ABSTRACT

Baryon acoustic oscillations (BAO) are a powerful probe of the expansion history of the universe, which can tell us about the nature of dark energy. In order to accurately characterize the dark energy equation of state using BAO, we must understand the effects of both nonlinearities and redshift space distortions on the location and shape of the acoustic peak. In a previous paper, we introduced a novel approach to second order perturbation theory in configuration space using the Zel'dovich approximation, and presented a simple result for the first nonlinear term of the correlation function. In this paper, we extend this approach to redshift space. We show how to perform the computation and present the analytic result for the first nonlinear term in the correlation function. Finally, we validate our result through comparison with numerical simulations.

Key words: cosmology: theory – large-scale structure of universe

1. INTRODUCTION

In the early universe, when photons were tightly coupled to baryons, the gravitational collapse of baryonic density perturbations was opposed by photon pressure, giving rise to acoustic waves in the baryon-photon plasma (Peebles & Yu 1970; Silk 1968; Sunyaev & Zel'dovich 1970; Bond & Efstathiou 1984). The signature of this effect is known as Baryon acoustic oscillations (BAO), and is observable in both the temperature power spectrum of the cosmic microwave background (de Bernardis 2001; Padmanabhan et al. 2007; Percival et al. 2007, 2010; Blake et al. 2011a).

The BAO signal is a useful cosmological probe because the scale of interest is still largely in the linear regime even at low redshift. The location of the peak thus acts as a “standard ruler” with which the expansion history of the universe can be measured as a function of redshift. This allows us to constrain cosmological parameters, including the equation of state of dark energy (Seo & Eisenstein 2003).

In order to accurately constrain the properties of dark energy using BAO, it is important to model the systematic uncertainty of the standard ruler. Linear theory, which predicts that the amplitude of the peak will scale as the square of the linear growth function, $D(t)$, does not take into account the nonlinear growth of structure, which causes the position and strength of the acoustic peak to change over time. Also, because we are forced to use redshifts to determine distances along the line of sight, we observe an anisotropic galaxy distribution instead of the expected isotropic distribution. The linear order effects of the redshift-space distortion is well understood (Kaiser 1987; Tian et al. 2011; Blake et al. 2011b; Seo et al. 2012). Understanding how these distortions affect higher order terms will be increasingly important as observations become more precise.

A great deal of work has been done to characterize the nonlinearities using cosmological perturbation theory (Jain & Bertschinger 1994; Bouchet et al. 1995; Bernardeau et al. 2002; Crocce & Scoccimarro 2006, 2008; Matsubara 2008b), and to extend perturbation theory into redshift space (Matsubara 2008a; Taruya et al. 2010; Valageas 2011; Carlson et al. 2013). Much of this previous work has been done almost exclusively in Fourier space, focusing on the power spectrum. However, configuration space has many advantages over Fourier space when analyzing the BAO signal. Observationally, it is more natural to work in configuration space, as the BAO signal is a localized peak in the correlation function. Also, in Fourier space, the higher order terms from the perturbation theory involve convolutions over complicated kernels. In configuration space, these terms may involve only sums of products of linear correlation functions. Finally, because redshift space is a simple transformation from configuration space, the full redshift-space correlation function can be straightforwardly computed to any order.

There has recently been renewed interest in using the Zel’dovich approximation to model the nonlinear evolution of dark matter (McCullagh & Szalay 2012; Carlson et al. 2013; White 2014; Tassev 2014a, 2014b). On BAO scales, the Zel’dovich approximation may provide higher accuracy with relatively less computational difficulty than the Fourier-space approach of the standard perturbation theory (White 2014; Tassev 2014a). We have previously shown that one can calculate the real-space correlation function to second order from the Zel’dovich approximation, and that the resulting expression agrees with the previously calculated nonlinear power spectrum (McCullagh & Szalay 2012; Grinstein & Wise 1987). In this paper, we extend our configuration-space approach to the perturbation theory in order to calculate the nonlinear correlation function in redshift space from the Zel’dovich approximation. In Section 2, we analytically derive the nonlinear term in the redshift-space correlation function starting from the Zel’dovich approximation and using the distant observer approximation to relate real space to redshift space. We show in Section 3 that the term is in agreement with numerical simulations. In Section 4, we validate our result through comparison with numerical simulations.
simulations of the Zel’ dovich approximation. We conclude in Section 4.

