Pyrene-based ammonium bromides combined with g-C3N4 for the synergistically enhanced fixation reaction of CO2 and epoxides†

Tao Chang, Xiaopeng Li, Yongjing Hao, Lianwei Kang, Tian Tian, Xiyong Fu, Zheng Zhu, ** Balaji Panchala† and Shenjun Qin†

A new type of pyrene-based ammonium bromides (PABs) was synthesized via the reaction of bromomethyl pyrene and tertiary amines with different alkyl chains combined with graphitic carbon nitride (g-C3N4) through π-π stacking interactions. The new pyrene-based ammonium bromides were investigated both in homogenous phase and heterogeneous phase combining with g-C3N4 for the CO2 fixation reaction of epoxides under mild conditions. Obviously, the combination was proved to be an efficient system for the conversion of epoxides. The interaction between g-C3N4 and PABs was confirmed by quantum chemical calculations. g-C3N4/Py-C12 exhibited an excellent yield of cyclic carbonates (above 93%) at 80 °C, atmospheric pressure and solvent-free conditions. A preliminary kinetic study was performed using g-C3N4/Py-C12 and the activation energy was calculated to be 61.5 kJ mol⁻¹.

Introduction

The anthropogenic carbon dioxide emission in atmosphere has far-reaching effects on sustainable society, and is considered as a major component of global greenhouse gas, leading to global warming and extreme weather events. However, the effective conversion of CO2 into high value-added chemicals has attracting widespread attention to scientists, because of which it has been regarded as an alternative, nontoxic, and sustainable C1 resource. Among these conversions, the generation of cyclic carbonates, a popular group of chemicals, is recognized as an effective route to convert inert CO2 with epoxides. In addition, cyclic carbonates are established as not only valuable materials with various industrial applications for polymer synthesis, aprotic polar solvents, fuel additives and electrolyte solvents in lithium-ion batteries but also crucial intermediates in the manufacturing of fine chemicals. In fact, there are quite a few materials on the utilization of CO2 fixation, including homogeneous and heterogeneous catalysts, for example, ionic liquids, organocatalysts, Salen, porphyrins, alkali salts, covalent-organic frameworks (COFs), metal–organic frameworks (MOFs) and covalent organic polymers (COPs). More intriguingly, some quaternary ammonium salts have been selected as catalysts for CO2 fixation with epoxides, which are more sustainable than traditional Lewis acid (base) alternatives because of such suit of metal-free organocatalysts according to a green chemistry view point. Apparently, with regard to ammonium catalysts, hydrogen bonding activating strategy of epoxides is crucial for accomplishing CO2 fixation. In addition, the conversion of CO2 to cyclic carbonates under mild conditions, such as low reaction temperature, atmospheric pressure, metal-free and solvent-free, is still challenging.

Recently, the syntheses and application of 2D materials of graphite carbon nitride (g-C3N4) have attracted wide attention on CO2 absorption due to the large amount of basic groups of amine and guanidine as nucleophilic sites for CO2 activation. It is predicted that the as-prepared and adjusted g-C3N4 could be optimized as catalysts for the capture and conversion of CO2. The C3N4 materials could be selected independently as the catalysts for CO2 fixation with epoxides; however, these processes suffer from severe reaction conditions to obtain excellent conversion. Some strategies were developed to increase the activity of C3N4 materials, including adjusted acid-base duality with doping of metal atoms, phosphorous, metal halides, and boric acid. Another is that co-catalysts, such as tetrabutyl ammonium bromide (TBAB), KI, and DMF are introduced and combined with g-C3N4, which play a crucial role in accelerating the rate-limiting step of opening epoxides by the nucleophilicity of halide anions. Although significant advances have been accomplished in g-C3N4 syntheses, some protocols suffer from harsh conditions, such as high temperature, high pressure and...
the presence of metal salts and co-solvents. In addition, most of the optimized procedures focus on modulating the texture structure and surface properties of g-C3N4. Predictably, the development of novel catalysts is still a fascinated alternative, which could interact tightly and realize the reaction synergistically with g-C3N4.

In contrast, the non-covalent methodology is more convenient and effective for the catalyst construction without the chemical modification of homogeneous catalysts. The π–π stacking interactions are an available non-covalent immobilization, and g-C3N4 provides a significant alternative for non-covalent adjustment via π–π stacking interactions with polyaromatic molecules, such pyrene-based moiety. From the above point, the preparation of a pyrene-based non-covalent catalyst anchored on the g-C3N4 surface is a potentially valuable strategy of the heterogenization of homogeneous catalysis. Herein, quaternary ammonium salts connected with pyrene-based tag and different substituted alkyl chains, which possessed the properties of immobilization onto the g-C3N4 surface, are accordingly reported (Scheme 1).

