ABSTRACT

Background: Physical activity helps people maintain a healthy weight and reduces the risk for several chronic diseases. Although this knowledge is widely recognized, adults and children in many countries around the world do not get recommended amounts of physical activity. While many interventions are found to be ineffective at increasing physical activity or reaching inactive populations, there have been anecdotal reports of increased physical activity due to novel mobile games that embed gameplay in the physical world. The most recent and salient example of such a game is Pokémon Go, which has reportedly reached tens of millions of users in the US and worldwide.

Objective: Quantify the impact of Pokémon Go on physical activity.

Methods: We study the effect of Pokémon Go on physical activity through a combination of signals from large-scale corpora of wearable sensor data and search engine logs for 32 thousand users over a period of three months. Pokémon Go players are identified through search engine queries and activity is measured through accelerometry.

Results: We find that Pokémon Go leads to significant increases in physical activity over a period of 30 days, with particularly engaged users (i.e., those making multiple search queries for details about game usage) increasing their activity by 1,473 steps a day on average, a more than 25% increase compared to their prior activity level (p < 10−15). In the short time span of the study, we estimate that Pokémon Go has added a total of 144 billion steps to US physical activity. Furthermore, Pokémon Go has been able to increase physical activity across varying cultural, geographic, social, and economic contexts [25].

Conclusions Mobile apps combining game play with physical activity lead to substantial activity increases, and in contrast to many existing interventions and mobile health apps, have the potential to reach activity-poor populations.

Keywords: physical activity, Pokémon Go, wearable

1. INTRODUCTION

Those who think they have not time for bodily exercise will sooner or later have to find time for illness.

Edward Stanley, Earl of Derby, 20 December 1873

Physical activity is critical to human health. People who are physically active tend to live longer, have lower risk for heart disease, stroke, Type 2 diabetes, depression, and some cancers, and are more likely to maintain a healthy weight (e.g., [20, 32, 46]). Recent analyses estimate that physical inactivity contributes to 5.3 million deaths per year worldwide [16] and that it is responsible for a worldwide economic burden of $67.5 billion through health-care expenditure and productivity losses [5]. Only 21% of US adults meet official physical activity guidelines [4, 22] (at least 150 minutes a week of physical activity for adults), and less than 30% of US high school students get at least 60 minutes of physical activity every day [4]. Efforts to stimulate physical activity hold opportunity for improving public health. Numerous studies have called for population-wide approaches [26, 27]. However, many interventions have been found to be either ineffective [8, 28], to reach only populations that were already active [17], or not to be scalable across varying cultural, geographic, social, and economic contexts [25].

Recently, there have been anecdotal reports of novel mobile games leading to increased physical activity, most notably for Pokémon Go [1, 2] (other examples include Ingress [4] and Zombies, Run [7]). Pokémon Go is a mobile game combining the Pokémon world through augmented reality with the real world requiring players to physically move around. Pokémon Go was released in the US on July 6, 2016 and was adopted widely around the world (25 million active users in the US [1] and 40 million worldwide [17]; 500 million downloads worldwide [18]). Due to this massive penetration, Pokémon Go can be viewed as intervention for physical activity on a societal-scale. However, its effectiveness for stimulating additional walking has yet to be determined.

Present Work. We study the influence of Pokémon Go on physical activity through a combination of wearable sensor data and search engine query logs for 31,793 users over a period of three months. Within these users, we identify 1,420 Pokémon Go users based on their search activity and measure the effect of playing the game on their physical activity (see Section 2.4). We further compare changes in physical activity for Pokémon Go users to changes for large control group of US wearable users and to other leading mobile health apps. Lastly, we estimate the impact of Pokémon Go on public health.

In summary, our main research questions are:
1. Is playing Pokémon Go associated with increases in physical activity? How large is this effect and how long does it persist?
2. Is this effect restricted to particular subpopulations or is it effecting people of all prior activity levels, ages, gender, and weight status?
3. How does Pokémon Go compare to leading mobile health apps in terms of its ability to change physical activity?
4. How has Pokémon Go impacted physical activity in the United States and what is its potential impact on public if the game was able to sustain the engagement of its users?