2. THEORY

In the Zel’dovich approximation, particles’ initial Lagrangian coordinate, \( q \), and their co-moving Eulerian coordinate, \( x \), are related through a displacement field \( \Psi \). The displacement field is the gradient of the linear potential, \( \phi(q) \), times the growth function \( D(t) \) (Zel’dovich 1970; Shandarin & Zeldovich 1989). The linear potential is related to the linear overdensity field through the Poisson equation:

\[
\nabla_q \cdot \Psi(q, t) = -D(t)\nabla_q^2 \phi(q) = -\delta_L(q, t). \tag{1}
\]

To a distant observer, the redshift coordinate \( s \) is related to the Eulerian coordinate \( x \) through the particle’s peculiar velocity along the line of sight:

\[
s(x) = x + f(\Psi(q, t) \cdot \hat{n})\hat{n}, \tag{2}
\]

where \( \hat{n} \) is the line-of-sight direction, and \( f \) is the logarithmic derivative of the growth function, \( D \) (see Hamilton 1998 for a review). Combining Equations (1) and (2), we write the transformation from Lagrangian to redshift coordinates in the Zel’dovich approximation in a similar way as Equation (1), but with an anisotropic displacement field:

\[
s(q) = q + \Psi(q, t), \tag{3}
\]

\[
\Psi(q, t) \equiv -D(t)\nabla_q \phi(q) + f(\nabla_q \phi(q) \cdot \hat{n})\hat{n}.
\]

We now follow the same approach outlined in McCullagh & Szalay (2012) to calculate the nonlinear overdensity, but using the anisotropic displacement field. Mass conservation allows us to relate the initial Gaussian overdensity to the final redshift-space overdensity through the (anisotropic) Jacobian of the transformation in Equation (3):

\[
\rho(s, t) = \rho \cdot \left| \frac{\partial s}{\partial q} \right|^{-1} = \frac{1}{J(q, t)} = 1 + \delta_q(q(s)), \tag{4}
\]

where \( s \) and \( q \) are related by Equation (3). Here, \( \delta_q \) (without subscript \( L \)) is the weakly nonlinear overdensity in redshift space, expressed through the Lagrangian coordinate \( q \).

As discussed in the previous paper, Equation (4) is only strictly valid before shell-crossing, where the mapping is one-to-one. We make the assumption that the effects of shell-crossing are negligible on the scales in which we are interested.

The Jacobian of the transformation from \( q \) to \( s \) can be computed using the relation in Equation (3). It can be expressed in terms of \( f \) and elements of the symmetric deformation tensor \( d_{ij}(q) \), which is the second derivative of the isotropic gravitational potential (Zel’dovich 1970):

\[
d_{ij}(q) = \frac{\partial^2 \phi(q)}{\partial q_i \partial q_j}, \tag{5}
\]

\[
J(q, t) = 1 - D(1(t_1) + f d_{nn}(q)) + D^2((1 + f)I_2(q) - f M_{nn}(q)) - D^3((1 + f)I_3(q), \tag{6}
\]

where \( d_{nn} \) is the line-of-sight component of \( d_{ij} \), \( M_{nn} \) is the corresponding minor of the matrix, and \( I_1 \), \( I_2 \), and \( I_3 \) are invariants of the matrix, which can be written in terms of its eigenvalues \( \lambda_1, \lambda_2 \), and \( \lambda_3 \):

\[
I_1(q) = \lambda_1 + \lambda_2 + \lambda_3, \\
I_2(q) = \lambda_1\lambda_2 + \lambda_1\lambda_3 + \lambda_2\lambda_3, \\
I_3(q) = \lambda_1\lambda_2\lambda_3. \tag{7}
\]

It is necessary to express the overdensity in terms of the redshift coordinate, rather than the Lagrangian coordinate, because we want the expression for the correlation function in terms of the observed redshift-space separation, \( s_1 - s_2 \). To do this, we first invert Equation (3):

\[
q(s) = s - \Psi(q(s), t), \tag{8}
\]

and use Taylor expansions of relevant quantities about the point \( q = s \). First, we express \( \Psi \) as a function of redshift coordinate:

\[
\Psi_i(s(q)) = \left( \Psi_i(q) - \sum_j \frac{\partial \Psi_i(q, t)}{\partial q_j} \Psi_j(q, t) + \ldots \right)|_{q=s}, \tag{9}
\]

where \( \Psi_i \) indicates the \( i \)th component of \( \Psi \). Because \( \Psi \) is proportional to \( D \), this expansion is a power series in \( D \).

