic lattice model were consistent with these arguments, and with the bulk \[12\]. Simulations of a simple stochastic lattice in the absence of coupling to a diffusion or laplace field in higher dimensions, and hence do give rise to $d+1$D KPZ scaling in the absence of coupling to a diffusion or laplace field in the bulk \[12\]. Simulations of a simple stochastic lattice model were consistent with these arguments, and with the earlier observations of \[1\].

Let us now turn to the analysis of the stochastic behavior of fronts which propagate along the $x$-direction into the linearly unstable state $\phi=0$. The crucial feature of pulled fronts is that even though the full dynamics of the fronts is nonlinear, it is essentially determined in the “leading edge”, the region ahead of the front where $\phi$ remains small enough that the nonlinear saturation term $-\phi^3$ which limits the growth, plays no role: the linear spreading and growth of perturbations about the state $\phi=0$ almost literally “pull the front along”. An important recent development has been the realization that this simple intuitive picture can be turned into a systematic scheme to calculate even the convergence of the front speed to its asymptotic value $v^*$. Remarkably, this relaxation is governed by universal power laws which can be calculated exactly even for general equations \[3\]. The fact that the stochastic fluctuation effects that we want to investigate are dominant relative to the deterministic velocity relaxation terms, suggests to calculate these along similar lines. For the deterministic case ($\eta=0$), fronts in \[1\] propagate with an asymptotic speed $v^* = 2\sqrt{D}$. In a frame $\xi = x - v^* t$ moving with this speed, the asymptotic front solution has an exponential fall-off $\sim e^{-\lambda^* \xi}$ with $\lambda^* = 1/\sqrt{D}$ for large positive $\xi$. The asymptotic relaxation analysis of deterministic fronts is based on the so-called leading edge transformation $\phi = e^{-\lambda^* \xi} \psi$, which transforms \[3\] into

$$\frac{\partial \psi}{\partial t} = D \nabla^2 \psi + (1 + \eta)\psi^3 e^{-2\lambda^* \xi} .$$

Here $\psi$ has been written in the frame moving with velocity $v^*$ in the $x$-direction: $\psi = \psi(\xi, r_\perp, t)$.

In the analysis of deterministic fronts \[1\], the nonlinear term on the right hand side (which is exponentially small for $\xi \gg 1$) essentially plays the role of a boundary condition for the semi-infinite leading edge region where $\phi$ is...
small — it allows the nonlinear region to match properly to the leading edge which “pulls” the front. As explained above, this holds a fortiori for fluctuating pulled fronts: their stochastic fluctuations are essentially determined by the region where the linearized equation can be used. Now, as is well known, upon making a Cole-Hopf transformation \( \psi = e^h \), the linearized equation transforms to

\[
\frac{\partial h}{\partial t} = D\nabla^2 h + D(\nabla h)^2 + \eta,
\]

which is nothing but the \((d+1)+1\)D KPZ equation \((6)\) for the \(d+1\) dimensional field \(h(\xi, r, t)\)

FIG. 1. Left panel: snapshot of the field \(\phi\) at time \(t = 20\) in a 2D simulation of \(\text{Eq. (5)}\) with \(D = 1\) and \(\epsilon = 10\). The thick line is the position of the front, defined by tracking the line where \(\phi(\xi, r, t) = 1/2\). Right panel: the same data as in the left figure, plotted in terms of the height variable \(h\). Note that \(h\) has the appearance of a (slanted) fluctuating surface. The flat portion on the left is the region behind the front and where \(h \approx \lambda^*\xi\) since \(\phi \to 1\). The thick line indicates the height fluctuations along a line of constant \(\xi\). This illustrates that the one-dimensional position fluctuations along the pulled front illustrated by the thick line in the left panel are related to the height fluctuations of the two-dimensional fluctuating surface of the leading edge variable \(h\). The scaling behavior of these is that of the \(2+1\)D KPZ universality class.