Our study provides guidance on societal-scale interventions represented by the Pokémon Go phenomenon and on the possibilities for increasing physical activity that could be achieved with additional engagement. We see this study on Pokémon Go as a step towards effectively leveraging games for public health purposes. Mobile games might not be appealing to everyone and therefore should be seen as a complement rather than a replacement for the interventions considered in the rich body of work on physical activity interventions (e.g., [8, 19, 26, 27, 28, 32]). To the best of our knowledge, this is the first study to combine large-scale wearable and search sensors to retrospectively evaluate physical activity interventions and the first to study the effect of Pokémon Go.

2. METHODS

We leverage and combine data from search engine queries with physical activity measurements from wearable devices. Specifically, we jointly analyze (1) queries to the Bing search engine mentioning “pokemon”. We use this to identify which users are likely playing Pokémon Go (see Section 2.1); and (2) physical activity as measured through daily number of steps on the Microsoft Band (see Section 2.2). We jointly use this data to measure differences in physical activity before and after each user shows strong evidence of starting to play Pokémon Go.

The main study population is 31,793 US users of Microsoft products who have agreed to link data from their Microsoft Band wearables and their online activities to understand product usage and improve Microsoft products. In Section 2.1 we show that 1,420 users can be classified as Pokémon Go players with high confidence. We compare changes in physical activity in this population to changes in a control group consisting of a random sample of 50,000 US Microsoft Band users. For all users, we have self-reported age, gender, height and weight, which we will use in Section 2.3 to estimate the effect of Pokémon Go on different groups of users. Section 2.1 details how we identify Pokémon Go users via strong evidence from search logs and Section 2.2 explains the accelerometer-based physical activity data. Section 2.3 gives details on study population demographics and Section 2.4 explains how we measure the impact of Pokémon Go on physical activity.

### Table 1: Representative experiential and non-experiential Pokémon Go queries [23].

| Search Queries | Experiential query |
|----------------|--------------------|
| pokemon go     | pokemon go iv calculator |
| pokemon go death san francisco | how to play pokémon go |
| pokemon go robberies | pokemon go guide |
| couple sues pokemon go | pokemon go servers |
| baltimore pokemon accident | pokemon go bot |
| pokemon games | bluestacks pokemon go |
| bluestacks pokemon go | pokemon go eevee evolution |

Among the 25,446 users who issued any queries during our time of observation, 1,420 or 5.6% issued an experiential query for Pokémon Go. This number very closely matches the estimated fraction of regular Pokémon users in the US (5.9% according to [25]) suggesting that our search-engine based method is effectively detecting a large number of Pokémon Go users. We use the time of each user’s first experiential query for Pokémon Go as a proxy for the time when they started playing Pokémon Go and denote this time as \( t_0 \).

Note that our method of identifying Pokémon Go players through experiential queries can potentially overestimate \( t_0 \) if players perform these queries several days after starting to play the game, but the opposite is less likely due to the nature of experiential queries targeting specific aspects of game play (see Table 1). However, note that any potential overestimates of \( t_0 \) lead to more conservative estimates of the effect of Pokémon Go since potential game-related increases in activity would be counted as activity before \( t_0 \) (assuming the effect is non-negative).

2.2 Measuring Physical Activity

We seek to measure the change in physical activity before and after the time of the first experiential query for Pokémon Go, \( t_0 \), when a user presumably started playing the game (see Section 2.1). We measure physical activity through daily steps as recorded by the 3-axis accelerometer/gyrometer of the Microsoft Band. Accelerometer-defined activity measures are preferred over subjective survey-based methods, that have been found to overestimate physical activity by up to 700% [27]. We use steps data from 30 days before the first experiential query (\( t_0 \)) until 30 days after the first experiential query. We note that, at the time of this study, very few users had been using Pokémon Go for more than 30 days. Further note that all Pokémon Go users included in our dataset have been using
the wearable device for a significant amount of time (median 433 days) such that differences in activity cannot be due to starting to use the wearable device. Since not every search engine user who we identified as a Pokémon Go player is also regularly tracking steps, there are 792 users that tracked steps on at least one day before and after \( t_0 \) (see Table 2). Note that the choice of this threshold parameter does not significantly impact our analysis as we find very similar results when restricting our analysis to users tracking for example seven days before and after \( t_0 \). We concentrate our analysis on this set of users and compare their activity to the control group described below.