Next, we want the final redshift-space overdensity in terms of \( s \), which we will call \( \delta_q(s) \). This function is equivalent to the overdensity \( \delta_q \) found in Equation (4), evaluated at the corresponding Lagrangian coordinate, \( q(s) \):

\[
\delta_q(s, t) \equiv \delta_q(q(s), t). \tag{10}
\]

In order to find the functional form of \( \delta_q(s) \), we rewrite the right-hand side of Equation (10) as:

\[
\delta_q(q(s), t) = \delta_q(s - \Psi(q(s))). \tag{11}
\]

A Taylor expansion of the right-hand side of Equation (11) gives:

\[
\delta(q, t) = \left( \delta(q, t) - \sum_i \frac{\partial \delta(q)}{\partial q_i} \Psi_i(q(s)) + \frac{1}{2} \sum_{i,j} \frac{\partial^2 \delta(q)}{\partial q_i \partial q_j} \Psi_i(q(s))\Psi_j(q(s)) + \ldots \right)|_{q=s}. \tag{12}
\]

The full expression for the redshift-space overdensity in terms of the Lagrangian overdensity to third order in \( D \) is

\[
\delta(s, t) = \left( \delta(q, t) - \sum_i \frac{\partial \delta(q, t)}{\partial q_i} \Psi_i(q) + \sum_{i,j} \frac{\partial \delta(q, t)}{\partial q_i} \frac{\partial \Psi_i(q, t)}{\partial q_j} \Psi_j(q, t) + \frac{1}{2} \sum_{i,j} \frac{\partial^2 \delta(q, t)}{\partial q_i \partial q_j} \Psi_i(q)\Psi_j(q) + \ldots \right)|_{q=s}. \tag{13}
\]

In this expression, \( \delta(q, t) \) is the Lagrangian overdensity computed from the inverse Jacobian, as in Equation (4). This is a function of the invariants of the deformation tensor, which are related to the linear overdensity \( \delta_L \). The quantity \( \Psi(q, t) \) in Equation (13) is simply the gradient of the linear potential, which is related to the linear overdensity through Poisson’s equation (Equation (1)). Thus, we have an expression for the

\[
\text{The Astrophysical Journal, 798:137 (8pp), 2015 January 10}
\]

McCullagh & Szalay
nonlinear Eulerian overdensity in redshift space as a function of the linear overdensity and its derivatives. This can now be used to compute the correlation function in redshift space.

In co-moving coordinates, the redshift-space correlation function is defined as

\[ \xi(s, t) = \langle \delta(s', t) \delta(s' + s, t) \rangle. \]  

Plugging in the density from Equation (13) and grouping terms by order in \(\delta_L\), we arrive at a perturbative expression for the correlation function that is a function only of the linear density and its derivatives. This can now be written as

\[ \xi(s, t) = D^2 \xi^{(1)}(s, t) + D^2 \xi^{(2)}(s, t), \]  

where the terms proportional to odd powers of \(D\) vanish because \(\delta_L\) is assumed to be a Gaussian random field. The \(\xi^{(1)}\) term is simply the variance of linear density \(\delta^{(1)}\) at separation \(s\). \(\xi^{(2)}\) contains two terms, one the expectation value between \(\delta^{(2)}\) and itself, and the other the expectation value of \(\delta^{(1)}\) and \(\delta^{(3)}\) at separation \(s\).

As in real-space, the redshift-space correlation function can be written in terms of the linear correlation functions:

\[
\xi_n(s) = \frac{1}{2\pi^2} \int_0^\infty P_L(k) j_n(k s) k^{n+2} dk.
\]

These functions are one-dimensional integrals of the linear power spectrum, and thus can be computed very quickly for each combination of \(n\) and \(m\).

