Supporting Information

ABSTRACT: The rapid development of nanomaterials with unique size-tunable properties forms the basis for a variety of new applications, including temperature sensing. Luminescent nanoparticles (NPs) have demonstrated potential as sensitive nanothermometers, especially in biological systems. Their small size offers the possibility of mapping temperature profiles with high spatial resolution. The temperature range is however limited, which prevents use in high-temperature applications such as, for example, nanoelectronics, thermal barrier coatings, and chemical reactors. In this work, we extend the temperature range for nanothermometry beyond 900 K using silica-coated NaYF₄ nanoparticles doped with the lanthanide ions Yb³⁺ and Er³⁺. Monodisperse ∼20 nm NaYF₄:Yb,Er nanocrystals were coated with a ∼10 nm silica shell. Upon excitation with infrared radiation, bright green upconversion (UC) emission is observed. From the intensity ratio between 2H₁₁/₂ and 4S₃/₂ UC emission lines at 520 and 550 nm, respectively, the temperature can be determined up to at least 900 K with an accuracy of 1−5 K for silica-coated NPs. For bare NaYF₄:Yb,Er NPs, the particles degrade above 600 K. Repeated thermal cycling experiments demonstrate the high durability and reproducibility of the silica-coated nanocrystals as temperature probes without any loss of performance. The present results open avenues for the development of a new class of highly stable nanoprobes by applying a silica coating around a wide variety of lanthanide-doped NPs.

INTRODUCTION

The broad range of potential applications for nanomaterials continues to stimulate research in the nanoregime where size-dependent physical and chemical properties are important in realizing technological breakthroughs.¹⁻⁸ One research area involves the development of detection techniques with sufficient spatial resolution enabled by the small size of nanomaterials. Temperature is an important parameter but is not easy to measure with sufficient resolution, that is at the (sub)micrometer scale. In order to measure temperature accurately, several techniques have been developed. These techniques can be divided into three different categories: electrical,⁹ mechanical,¹⁰ and optical techniques.¹¹,¹² Most electrical techniques combine the relation between temperature and resistance, voltage, conductivity, or electrical capacity with atomic force microscopy (AFM). Mechanical techniques revolve around an AFM tip composed of two metals and the temperature-dependent contact potential between these metals. Although high resolution can be reached with these techniques, the techniques are limited to surfaces. Furthermore, the techniques require contact with the sample and can therefore initiate artificial heat fluxes.

Optical techniques rely on changes in the absorption or emission spectrum induced by temperature changes and do allow for remote temperature sensing. A promising method is luminescence thermometry.¹³,¹⁴ Luminescence thermometry exploits the temperature dependence of the spectral position, bandwidth, intensity, polarization, or lifetime of emission. However, most of these optical properties can also depend on other parameters, such as the concentration of luminescent centers, spectral or intensity shifts induced by other factors besides temperature, or fluctuations in the excitation power or spectral alignment. Fluorescence intensity ratio thermometry (FIRT) is a ratiometric measuring technique and consequently does not depend on variations in sample concentration, alignment, or excitation power. This makes FIRT the ideal technique to measure temperature because it does not require an internal standard.

FIRT is an active and expanding field of research. Most of the research presently focuses on in vivo thermometry for bioimaging.¹⁵,¹⁶ Research has, for example, shown that FIRT can be applied for cancer diagnosis.¹⁷ In cancer, rapid mitosis leads to increased cell temperatures. These increased cell temperatures can be monitored at an earlier stage than with conventional techniques for cancer diagnosis. The temperature probes should have high accuracy in the physiological range. The range and the accuracy of the temperature measurements cannot be optimized simultaneously. Consequently, the highly
sensitive temperature probes used for cancer diagnosis have a very limited measuring range (below 350 K).

Many applications, for example, temperature sensing in nanoelectronics,18,19 nanophotonics,20,21 thermal barrier coatings,22,23 and chemical reactors,24,25 require a much broader temperature range compared to bioimaging. FIRT can be a promising technique in a wider temperature range. However, this requires the temperature probes to be robust and photostable up to elevated temperatures. Ln3+-doped materials are ideal candidates as temperature probes due to their sharp emission lines (easy detection against a broad background), high thermal quenching temperatures of their emission, and high photostability. The Ln3+-doped materials can be organic clusters, metal/organic frameworks, glasses, or (nano-)crystals.26–29 The use of lanthanides in inorganic hosts is favored over organometallic materials, mostly because of the higher (thermal and photo) stability of the inorganic host and the lower energies of vibrations (phonons) in close proximity to the Ln3+ ion. It is well-known that the main mechanism for quenching of the 4f–4f emission of Ln3+ is multiphonon relaxation, a process in which energy is transferred from a Ln3+ excited state to vibrational excited states (heat) of the surrounding matrix. The relaxation rate depends exponentially on the number of phonons that needs to be excited. As a result, multiphonon relaxation has a much lower probability in inorganic hosts that have low-energy phonons (ca. 600 cm−1 for fluorides and oxides) compared to organic materials where large energy gaps can be bridged by a small number of high-energy vibrations (e.g., 3000 and 3500 cm−1 for C–H and O–H vibrations, respectively).30