Control Group. We further compare the differences in activity in the Pokémon Go user population to any changes in the control group, a random sample of US Microsoft wearable users. For example, summertime along with improved weather conditions and potential vacation time might be linked to increases in the steps of the control group as well. Since there are no experiential queries for any of the control users, we need to define a suitable substitute for \( t_0 \) for the control group in order to compare both groups. We will use this reference point \( t_0 \) to measure changes in physical activity before and after for both the Pokémon Go user group as well as control users. For the Pokémon Go users, \( t_0 \) corresponds to the date of the first experiential query for Pokémon Go (e.g., July 6, 2016, or July 7, 2016, etc.). One could consider using a single point in time \( t_0 \) for all control users, for example the July 6, 2016 release date of Pokémon Go. However, this choice would temporarily align all control users such that weekend, weather, or other effects could lead to confounding. In the Pokémon Go user group, all users have potentially different \( t_0 \) based on their first experiential query and therefore such effects are not aligned. In order, to match observation periods between both groups, we therefore use the exact same distribution of \( t_0 \) for control users; that is, for each control user, we randomly sample a Pokémon Go user and use the same value for \( t_0 \) for the control user. This ensures that we will compare physical activity over matching observation periods.

Wear Time. Furthermore, we also measure the wear time of the activity tracking device for each day in the dataset. Differences in recorded number of steps could potentially stem from simply an increase in wear time rather than an actual increase of physical activity. However, we find that during the study duration the wear time for both Pokémon Go and control users was effectively constant with the ratio between the groups changing by less than one percent. Therefore, we attribute any differences in recorded number of steps to an actual increase in physical activity due to the engagement with Pokémon Go.

Example Time Series of Physical Activity. Figure 1 displays the daily number of steps before and after the user’s first experiential query for two example users. Both users significantly increase their activity after their first experiential query for Pokémon Go by several thousand steps each day. In Section 2.3, we analyze whether this large increase in physical activity is representative of the study population and how it varies across individuals.

2.3 Study Population Demographics

Demographic statistics on identified Pokémon Go users and control users are displayed in Table 3. We find that Pokémon Go users are younger than the average user in our wearable dataset, and much less often female. Furthermore, there is a significant fraction of overweight and obese users, similar to the proportion expected in the US population [21]. This fraction of overweight and obese

| Minimum number of exp. | # Users | # Days with steps data |
|------------------------|--------|------------------------|
| Pokémon Go queries     |        |                        |
| 1                      | 792    | 36,141                 |
| 2                      | 417    | 18,804                 |
| 3                      | 262    | 11,916                 |
| 4                      | 199    | 9,132                  |
| 5                      | 143    | 6,633                  |
| 6                      | 113    | 5,186                  |
| 7                      | 85     | 3,819                  |
| 8                      | 70     | 3,131                  |
| 9                      | 56     | 2,512                  |
| 10                     | 50     | 2,218                  |

Table 2: Number of Pokémon Go users and number of days of steps tracking for these users included in dataset. We count days up to 30 days before and after each user’s first experiential query, and only consider users with at least one day tracked before and after their first experiential query.

| Pokémon Go Users | Wearable Users |
|------------------|----------------|
| # users          | 1,420          | 50,000         |
| # users with sufficient activity data | 792 | 26,334 |
| Median age       | 33             | 42             |
| % female         | 3.8            | 25.7           |
| % underweight (BMI < 18.5) | 1.1 | 1.2 |
| % normal weight (18.5 ≤ BMI < 25) | 34.2 | 31.4 |
| % overweight (25 ≤ BMI < 30) | 36.5 | 38.4 |
| % obese (30 ≤ BMI) | 28.2 | 29.1 |
| Average daily steps overall | 6,258 | 6,435 |

Table 3: Dataset statistics. Wearable users refers to random sample of US Microsoft Band users. We only consider users with at least one day of steps tracking before and after the user’s first experiential query. BMI refers to body mass index.