The calculations of the expectation values in redshift space are very similar to those in real space, but now involve the anisotropic displacement vector. For example, the expectation value between the line-of-sight component of the displacement vector and its line-of-sight derivative is

\[
\langle \Psi_n(s_1) \frac{\partial \Psi_n(s_2)}{\partial q_n} \rangle
\]

\[= \left(1 + f\right) \left(\frac{2}{5} P_3(\mu) \xi_1^{-1}(s) - \frac{3}{5} P_1(\mu) \xi_1^{-1}(s) \right). \]

In real space, the result would be the same but without the factor of \((1 + f)^2\). See McCullagh & Szalay (2012) for a more detailed description of how to calculate these expectation values using spherical harmonics.

The linear redshift-space correlation function, \(\xi^{(1)}(s)\), can be computed as

\[
\xi^{(1)}(s, \mu) = \left(1 + \frac{2f}{3} + \frac{f^2}{5}\right) \xi_0^0(s) - \left(\frac{4f}{3} + \frac{4f^2}{7}\right)
\]

\[\times P_2(\mu) \xi_1^0(s) + \frac{8f^2}{35} P_4(\mu) \xi_1^2(s), \]

where \(P_\ell(\mu)\) is the Legendre polynomial of the order of \(\ell\). This is the configuration-space equivalent of the linear Kaiser formula (Kaiser 1986; Hamilton 1992; Hamilton & Culhane 1996).

As in real space, the first nonlinear term contains expectation values of four linear quantities, which simplifies to products of Wick’s theorem. In redshift space, the term has an additional dependence on \(f\) and \(\mu\), as expected. We have condensed the terms for convenience, and give the full expression in the Appendix.

\[
\xi^{(2)}(s, \mu) = \sigma_\ell^2 \sum_{\ell = 0}^4 \sum_{n_1, n_2} f^{\ell/2} B_\ell(f) \xi_\ell^n(r) P_\ell(\mu) + \sum_{\ell = 0}^8 \sum_{n_1, n_2} \sum_{m=0}^2 f^{\ell/2}
\]

\[\times A_{n_1, n_2}^m(f) \xi_{n_1}^m(s) \xi_{n_2}^{-m}(s) P_\ell(\mu), \]

where

\[
\sigma_\ell^2 = \frac{1}{6\pi^2} \int_0^\infty P_L(k) dk.
\]

There are several interesting cases we can study using this expression. The azimuthally averaged correlation function, which uses a \(\sin \theta \, d\theta\) weighting, selects only the \(\ell = 0\) terms from the anisotropic correlation function. This is due to the orthogonality of the Legendre polynomials.

The linear contribution to the azimuthally averaged correlation function is \(\xi^{(1)}(s) = (1 + (2/3) f + (1/5) f^2)\xi_0^0(s)\). Using Equation (19), we can easily compute the nonlinear contribution to the averaged correlation:

\[
\xi^{(2)}(s) = \sigma_\ell^2 \sum_{n_1, n_2} f^{\ell/2} B_\ell(f) \xi_\ell^n(r) P_\ell(\mu) + \sum_{\ell = 0}^8 \sum_{n_1, n_2} \sum_{m=0}^2 f^{\ell/2}
\]

\[\times A_{n_1, n_2}^m(f) \xi_{n_1}^m(s) \xi_{n_2}^{-m}(s) P_\ell(\mu). \]

Similarly, the quadrupole term can be computed by choosing only the \(\ell = 2\) terms, and so on. The full expressions for the nonlinear monopole and quadrupole are given in the Appendix.

3. DISCUSSION

In our previous paper, in order to verify our real-space result for the nonlinear correlation function, we were able to Fourier transform the expression and compare it with the previously calculated Fourier-space result. We then developed a numerical simulation of the Zel’dovich approximation in Python whose results agreed with the analytical expression. We developed the numerical code in order to test future results, where analytical comparisons are not available to us, such as the redshift-space result presented in this paper. Here, we rely solely on these numerical simulations of the Zel’dovich approximation to verify the result.

We use \textsc{CAMB} (Lewis et al. 2000) to generate the initial power spectrum, with the cosmological parameters \(\Omega_m = 0.71\), \(\Omega_\Lambda = 0.29\), \(\Omega_b = 0.045\), \(h = 0.7\), and \(\sigma_8(z = 0) = 0.89\). Each realization is a 1 Gpc \(h^{-1}\) box with 1024\(^3\) particles. The particles are displaced from the initial grid to their redshift-space positions at \(z = 10, 5, 1, 0\). We calculate the final redshift-space density using a cloud-in-cell (CIC) scheme on a 512\(^3\) grid.