As illustrated for two bulk dimensions in Fig. \(\text{II}\), the 1D fluctuations in the front position in the propagation direction are defined by tracing a line where \(\phi = \text{const.}, \text{e.g.}, \phi = 1/2\). Since \(\phi = e^{-\lambda^*\xi+h}\), the front fluctuations in the \(\xi\) direction are given by \(\xi(r, t) = h(\xi, r, t)/\lambda^* + \xi_0 \approx h(\xi_0, r, t)/\lambda^* + \xi_0\), where the constant \(\xi_0\) is determined by the level curve of \(\phi\) which we trace to determine the front position. Thus indeed the position fluctuations of a \(d\)-dimensional pulled front in \(d+1\) bulk dimensions map onto the height fluctuations along a line of a KPZ surface in \(d+1\) dimensions — see Fig. \(\text{II}\). The growth and roughness exponents are therefore those of the \((d+1)+1\)D KPZ universality class!

The above scenario unifies a number of different results. It can immediately be compared with the simulation results of the stochastic lattice model of \(\text{[3]}\). In that paper a 2D lattice model was introduced in which by changing a simple birth and death rule of particles \(1D\) fronts could be tuned from pushed to pulled. The scaling exponents of the pushed model were found to be the standard \(1+1\)D KPZ ones, as it should, while those of the pulled variants were close to those of the \(2+1\)D KPZ universality class. More importantly, without any adjustable parameters, the distribution functions for the long-time saturated width of the fronts in this model for finite transverse width \(L_{\perp}\) \(\text{[19]}\) are completely in accord with our scenario \(\text{[3]}\). Moreover, although fronts in \(1D\) do not have transverse fluctuations, the wandering of the position of pulled fronts in one dimension is also consistent with \(1+1\)D KPZ scaling \(\text{[13]}\). Finally, the observations of Riordan et al. \(\text{[3]}\) that in three (and higher) bulk dimensions their fronts did not appear to show a power law growth of the front width finds a natural explanation. According to \(\text{[3]}\) their fronts are pulled and so they should be governed by the \(3+1\)D KPZ equation. The free \(\lambda = 0\) fixed point in this equation is stable and has no divergent interface width. Apparently above two dimensions the model of \(\text{[3]}\) is in the weak-coupling limit.

On hindsight, our arguments also justify the regularization of \(\text{[3]}\) of the mean-field equations for DLA in a channel: the full problem involves pushed fronts but the mean-field equations have pulled front solutions. The regularization effectively cures this by making the fronts into pushed ones.

![Diagram](image)

FIG. 2. The increase of the root mean square front width \(W = \langle \left(\langle h - h_0^2 \rangle^2 \right)^{1/2} \rangle\) (with the overbar denoting an average over \(r_{\perp}\)) as a function of time. Data are for simulations of Eq. \((\text{II})\) both with nonlinearity (full line) and without nonlinearity (dashed line), for \(\epsilon = 5\) and an effective diffusion constant \(D = 0.4\), which corresponds to dimensionless KPZ coupling constant \(\lambda = 25\) \(\text{[22]}\). The front position \(h\) in the \(x\) direction is defined as the level line where \(\phi = 0.5\). The fact that the growth exponent is essentially the same with and without nonlinearity in the \(\phi\) equation justifies our assertion that these terms do not affect the dominant scaling behavior of pulled fronts.

The validity of the crucial step of our derivation, the assertion that the nonlinearities in \(\text{[3]}\) or \(\text{[4]}\) can be neglected because the leading edge where \(\phi \ll 1\) is the essential region, can be tested independently. In Fig. \(\text{III}\) we show simulation data of the wandering of the lines where \(\phi = 0.5\) in Eq. \((\text{II})\) in 2D, both with and without the nonlinearity. Following \(\text{[3]}\), where the linearized version
of \( h \) was already employed to study the 2+1D KPZ exponents numerically, we have taken parameters so as to make the dimensionless coupling \( \lambda = 2\lambda^2/\nu^3 \approx 25 \). This value appears to be close to the fixed point value and so slow transients are minimized \[24\]. We find indeed that the two datasets with and without the nonlinear term in \[1\] show the same growth exponent, with a value close to the one \( \beta \approx 0.24 \) of the 2+1D KPZ equation. This gives confidence in the validity of our assertion that the nonlinear terms in the front equation are not important for the scaling behavior of pulled fronts.