Figure 1: Time series of daily steps for two sample users. Both cases show significant increases in daily steps after the first experiential query for Pokémon Go (\( t_0 \)). While before \( t_0 \) both users take less than 5,000 steps a day, after \( t_0 \) they regularly reach around 15,000 steps a day.
users is very similar in the Pokémon Go and control user groups indicating lack of a selection effect based on weight status. The average activity level of Pokémon Go users is below that of the control group indicating that Pokémon Go is attracting users that get less than average activity. Note that this difference is unlikely to stem from other differences between the two groups since younger users are typically more active than older users and males typically get more physical activity than females \(^{(38)}\) \((i.e.,\) we would expect a larger number of steps for the Pokémon Go group given the other differences).

2.4 Measuring the Impact of Pokémon Go

This section details the methods used to measure the impact of Pokémon Go on physical activity.

2.4.1 Longitudinal Analysis

We compare the physical activity levels of Pokémon Go users to those of the control group population over time in relation to every user’s first experiential query \((t_0)\). Note that we use randomly sampled \(t_0\) for users in the control group \(\text{see Section 2.2}\).

We measure the average number of steps over a period of 30 days before the first experiential query until 30 days after the first experiential query. Note that on some days a user might not have recorded any steps and we ignore this user on that day. We measure this average activity separately for the Pokémon Go user group and the control group. To improve graph readability, we smooth the daily average activity through Gaussian-weighted averaging with a window size of seven days, but we report statistical tests on the raw data. We estimate 95% confidence intervals through a bootstrap with 500 resamples \(\text{[11]}\).

2.4.2 Dose-Response Relationship between Pokémon Go and Physical Activity

Dose-response relationships between the amount of physical activity and various health outcomes have been well established \(\text{[9, 17]}\). We expect that high engagement with Pokémon Go would be reflected in a larger number of experiential queries. Particularly engaged users might also exhibit larger increases in physical activity. We quantify the exact effect sizes for these increases and study this potential dose-response relationship between the Pokémon Go related engagement on a search engine and real-world physical activity. We measure the difference in the average number of daily steps across all users and days for the 30 days before versus 30 days after each user’s first experiential query as the effect size.

2.4.3 Does Everyone Benefit?

We measure the effect on individual users’ physical activity after starting to play Pokémon Go and relate the magnitude of this effect to demographic attributes of the user including age, gender, weight status \(\text{(body mass index; BMI)}\), and prior activity level. We investigate whether only certain user groups are benefiting from the game or whether the potential health benefits might apply more widely to the game’s user population. We estimate the effect of playing Pokémon Go on each individual user defined as the difference in the average number of daily steps 30 days before and 30 days after the first experiential query. We include only Pokémon Go users with at least seven days of steps tracking before and after this event to reduce noise and apply the same requirement to the control group. These constraints result in 677 Pokémon Go users and 26,334 control users.

2.4.4 Comparison to Existing Health Apps

We compare the effect of Pokémon Go to the effect of other mobile health apps. The Microsoft Band can be connected to other fitness and health applications and we have data on when these connections first happen \((i.e.,\) explicit knowledge of \(t_0\) for users of these apps). We study four leading mobile health applications with anonymized names for legal reasons. These apps regularly are rated among the top health apps on both iOS and Android platforms and represent the state-of-the-art in consumer health applications. Again, we measure the number of daily steps 30 days before a user starts using one of these apps until 30 days after. We only include users that started using the health applications after July 1, 2016 to control for seasonal effects and make the data comparable with our Pokémon Go user group. We only include users that were tracking steps on at least 7 days before and after the first experiential query \(\text{(for Pokémon Go group)}\) or first connecting the health app \(\text{(for the comparison groups)}\). For the four apps, 1,155 users are included for app A, 313 for app B, 625 for app C, and 296 users for app D. Note that these users had been using the wearable device for a significant amount of time before connecting to the health app \(\text{(median time in days for the four apps are 87, 57, 103, and 76 days, respectively)}\). Therefore, any differences in average activity are likely due to the connected health app rather than cumulative effects of starting to use a wearable activity tracker.