To compute the two-dimensional redshift-space correlation function, we first fast Fourier transform (FFT) the density grid, square it to get the three-dimensional power spectrum, and then inverse FFT the result. We compute averages along transverse slices of the three-dimensional correlation function in order to find the two-dimensional \(\xi(\sigma, \pi)\) in a given realization. The average of the two-dimensional correlation functions over 600 realizations at each redshift allows us to study the behavior of the correlation function over time.

First, we consider the analytic prediction for the correlation function. Figure 1 shows the redshift-space correlation function expected from linear theory, Equation (18). The \(x\)-axis is the transverse direction \((\sigma)\), and the \(y\)-axis is the line-of-sight direction \((\pi)\). The BAO feature shows up as an anisotropic arc in the two-dimensional redshift-space correlation function.

Figure 2 shows the prediction for the nonlinear correction term from the Zel’dovich approximation, Equation (19). The negative value along the BAO arc indicates that this term dampens the BAO feature. Along the line of sight, this term
McCullagh & Szalay

Figure 1. Two-dimensional linear correlation function in redshift space. We plot \( \sinh^{-1}(500\xi(s)) \), which is linear near zero and logarithmic for high values of \( \xi \).

Figure 2. Second order term of the Zel’dovich correlation function in redshift space. Again, we plot \( \sinh^{-1}(500\xi(s)) \).

also tends to broaden the arc, due to the positive contribution on either side of the peak.

Next, we look at the results from the Zel’dovich simulations. A useful way to study the redshift-space correlation function is through its multipole moments. The linear term, Equation (18), contains multipoles \( \ell = 0, \ell = 2, \) and \( \ell = 4 \). The nonlinear term contains even poles up to \( \ell = 8 \). Figure 3 shows the monopole and quadrupole of the measured redshift-space correlation functions at \( z = 10 \) and \( z = 0 \) compared to the prediction from linear theory. The correlation functions have been normalized by \( D(z)^4 \) so they lie on top of each other. As expected, the correlation function at \( z = 10 \) agrees very well with linear theory. This agreement breaks down at \( z = 0 \), where nonlinear evolution has damped the BAO feature significantly compared to the linear theory prediction. From this figure, we can see that the amplitude of the nonlinear correction at \( z = 0 \) is about 10\%–20\% at the BAO peak in the monopole and quadrupole terms.

We test the validity of our analytic expression for the nonlinear correction, Equation (19). To directly compare the simulations to our expression for the nonlinear term, we subtract off the linear term at each redshift and only look at the difference. Figure 4 shows the average nonlinear contribution to the correlation functions at redshifts \( z = 10, 5, 1, 0 \) from the Zel’dovich simulations. We have divided each by \( D(z)^4 \) so they are all on the same scale. Note that at high redshift, what is shown is the difference between two already small values (the measured and linear correlation functions), divided by \( D(z)^4 \), which is also very small. Thus, the signal at high redshifts is noisier, even when averaged over 600 simulations. Window function and discreteness effects are also amplified. At \( z = 0 \), where the nonlinear signal is larger, higher-order contributions become non-negligible, and thus agreement with our theoretical expression is not guaranteed. At \( z = 1 \), we see the best agreement with our theoretical prediction, because the nonlinear term is larger, and higher-order terms are still small. We compare the results from the simulations at various redshifts in Figure 4 to the analytical expression in Figure 2. The shape of the nonlinear term matches well with the analytical result at all redshifts. The damping of the BAO feature and broadening along the line of sight are clear.

To more easily compare the numerical results to the analytical expression, we look at the monopole and quadrupole moments of the nonlinear correction term. Figure 5 shows the monopole and quadrupole moments of the analytic expression, Equation (19), compared to those measured from the Zel’dovich realizations. The multipoles are estimated numerically by performing azimuthal averages over the two-dimensional correlation function, weighted by the corresponding Legendre polynomial. Measuring poles higher than \( \ell = 2 \) in this way is limited by the resolution of the grid, since the poles become increasingly oscillatory. However, we can see that the first two poles of
the nonlinear term agree well with the analytic prediction, especially at high redshift. At low redshift, the contribution from higher-order terms is not negligible, and thus the agreement is not perfect. The overall agreement between the numerical and analytical results allows us to conclude that our expression for the nonlinear term in redshift space is correct.