The main steps of our line of argument are elegantly direct and build on various previously established ideas; at the same time our scenario also raises a number of new questions and challenges for further research:

(i) There is no systematic theory for the transition from the pushed to the pulled regime in stochastic lattice models, so it is difficult to determine a priori which models lead to the standard pushed fronts and which ones to pulled ones. E.g., fronts in the directed percolation problem are pushed and obey KPZ scaling in one special case \[23\], but it is not known whether this is generally so.

(ii) Finite size scaling of the KPZ equation is normally done for interfaces of size \( L_{\perp} \) in all directions. Our scenario, on the other hand, leads one to consider anisotropic scaling, since there is effectively a time-dependent cutoff in the \( \xi \)-direction \[13\]. The crossover scaling is completely unexplored, but is most likely quite tricky: for fixed \( L_{\perp} \) the results of \[13\] for fronts in one dimension suggest that one should see subdiffusive wandering of the average front position, \( \langle (h)^2 \rangle \sim \sqrt{t} \) (rather than \( \sim t \)) because the cutoff in the \( \xi \)-direction grows as \( L_{\xi} \sim \sqrt{t} \), but our simulations seem to suggest that the crossover to this regime happens at such extremely long times that it can not convincingly be seen in practice.

Moreover, the crossover is likely to depend significantly on the initial conditions \[13\].

(iii) According to the results of \[11,4,7\], pulled fronts are very sensitive to finite particle effects, so that the convergence to a continuum limit is extremely slow. This crossover is poorly understood, especially in higher dimensions where it is not even known how important the effects are in practice.

In conclusion, we have put forward an effective field equation for pulled fronts and argued on the basis of it that pulled fronts in \( d+1 \) bulk dimensions are in the \( (d+1)+1 \)D KPZ universality class rather than the \( d+1 \)D KPZ universality class. The scenario ties together various results in the literature and brings up various new issues for future research.

[17] Actually, as is well known, the Stratonovich field equation is only well defined if the noise correlation length is made finite by writing \( \langle \eta(r,t)\eta(r',t') \rangle = 2/\Lambda^4 C(|r-r'|/\Lambda) \delta(t-t') \), with \( \int d^d r C(r) = 1 \). This cutoff does not affect the universal long time scaling.
[18] Although our argument is equally valid in the Itô case, we note that in the Stratonovich case, the finiteness of the relative fluctuations and of the renormalized front speed are connected. Indeed, the fluctuation average of the multiplicative noise term is then \( \langle g(\phi(\eta)) \rangle = \epsilon \Lambda^{-d} C(0) \langle g'(\phi)g(\phi) \rangle \) (see e.g. \[16\]). Here \( C(0) \) is the value in the origin of the regularization of the delta-function, see \[17\] above. For \( g \sim \phi^\alpha \), this gives a term proportional to \( \phi^{2\alpha-1} \), which for \( \alpha < 1 \) leads to an infinite front velocity. Note also that for \( \alpha > 1 \) the analysis in the text implies that the pulled front is unaffected by the noise, so only the choice \( \alpha = 1 \) is consistent.

[21] Our simulations were done on a grid with spacing \( \Delta x = 1 \) and bare diffusion constant \( D_0 = 0.1 \). According to section 5.6.6 of \[1\] this translates into an effective diffusion coefficient \( D = 0.40039 \) in the \( \psi \)-equation \[1\]. Our spatial noise correlation function \( C \) of (see footnote \[1\]) is a linear function that goes to zero at \( \Lambda = 5 \) gridpoints.