2.4.5 Estimating the Public Health Impact of Pokémon Go

In order to quantify the effect of Pokémon Go on public health, we estimate \(1\) how many steps were added to US users’ physical activity during the first 30 days, \(2\) how many users met physical activity guidelines before and after Pokémon Go, and \(3\) the potential impact on life expectancy if Pokémon Go could sustain the engagement of its users.

The official physical activity guidelines \(\text{[4, 22]}\) are equivalent to approximately 8,000 daily steps \(\text{[39, 40]}\). Only 21% of US adults meet these guidelines. We use all users tracking steps at least seven days before and after their first experiential query for Pokémon Go. We then measure the fraction of users with more than 8,000 average daily steps both 30 days before and after the first experiential query. This analysis is repeated for Pokémon Go users with at least one and at least ten experiential queries, and the control group.

If there is a substantial impact on physical activity, Pokémon Go could have a measurable impact on US life expectancy due to well-established health benefits of physical activity on heart disease, stroke, Type 2 diabetes, depression, some cancers, obesity, and mortality risk \(\text{[5, 16, 20, 32, 40]}\). If we assume that Pokémon Go users would be able to sustain an activity increase of 1,000 daily steps, this would be associated with a 6% lower mortality risk. Using life-table analysis similar to \(\text{[16]}\) based on mortality risk estimates from \(\text{[10]}\) and the United States 2013 Period Life Table \(\text{[51]}\) we estimate the impact on life expectancy based on this reduction of mortality risk.

3. RESULTS

We now present results on the influence of Pokémon Go usage on physical activity. We study longitudinal physical activity data in Section 3.1. We quantify the dose-response relationship between interest in Pokémon Go and physical activity in Section 3.2. Next, we examine potentially heterogeneous treatment effects by examining various subgroups based on several demographic attributes in Section 3.3. We compare Pokémon Go to four popular mobile health apps in terms of their effect on physical activity in Sec-
3.1 Longitudinal Analysis

Starting to play Pokémon Go is associated with significant increases in physical activity. Changes in average activity level over time are illustrated in Figure 2. The top plot shows activity for Pokémon Go users with at least one experiential query and the bottom plot shows activity for Pokémon Go users with at least ten experiential queries (i.e., users who expressed significant interest in details of Pokémon Go commands and operation).

We observe a significant increase in physical activity after the first experiential query for Pokémon Go users compared to the control group. The control group slightly decreased their activity by 50 daily steps on average ($p < 10^{-20}$; we use Mann–Whitney U-Tests for hypothesis tests unless noted otherwise). In contrast, Pokémon Go users increased their activity by 192 daily steps ($p < 10^{-27}$). The plot shows a steep increase on the day of the first experiential query ($t_0$) suggesting that the observed increased activity indeed stems from engaging with Pokémon Go. We find that Pokémon Go users initially have less activity than the average Microsoft Band user in the US (dashed blue line; 178 daily steps less; $p < 10^{-20}$). However, following the start of Pokémon Go play, their activity increases to a level larger than the control group (65 daily steps more; $p < 10^{-20}$).

The bottom row in Figure 2 shows similar but much larger effects for Pokémon Go users with at least ten experiential queries; that is, users who showed significant interest in Pokémon Go. These users are initially significantly less active than the average Microsoft Band user in the US, getting 5,756 daily steps compared to 6,435 daily steps in the control group ($p < 10^{-20}$). After they start playing Pokémon Go they exhibit a large increase in activity to an average of 7,229 daily steps (1,473 daily steps difference; $p < 10^{-15}$), which now is about 13% larger than the control population ($p < 10^{-20}$). This observation suggests that there is a dose-response relationship between interest in Pokémon Go and the effect on physical activity, which we analyze in detail in Section 3.2.