Results and discussion

In order to illustrate the potentiality for a catalytic reaction, the fixation of epichlorohydrin and CO2 as a model reaction was implemented in the presence of pyrene-based ionic liquids under mild conditions (Table 1, entries 1–5). Gratifyingly, all ionic liquids fabricated with mediated alkyl chains exhibited considered activities, which were superior to that of dodecyl trimethyl ammonium bromide (entry 6). Therefore, it is of significance to explore such catalysts deeply. As shown in Tables 1 and 2, when Py-Cn was used with different substitutes, there was only a slight change. The trend is that with the increase in the length of alkyl chains, the carbonate yield was ascending marginally. Predictably, the combination of g-C3N4 and Py-Cn was selected as the catalyst for CO2 conversion because a large number of amine and guanidine groups were grafted, which are beneficial to the absorption and activation of CO2. An increase in the fixation of CO2 was detected in the presence of g-C3N4 (Table 2, entries 1–5). Thus, it is certain that g-C3N4 plays a crucial role in realizing the CO2 fixation reaction. The results were better than that of DTAB combined with Py-Cn, which meant that Py-Cn could interact with g-C3N4. Therefore, a synergistic effect through π–π stacking interactions between Py-Cn and g-C3N4 was proposed, which is significant to realize the organic reaction.

The reaction time was found to influence the CO2 fixation and be an important factor to realize the reaction completely. Then, the influence of the reaction time ranged from 4 to 24 h on the CO2 conversion was explored. As demonstrated in Fig. 1, the cyclic carbonates yield increased with prolonged time, and

⁶ Reaction conditions: ECH (10 mmol, 0.78 mL), Py-Cₙ (0.0375 mmol), g-C₃N₄ (12 mg), CO₂ (0.1 MPa), 70°C, 8 h. In the absence of Py-Cₙ, no reaction.

![Fig. 1 Effect of the reaction time.](image-url)

![Fig. 1 Effect of the reaction time.](image-url)
75.2% yield was obtained after 8 h. From 8 h to 24 h, the well-distributed growth trend of the yield was detected. Therefore, the appropriate reaction time was selected as 16 h, beneficially, this time was not only effective, but also more economical.

Temperature plays a crucial effect on organic reactions. Thus, the influence of temperature varied from 60 °C to 90 °C was investigated for the fixation reaction of ECH with CO2. As shown in Fig. 2, the yield improved rapidly when the reaction was carried out at 60 °C after 16 h, and a yield of 70.2% was detected. The varied yields of 82.6%, 90.1% and 95.2% were obtained when the temperature was risen from 70 °C to 90 °C. Although an excellent yield was explored at 90 °C, temperature of 80 °C was reasonable according to the energy cost.

The yield is strongly related to the amount of the combined catalyst in this reaction. The results were illustrated in Table 3. A yield of 80.1% was obtained at a low catalyst amount with a constant ratio of g-C3N4 to Py-C12 (entry 1) because lower catalytic concentration can not provide sufficient active sites to promote the reaction availability. Increasing the catalyst amount improved the activity of this combined system because of the enhancing synergistic interaction between the catalyst and substrates. A superior yield of 95.2% was observed, and a substantial increase was not obtained by increasing the catalytic amount to higher than 15 mg and 23.8 mg of g-C3N4 and Py-C12, respectively.

In order to expand the versatility of the present catalytic system, the catalyst of Py-C12 with g-C3N4 was evaluated for the CO2 fixation of various epoxides at optimum reaction conditions. All results are summarized in Table 4; as expected, excellent yields varied from 93% to 96% were observed for all epoxides tethered with diverse functional groups. Epoxides exhibited different conversion ability, and some epoxides such as ECH, epibromohydrin, glycidyl phenyl ether and allyl glycidyl ether were converted within 16 h (entries 1–4). In contrast, butyl glycidyl ether and styrene oxide needed a slightly longer time to obtain high yields (entries 5 and 6). In addition, glycol diglycidyl ether could also be considered as a candidate substrate and generated into corresponding cyclic carbonate with good yield at 48 h (entry 7).

The catalytic activity of g-C3N4/Py-C12 was compared with other catalysts for the CO2 fixation reaction, as summarized in Table 5. In most studies, the CO2 fixation reactions were realized at high temperatures and pressures. Comparatively, the reactions were carried out at mild conditions and with lower catalyst amount in our study. Clearly, the catalyst could catalyze the fixation reaction of CO2 by decreasing the activation energy \( (E_a) \), along with a high-speed reaction rate at a lower activation energy. In this regard, the capability of Py-C12 coordinated with g-C3N4 in lowering the activation energy of the fixation reaction was exactly examined at varied temperatures from 50 to 80 °C under the optimum conditions.