Other recent work using the Zel’dovich approximation to model the nonlinear evolution of matter, such as White (2014), Carlson et al. (2013), Tassev (2014a), and Tassev (2014b), show similar results. The Zel’dovich expression computed in Carlson et al. (2013, Equation 34) and used in White (2014) gives the full Zel’dovich correlation function in closed form, involving a numerical integral of a Gaussian function. This result would presumably agree exactly with our numerical Zel’dovich realizations at all redshifts.

In contrast, the result presented here is a perturbative expansion of the full Zel’dovich approximation, giving the equivalent of the standard perturbation theory one-loop correlation function for the Zel’dovich approximation. This result is computationally simpler than the full Zel’dovich expression, involving only products of linear correlation functions ($\xi_m^n(\tau)$), which are one-dimensional integrals and can be tabulated easily for a given initial power spectrum. As with standard perturbation theory, the one-loop correlation function does not exactly predict the low-redshift behavior of the full Zel’dovich approximation due to higher-order terms becoming non-negligible, as seen in Figure 5.

We now compare our result to full N-body simulations. We use the Indra suite of simulations, which consists of 100 dark-matter-only simulations run with the Gadget code (J. Wang & A. S. Szalay, in preparation). Each realization is a $(1 \text{Gpc}/h)^3$ box with $1024^3$ particles and Wilkinson Microwave Anisotropy Probe nine parameters (Komatsu et al. 2011). We compute the redshift-space correlation functions as described above using a $1024^3$ CIC scheme for the density.

Figure 6 shows the monopole and quadrupole moments of the measured redshift-space correlation functions at $z = 0$ compared to the predictions from linear theory and our perturbative expansion of the Zel’dovich approximation. The error bars show the standard error of the multipoles measured in

Figure 4. Nonlinear correlation functions from 1000 Zel’dovich simulations, at $z = 10$ (top left), $z = 5$ (top right), $z = 1$ (bottom left), and $z = 0$ (bottom right).
the 100 realizations. The results from these N-body simulations agree quite well with our analytic expression on BAO scales at low redshift. This indicates that the one-loop Zel’dovich correlation function may be sufficient for modeling the BAO peak at low redshift. One application of our result is that it could be used as a template for determining the BAO peak location.

4. CONCLUSION

We have shown that our configuration-space approach to perturbation theory can be extended to redshift space to give the nonlinear redshift-space correlation function to second order in the Zel’dovich approximation. We validate our result through comparison with numerical simulations of the full Zel’dovich approximation. While the expression for the nonlinear contribution is made up of many terms, it is computationally simple because it is a closed-form expression made up of products of linear correlation functions, $\xi^m_n(s)$.

We then compared our analytical model to results from full N-body simulations. We showed that it predicts the first two multipole moments of the redshift-space correlation function quite well on BAO scales at $z = 0$. Due to the numerical simplicity of the result, it may be useful as a template for constraining cosmological parameters from BAO measurements.

In principle, this method can be extended both to higher orders in the Zel’dovich approximation, beyond second order, and to higher orders in Lagrangian perturbation theory, beyond the Zel’dovich approximation. Beyond second order, the terms will be made up of more products of linear correlation functions, and should be straightforward to compute. Extending this method to higher orders in Lagrangian perturbation theory would result in more accurate results, comparable to standard perturbation theory. We leave these extensions to future work.

We thank Mark Neyrinck and Xin Wang for many useful discussions. This research has been supported by the Gordon and Betty Moore Foundation and NSF OIA grant CDI-1124403.