We note that increases in steps before $t_0$ could stem from starts with the game in advance of queries about Pokémon Go, as we are using the first experiential query as a proxy for the start of play. If users begin to play without ever issuing a search query about Pokémon Go, we could see increases in activity before $t_0$. However, since we observe steep increases in activity exactly at $t_0$, this suggests that the proxy for starting is valid for most users.

Note that physical activity for both Pokémon Go user groups (top and bottom row) decreases again after about three to four weeks after the first experiential query. However, also note that the activity for the more strongly engaged group (bottom) drops down to a higher level than they started out with. This suggests that there could be a longer-term behavior change and that future work is needed to study long-term effects of Pokémon Go.

3.2 Dose-Response Relationship between Pokémon Go and Physical Activity

We find that users that are more engaged with Pokémon Go exhibit larger increases in physical activity (see Figure 3). For users that expressed any interest in Pokémon Go we find significant increases in activity compared to the control group which decreases their activity by 50 steps a day. Further, we find that these increases in steps scale roughly linearly with the number of experiential queries from 192 daily steps increase (3%) for users with one or more experiential queries up to an increase of 1473 daily steps (26%) for users with ten or more experiential queries.

Furthermore, the linear increase in physical activity with the number of experiential Pokémon Go queries strongly suggests that activity increases observed in users querying a search engine for Pokémon Go are causally explained by their engagement with Pokémon Go. If there were other confounding factors that explained the difference in activity between our Pokémon Go group and the control group over time and those changes had nothing to do with Pokémon Go, then one would not expect to find such a clear dose-response relationship as given in Figure 3.

3.3 Does Everyone Benefit?

Since this analysis is on user level, we only consider users who track their activity at least seven days before and after $t_0$. Overall, the Pokémon Go users increased their activity by 194 daily steps ($p < 0.01$; Wilcoxon Signed-Rank-Test). Over the same time period, the control users decreased their activity by 104 steps ($p < 10^{-20}$; Wilcoxon Signed-Rank-Test). Figure 4 illustrates the
effect size split by previous activity level (top left), age (top right), body mass index (BMI; bottom left) and gender (bottom right).

We find that Pokémon Go has increased physical activity across men and women of all ages, weight status, and prior activity levels. In particular, we find that both Pokémon Go users and control users who are very inactive exhibit large activity increases and users who are relatively active even exhibit a decrease in activity on average. However, we find that Pokémon Go users exhibit larger effects than the control across all levels of prior activity (all \( p < 0.025 \)). We find the largest differences between the two groups for users that previously were sedentary (i.e., below 5,000 daily steps [38]). Furthermore, Pokémon Go users exhibit bigger increases in activity than control users across all age groups (all \( p < 0.040 \); except 10-20 year old group which was small) though we find largest effects for younger users between 10 and 30 years. We also find that the positive effect on physical activity does not vary much across all BMI groups, which is encouraging since obese individuals (30 < BMI ≤ 40) are typically less active than healthy subjects [6]. The activity differences in the Pokémon Go groups were always larger than the differences in the control group across all BMI groups (all \( p < 0.021 \)). Lastly, we find that activity differences in the Pokémon Go groups were larger than the differences in the control group for both men and women (all \( p < 0.022 \)). Increases for women were not significantly different from increases for men ( \( p = 0.110 \); note small sample size for women).

In summary, we find that Pokémon Go increased activity all across the studied population, largely independent of prior activity level, age, weight status, or gender. These results are encouraging since they suggest that any positive effects due to Pokémon Go are available even to sedentary, obese, and older users. Effectively reaching these users with physical activity interventions is critical for public health [2].