On the basis of these advantages, both doped glasses31,32 and doped crystalline materials33–35 have been investigated as functional materials for remote temperature sensing using FIRT. However, most of the works focus on bulk materials, with limited spatial resolution and no possibility to measure temperature in stable dispersions. Furthermore, research into both bulk and nanomaterials has led to temperature probes in a range up to 700 K.32,33,35 However, some applications require much higher temperatures, even up to 1500 K,36 which cannot be measured with the currently available temperature probes. To measure temperature with sufficient spatial resolution and at elevated temperatures, new temperature (nano)probes need to be developed.

In this work, we report the application of NaY0.8Er0.02Yb0.18F4 nanocrystals (NCs) and NaY0.9Yb0.11Er0.02F4/SiO2 core/shell (NaYF4@SiO2) NCs as upconverting (UC) nanothermometers. The elemental composition of the NCs was determined by EDX (Figure S1a,b, SI). From the observed peaks, it can be concluded that Na, Y, F, Er, and Yb are all present in the NaYF4 NCs and NaYF4@SiO2 NCs. For the NaYF4@SiO2 NCs, an additional peak for Si is observed along with a strongly increased peak corresponding to O, as expected for silica overgrowth. The calculated stoichiometry for the NaYF4 NCs, NaY0.9Yb0.11Er0.02F4, is in fair agreement with the expected stoichiometry of Na1Y0.8Er0.02Yb0.18F4.

Figure S1c,d (SI) shows that the NCs have a hexagonal crystal structure (JCPDS No. 00-028-1192, cyan lines), as expected. Using the Scherrer equation,47 a rough estimate of the core crystallite size can be calculated, which is ~18 and 17 nm for the NaYF4 and NaYF4@SiO2 NCs, respectively. For the NaYF4@SiO2 NCs, an extra broad band is present centered at a diffraction angle of ~28°, which is due to the amorphous silica.

By combining the data from TEM and EDX, it was shown that NaYF4 NCs doped with Er and Yb can be synthesized. The crystallite size from XRD and the NP size from TEM match very closely, indicating monocristalline core NCs. Furthermore, silica overgrowth results in monodisperse NaYF4@SiO2 NCs in which the size, shape, and crystal phase of the core NCs are unaltered.

■ LUMINESCENCE PROPERTIES

To determine the size, shape, and crystallinity of both the NaYF4 NCs and NaYF4@SiO2 NCs, we used different characterization methods such as transmission electron microscopy (TEM), energy dispersive X-ray spectroscopy (EDX), and powder X-ray diffraction (XRD) measurements. Figure 1 shows TEM images of the prepared NCs, and Figure S1 (Supporting Information (SI)) shows the corresponding EDX spectra and XRD diffractograms.

Figure 1a shows that the synthesis yields monodisperse NCs of 21.7 ± 1.1 nm. The individual NCs are well separated due to the steric effects of the ligand layer, which suggests that the NCs can form a colloidal stable dispersion. These monodisperse NCs form hexagonally ordered domains, which is illustrated with the Fourier transform in the inset. The overgrowth with silica yields monodisperse NaYF4@SiO2 NCs with an unaltered core and a uniform shell of 10.0 ± 0.7 nm, which are charge stabilized by surface silanol groups.

The elemental composition of the NCs was determined by EDX (Figure S1a,b, SI). From the observed peaks, it can be concluded that Na, Y, F, Er, and Yb are all present in the NaYF4 NCs and NaYF4@SiO2 NCs. For the NaYF4@SiO2 NCs, an additional peak for Si is observed along with a strongly increased peak corresponding to O, as expected for silica overgrowth. The calculated stoichiometry for the NaYF4 NCs, NaY0.9Yb0.11Er0.02F4, is in fair agreement with the expected stoichiometry of Na1Y0.8Er0.02Yb0.18F4.