### Table 3 Effect of the catalyst amount

In general, the rate equation for the CO₂ fixation was represented as eqn (1). Usually, eqn (1) could be simplified as eqn (2), because the reaction was implemented at constant catalyst concentration and excessively CO₂ conditions. According to previous reports, the fixation reaction was described as pseudo first order reaction on the ECH concentration. Then, the equation was supported as eqn (3) and (4), where k is the rate constant, t is the reaction time and x is the conversion yield.

\[
r = \frac{dx}{dt} = k [\text{ECH}]^{a} [\text{CO}_2]^b [\text{cat.}]^c
\]

\[
r = \frac{dx}{dt} = k [\text{ECH}]^{a}
\]

\[
r = \frac{dx}{dt} = k [\text{ECH}]
\]

\[
\ln(1 - x) = kt + C
\]

\[
\ln k = E_a / RT + C
\]

Therefore, the process kinetics and \( E_a \) of the production were investigated, and the results are demonstrated in Tables S1–S5†, Fig. 3 and 4. As shown in Fig. 3, a linear relationship between \( \ln(1 - x) \) versus time was obtained, that meant that the hypothesis of pseudo first order reaction on the ECH concentration was rational. Thus, the \( k \) values described in Table S5† were calculated from curve of \( \ln(1 - x) \) versus \( t \) at various temperatures. The \( E_a \) to cyclic carbonates could be obtained according to Arrhenius law (eqn (5)). The slope of \( \ln k \) versus \( 1/T \) is the value of \( E_a/T \), consequently, the \( E_a \) was calculated as 61.5 kJ mol\(^{-1} \) (Fig. 4).

In order to investigate the fixation reaction mechanism of CO₂ and epoxides enhanced by pyrene-based ammonium bromides combined with g-C₃N₄, density functional theory (DFT) calculations were performed using a DMol³ module of Material Studio 2016. Molecular orbitals were used to investigate the type of bonding and the interactions between the new pyrene-based ammonium bromides and g-C₃N₄ during the catalytic process. The surfaces of the molecular orbitals were drawn at the 0.03 a. u. iso level, and they described the electron density in both the GS and the excited state in Fig. S1.† In case of g-C₃N₄/Py-C₄ and g-C₃N₄/Py-C₁₈, it was a π-type bond and the electron density was localized on g-C₃N₄ and the tertiary amine group \((-(\text{CH}_2)_2-\text{N-(CH}_2)_2-)^+\) and Br⁻. The molecular orbitals that characterized this π-type bond were HOMO orbitals. The process included a slight delocalization of electron density from the g-C₃N₄ ring. On the basis of g-C₃N₄/Py-C₈ and g-C₃N₄/Py-C₁₆, the π-type bond exited between them, and the electron density was localized on the g-C₃N₄ and the pyrenephenyl group. The molecular orbitals that characterized this π-type bond were also HOMO orbitals. The π-extended electron density conjugation appeared as an effect of an intramolecular interaction between

electron density was localized on the g-C3N4 and the tertiary electron density was localized on the g-C3N4 and pyrene-based ammonium interacting tightly with g-C3N4 to epoxides is attacked by the nucleophilic bromide ion from the result, the increasing electrophilicity of the terminal carbon of group. Therefore, a series of varying alkyl chain-substituted amine group (Py-C12 is depicted in Scheme 2. First, the interaction of g-C3N4 with Py-C12 happens through π–π stacking interactions as exhibited to have predominant conjugation effects, and the electron density was localized on the g-C3N4 and pyrenephyl group. Based on g-C3N4/Py-C12, a scheme of synergetic efffects, and the interaction catalyzed by g-C3N4/pyrenephyl group and g-C3N4 ring. Based on g-C3N4/Py-C12, the stronger interaction was π–π conjugation effects, and the electron density was localized on the g-C3N4 and the tertiary amine group (–(CH2)3–N–(CH3)2–) and Br−. Meanwhile, the weaker interaction was π → π conjugation effects, and the electron density was localized on the g-C3N4 and pyrenephyl group. Therefore, a series of varying alkyl chain-substituted pyrene-based ammonium bromides combining with g-C3N4 by π–π stacking interactions were exhibited to have predominant activity for CO2 fixation with various epoxides.