### 3.4 Comparison to Existing Health Apps

Pokémon Go leads to larger increases in physical activity than other mobile health apps and further attracts more users who are not yet very active. The average daily steps over time is visualized in Figure 5 (using same smoothing method as before). First, we observe that users of all four health apps are significantly more active than the average wearable user (6,514 daily steps) even before starting to use the health app (6,997-7,616 daily steps; see activity before \( t_0 \) in Figure 5 for apps A,B,C,D). Pokémon Go users were less active than the average user (5,901-6,265 daily steps). This demonstrates that Pokémon Go app is attracting a different group of users which is less active and therefore would see larger health benefits from improving their activity [4, 22]. The temporal pattern for the health apps do not contribute strong evidence that these apps are leading to significant behavior change. One exception is app A with its users significantly increasing their activity at day 0. However, this increase in activity is lower compared to the effect of Pokémon Go. Users of app A increased their activity on average by 111 daily steps or 1.6%. Compare this to 194-1502 daily steps or 3.1-25.5% for Pokémon Go users with at least one or ten experiential queries, respectively. In particular, users demonstrating large engagement with Pokémon Go exhibit much larger increases in activity than users of any other app in our comparison.

These results emphasize the special contribution that activity-encouraging games could have on physical activity and public health. These games attract a wide range of people including those with low prior physical activity. We have demonstrated throughout this paper that such games can lead to significant activity increases.

### 3.5 Estimating the Public Health Impact of Pokémon Go

Figure 4: Effect sizes of physical activity increase or decrease by user demographics, including prior physical activity level (top left), age (top right), body mass index (BMI; bottom left) and gender (bottom right). In all cases, we find that Pokémon Go users (red) exhibit larger changes then their respective control group (blue; see Section 3.3). These results suggest that physical activity increases due to Pokémon Go are not restricted to particular subgroups of users but widely spread across the overall study population.
Effect on Meeting Activity Guidelines. Using all users tracking steps at least seven days before and after their first experiential query for Pokémon Go, we find that that the fraction of users meeting physical activity guidelines (i.e., getting 8,000 average daily steps [39][40]) stays approximately constant for users with one or more experiential queries (22.0% before vs. 21.9% after $t_0$) and control users (24.1% before vs. 23.5%). However, for highly engaged Pokémon Go users with at least ten experiential queries, we find that during the 30 days after they start playing 160% more users achieve 8,000 average daily steps (12.2% before vs. 31.7% after; relative increase of 160%). For comparison, 21% of US adults meet these guidelines [4][22].

Effect on Life Expectancy. We found that more engaged users exhibited average physical activity increases of up to 1,473 daily steps (see Section 3.2). This substantial impact on exercise across the society could have a measurable impact on US life expectancy due to well-established health benefits of physical activity [5][16][20][22][46]. If we assume that Pokémon Go users, between 18 and 49 years old, would be able to sustain an activity increase of 1,000 daily steps, this would be associated with 41.4 days of additional life expectancy. Across the 25 million US Pokémon Go users [1], this would translate to 2.825 million years additional life added to US users.

4. DISCUSSION

The Pokémon Go phenomenon has reached millions of people overnight and dominated news media for weeks after its release [1][25][47]. Health professionals have pointed out potential benefits including increased physical activity, spending more time outside and exploring the neighborhood and city, social interactions, and mastering game challenges but have also raised concerns such as injury, abduction, trespassing, violence, and cost [2][29]. In this study, we have precisely quantified the impact of Pokémon Go on physical activity and studied the effect on different groups of individuals.

4.1 Principal Results

We find that playing the game significantly increased physical activity on the group-level (see Section 3.1) and Section 3.2) as well as the individual-level (see Section 3.3) over an observation period of approximately four weeks. The more interest the users showed in Pokémon Go (measured through intensity of search queries seeking details about game usage), the larger the increase of physical activity (see Section 3.2). For example, users that issued ten Pokémon Go queries on details of the game within the two months after release of the game, increased their activity by 1479 steps a day or 26%. These increases are not restricted to already active and healthy individuals but also reach individuals with low prior activity levels and overweight or obese individuals. Comparing Pokémon Go to existing mobile health apps, we find further evidence that Pokémon Go is able to reach low activity populations while mobile health and fitness apps largely draw from an already active population (see Section 3.4). This highlights the promise of game-based interventions versus traditional approaches, which have often been ineffective for these groups of people [7][19].

Given its great popularity, Pokémon Go has significantly impacted US physical activity and added an estimated 144 billion steps to US physical activity which is about 2,724 times around the world or 143 round trips to the moon. Furthermore, highly engaged users were almost three times as likely to meet official activity guidelines in the 30 days after starting to play Pokémon Go compared to before. If this user engagement could be sustained,
Pokémon Go would have the potential to measurably affect US life expectancy.