$$A_{0,0}^{0,0} = \frac{1}{45}(105 + 140 f + 140 f^2 + 72 f^3 + 15 f^4)$$

$$A_{0,0}^{0,2} = \frac{2}{315}(105 + 140 f + 119 f^2 + 54 f^3 + 10 f^4)$$
\[ B_2 = \frac{2}{735} (980 + 1295 f + 738 f^2 + 159 f^3) \]
\[ A_{2,0}^2 = -\frac{4}{315} (385 + 484 f + 261 f^2 + 54 f^3) \]
\[ A_{2,2}^2 = \frac{4}{307} (1309 + 1786 f + 1017 f^2 + 216 f^3) \]
\[ A_{3,2}^4 = \frac{16}{1137} (77 + 110 f + 66 f^2 + 16 f^3) \]
\[ A_{1,1}^4 = \frac{4}{1275} (581 + 740 f + 417 f^2 + 90 f^3) \]
\[ A_{1,3}^4 = -\frac{16}{315} (231 + 315 f + 182 f^2 + 40 f^3) \]
\[ A_{2,4}^2 = -\frac{4}{378} (98 + 131 f + 72 f^2 + 15 f^3) \]
\[ A_{3,2}^2 = \frac{2}{315} (77 + 92 f + 49 f^2 + 10 f^3) \]

\[ B_3 = -\frac{8}{225} (21 + 19 f + 6 f^2) \]
\[ A_{3,1}^2 = \frac{51}{1175} (51 + 46 f + 12 f^2) \]
\[ A_{3,2}^4 = \frac{144}{122525} (715 + 702 f + 216 f^2) \]
\[ A_{1,3}^4 = \frac{16}{1575} (251 + 227 f + 60 f^2) \]
\[ A_{1,4}^4 = \frac{16}{4565} (121 + 109 f + 30 f^2) \]
\[ A_{2,4}^2 = \frac{4}{725} (61 + 56 f + 15 f^2) \]
\[ A_{3,2}^2 = \frac{32}{1775} (143 + 119 f + 30 f^2) \]

The nonlinear contribution to the monopole (\(\ell = 0\)) term is

\[ \xi_0^{(2)}(s) = \left( \frac{19}{15} + \frac{76 f}{45} + \frac{64 f^2}{25} + \frac{16 f^3}{25} + \frac{3 f^4}{25} \right) \xi_0^0(s)^2 + \left( \frac{1}{3} + \frac{4 f}{9} + \frac{4 f^2}{9} + \frac{8 f^3}{35} + \frac{f^4}{21} \right) \xi_0^0(s) \times \left( \xi_0^{-2}(s) - 3 \sigma_e^2 \right) \]

The nonlinear contribution to the quadrupole (\(\ell = 2\)) term is

\[ \xi_2^{(2)}(s) = -\left( \frac{28 f}{225} + \frac{262 f^2}{1575} + \frac{16 f^3}{1575} + \frac{2 f^4}{1575} \right) \xi_0^0(s) \xi_2^{-2}(s) - \left( \frac{44 f}{45} + \frac{1936 f^2}{1575} + \frac{116 f^3}{1575} + \frac{24 f^4}{1575} \right) \xi_0^0(s) \xi_2^{-2}(s) \]

The nonlinear contribution to the hexadecapole (\(\ell = 4\)) term is

\[ \xi_4^{(2)}(s) = -\left( \frac{748 f}{2205} + \frac{7144 f^2}{15435} + \frac{452 f^3}{1715} + \frac{96 f^4}{1715} \right) \xi_2^0(s)^2 + \left( \frac{8 f}{45} + \frac{74 f^2}{315} + \frac{164 f^3}{1225} + \frac{106 f^4}{3675} \right) \xi_2^0(s) + \left( \frac{76 f}{125} + \frac{136 f^2}{175} + \frac{1132 f^3}{2625} + \frac{16 f^4}{175} \right) \xi_2^3(s) \]

The nonlinear contribution to the octadecapole term is

\[ \xi_6^{(2)}(s) = -\left( \frac{332 f}{875} + \frac{592 f^2}{1225} + \frac{1668 f^3}{6125} + \frac{72 f^4}{2205} \right) \xi_2^{-1}(s)^2 \xi_2^{-1}(s) - \left( \frac{64 f}{245} + \frac{2864 f^2}{8575} + \frac{1696 f^3}{8575} + \frac{384 f^4}{8575} \right) \xi_2^0(s) \xi_2^{-2}(s) \]

The nonlinear contribution to the decapole term is

\[ \xi_8^{(2)}(s) = -\left( \frac{16 f}{315} + \frac{2 f^2}{2205} + \frac{256 f^3}{6615} + \frac{128 f^4}{15453} \right) \xi_2^3(s) \]