Therefore, based on the present experimental and previous references,11,41,44,50–52 the proposed mechanism derived from the concept of synergetic effect for CO2 fixation catalyzed by g-C3N4/Py-C12 is depicted in Scheme 2. First, the interaction of g-C3N4 with Py-C12 happens through π–π stacking certified by DFT and previous reports.57,58 Thus, the combined catalytic system is favorable for synergistic interaction between catalytic sites of amino groups and the nucleophilic reagent (Scheme 2, intermediate I). Second, the amino groups in g-C3N4 play a significant role in activating the epoxides and carbon dioxide through hydrogen bonding. The activation of epoxides through hydrogen bonding with primary amino group and CO2 via secondary and tertiary amine possibly occurs simultaneously, which allows the coordination of intermediate II.26,44 As a result, the increasing electrophilicity of the terminal carbon of epoxides is attacked by the nucleophilic bromide ion from the pyrene-based ammonium interacting tightly with g-C3N4 to generate the negative bromo-alkoxide intermediate III, which is stabilized by hydrogen bonding. Consequently, the attack of activated CO2 with bromo-alkoxide and intermediate IV of linear bromo-carbonate are generated. Finally, the intramolecular ring-closing of intermediate IV occurs, and the generated cyclic carbonate regenerates the catalyst.

Experimental section

Preparation of pyrene based quaternary ammonium salts and g-C3N4

Synthesis of bromomethyl pyrene (PyBr). It was synthesized through the reaction of pyrene methanol with PBr3 under argon gas atmosphere. The classic procedure was as follows: 1-pyrene methanol (1 g, 4.3 mmol) was added into a Schlenk flask, sealed with a rubber tap, and charged with Ar three times. Then, 50 mL anhydrous toluene was injected into the flask, which was placed into an ice bath. PBr3 (1 mL, 10.5 mmol) was injected into the flask. The mixture was stirred for another 5 h. When the reaction finished, a saturated sodium carbonate solution (20 mL) was added into the flask, the organic phase was separated and washed with 20 mL water and saturated NaCl solution twice, respectively, and dried with anhydrous MgSO4. Finally, most toluene was evaporated and crystallized in a refrigerator. The pale-yellow crystal was obtained, and the yield was 85%.

Synthesis of pyrene based quaternary ammonium salts. Various alkyl-substituted pyrene-based quaternary ammonium salts were prepared via the reaction of PyBr with alkyl tertiary amines. PyBr (1.0 g, 3.39 mmol), alkyl tertiary amine (3.39 mmol) and 20 mL toluene were mixed in a flask at 55 °C for 48 h. After the reaction completion, the white solid was filtered, and dried under vacuum.

Synthesis of g-C_{3}N_{4}. g-C_{3}N_{4} was synthesized according to a previous study,\(^6\) and in a typical procedure, melamine (20 g) was placed into a quartz boat and heated at 550 °C under N\(_2\) atmosphere for 4 h. The yellow powder was obtained and used without further purification.

Procedure of CO\(_2\) fixation with epoxides

At room temperature, Py-C\(_{m}\) g-C\(_3\)N\(_4\) and epoxides were charged into a Schlenk tube, respectively. To enable the catalysts completely, the mixture was sonicated for 20 min. Then, CO\(_2\) was injected into the tube through a balloon, which was placed into a heater and stirred at a fixed temperature. After the reaction, the mixture was cooled at room temperature, and the excess CO\(_2\) was vented. After centrifugation, a small amount of clearly crude product was separated and detected by \(^1\)H NMR to identify the conversion.

DFT calculations

The DFT calculations were performed using a DMol\(^3\) module of Material Studio 2016. During optimization, all atoms of the paddlewheel cluster and adsorbing molecules, except terminating atoms, could relax. The generalized gradient approximation (GGA) method with the Perdew–Burke–Ernzerhof (PBE) function was employed to describe the interactions between the core and electrons. An energy cutoff of 450 eV was used for the plane wave expansion of the electronic wave function. The force and energy convergence criteria were set to 0.03 eV Å\(^{-1}\) and 10\(^{-5}\) eV, respectively.

Conclusions

A series of ranged alkyl chain-substituted pyrene-based ammonium bromides combining with g-C\(_3\)N\(_4\) by \(\pi\)–\(\pi\) stacking interactions exhibited a predominant activity towards CO\(_2\) fixation with various epoxides, and above 93% yields of the corresponding cyclic carbonates were detected at 80 °C, 0.1 MPa CO\(_2\) pressure under solvent-free conditions. It could be predicted that the effectiveness of such a combination system originated from the synergetic interactions between \(\pi\)–\(\pi\) stacking, amino group and bromide ion nucleophile. This method provides a new strategy that the simple immobilized g-C\(_3\)N\(_4\) can be used as a catalyst for the fixation reaction of CO\(_2\) under mild conditions.