Our study shows the large potential impact that activity-encouraging games could have on society. However, we have also highlighted challenges in realizing this potential. Most importantly, games would need to be able to sustain long-term engagement and lead to sustained behavior change. Furthermore, these games might not be appealing to everyone (e.g., we observed males to be more likely to play the games than females), and clearly these games should not replace but complement existing physical activity programs (e.g., [8] [19] [26] [27] [28] [32]). Understanding how to design games and how to bring together games and health interventions will be important to public health in the future. As a first step, our study helps to provide guidance on what could come of continuous engagement and with additional engagement.

4.2 Limitations

Out study is not without limitations. First, the study population is not a random sample of US population. Subjects were able to afford a wearable device for activity tracking and willing to share their data for research purposes. Further, we use individuals search queries as a proxy for playing Pokémon Go and consider the number of queries as indicating the degree of engagement. However, we find strong evidence that the proxies for usage and engagement are effective. The method identifies a fraction of users that is very similar to to independent estimates of Pokémon Go penetration in the US (see Section 2.1) and we find a strong dose-response relationship between the number of Pokémon Go queries and increased physical activity (see Section 3.2). Lastly, our follow-up period is currently restricted to 30 days. Future work is needed to study the long-term effectiveness of games such as Pokémon Go to increase physical activity.

4.3 Comparison with Prior Work

The link between physical activity and improved health outcomes has been well-established (e.g., [5] [16] [20] [32] [46]). At the same time, only a small fraction of people in developed countries meet official physical activity guidelines [4] [22]. Consumer wearable devices for activity tracking are becoming more prevalent in the general population. The devices can enable us to better understand real-world physical activity and how to best support and encourage healthier behaviors [13] [30].

Few research studies to date have harnessed data obtained from consumer wearables to study influences of the devices on physical activity. However, a number of medical studies have examined accelerometer-defined activity (e.g., [16] [35]), rather than relying on self-report measures. Studies have found that use of pedometers and activity trackers for self-monitoring can help increase activity [35] [43] but other studies have reported mixed results [42]. Beyond enabling self-monitoring, encouraging additional activity through reminders lead to increased activity only for the first week after the intervention and did not lead to any significant changes after six weeks in a randomized controlled trial [42].

To encourage healthy behavior change, researchers have studied the design of “exergames” [12] [31] [33], video games combined with exercise activity, and location-based games where game play progresses through a player’s location [3]. However, no such game has been nearly as popular and widely used as Pokémon Go. Such games have yet to be integrated into physical activity programs, even though one US college recently announced a physical education class based on Pokémon Go [14].

There is a growing body of work on using large-scale search query logs to identify subjects with particular conditions for re-search studies, including such efforts as detecting adverse reactions to medications and identifying signals that could help with screening for cancer [23] [44] [45]. Other work has studied activity-related posts on social media to better understand the sharing of health behaviors [15] [24] [34] but has not yet connected such data to ground-truth health behaviors or focused on interventions on a large scale.

To the best of our knowledge, this is first study of the link between the usage of Pokémon Go or similar games on physical activity and health. Also, this is the first effort to combine data from wearable devices with information drawn from search engine queries.

4.4 Conclusions

Novel mobile games which require players to physically move in the real world appear to be an effective complement to traditional physical activity interventions and they are able to reach millions of engaged users. We studied the effect of Pokémon Go on physical activity through a combination of large-scale wearable sensor data with search engine logs, and showed that the game leads to significant increases in physical activity over a period of 30 days, with particularly engaged users increasing their average activity by 1,473 steps a day or 26%. Based on our findings, we estimate that the game has already added an estimated 144 billion steps to US physical activity. If engagement with Pokémon Go could be sustained over the lifetime of its many users, we estimate that the game would add an estimated 2.825 million years of additional lifetime to its US users. We see great promise for public health in designing geocentric games like Pokémon Go and in working to sustain users’ engagement with them.