Figure S1c,d (SI) shows that the NCs have a hexagonal crystal structure (JCPDS No. 00-028-1192, cyan lines), as expected. Using the Scherrer equation,47 a rough estimate of the core crystallite size can be calculated, which is ~18 and 17 nm for the NaYF4 and NaYF4@SiO2 NCs, respectively. For the NaYF4@SiO2 NCs, an extra broad band is present centered at a diffraction angle of ~28°, which is due to the amorphous silica.

By combining the data from TEM and EDX, it was shown that NaYF4 NCs doped with Er and Yb can be synthesized. The crystallite size from XRD and the NP size from TEM match very closely, indicating monocristalline core NCs. Furthermore, silica overgrowth results in monodisperse NaYF4@SiO2 NCs in which the size, shape, and crystal phase of the core NCs are unaltered.

Figure 1a shows that the synthesis yields monodisperse NCs of 21.7 ± 1.1 nm. The individual NCs are well separated due to the steric effects of the ligand layer, which suggests that the NCs can form a colloidal stable dispersion. These monodisperse NCs form hexagonally ordered domains, which is illustrated with the Fourier transform in the inset. The overgrowth with silica yields monodisperse NaYF4@SiO2 NCs with an unaltered core and a uniform shell of 10.0 ± 0.7 nm, which are charge stabilized by surface silanol groups.

The elemental composition of the NCs was determined by EDX (Figure S1a,b, SI). From the observed peaks, it can be concluded that Na, Y, F, Er, and Yb are all present in the NaYF4 NCs and NaYF4@SiO2 NCs. For the NaYF4@SiO2 NCs, an additional peak for Si is observed along with a strongly increased peak corresponding to O, as expected for silica overgrowth. The calculated stoichiometry for the NaYF4 NCs, NaY0.9Yb0.11Er0.02F4, is in fair agreement with the expected stoichiometry of Na1Y0.8Er0.02Yb0.18F4.

Figure S1c,d (SI) shows that the NCs have a hexagonal crystal structure (JCPDS No. 00-028-1192, cyan lines), as expected. Using the Scherrer equation,47 a rough estimate of the core crystallite size can be calculated, which is ~18 and 17 nm for the NaYF4 and NaYF4@SiO2 NCs, respectively. Furthermore, silica overgrowth results in monodisperse NaYF4@SiO2 NCs in which the size, shape, and crystal phase of the core NCs are unaltered.
Article

Er\textsuperscript{3+}, in agreement with earlier reports.\textsuperscript{38} The luminescence state i. Emission intensities scale linearly with the population of decay time of excited states that are thermally coupled. \textit{nm}) excited states are nearly identical, which is expected for the \textit{2H}_{11/2} (top) and \textit{4S}_{3/2} (bottom) excited state. The \textit{525}, \textit{545}, and \textit{660} \textit{nm} excited states are observed. The rise times be explained by the UC energy transfer from Yb\textsuperscript{3+} to Er\textsuperscript{3+}. The \textit{0.996}, is close to unity, and the steepness of the \textit{fi} in luminescence is observed. The rise times are measuring the intensity ratio of emission lines from thermally coupled excited states. The population ratio of two excited states \textit{Ni} is determined by a Boltzmann distribution, which includes a temperature-dependent factor, as shown ineq \textit{1}.

\begin{equation}
\frac{\textit{N}_2}{\textit{N}_1} = e^{\frac{-\Delta E}{\textit{kT}}}
\end{equation}

Here, \(\Delta E\) is the energy difference between the two excited states, \textit{k} is the Boltzmann constant, and \textit{N}_i is the population of state \textit{i}. Emission intensities scale linearly with the population of an emitting state. This results in a temperature dependence of the luminescence intensity ratio, as shown in eq \textit{2}.

\begin{equation}
\frac{\textit{I}_2}{\textit{I}_1} = \frac{\textit{g}_2\textit{A}_2\textit{h}\textit{\nu}_2\textit{N}_2}{\textit{g}_1\textit{A}_1\textit{h}\textit{\nu}_1\textit{N}_1} = C e^{\frac{-\Delta E}{\textit{kT}}}
\end{equation}

Figure 2. Emission spectrum of NaYF\textsubscript{4} NCs between 500 and 700 nm while exciting Yb\textsuperscript{3+} at 980 nm (a). Energy diagrams of Er\textsuperscript{3+} and Yb\textsuperscript{3+}, including the transitions involved in the UC process (b). Time-resolved luminescence measurements of emission from the \textit{2H}_{11/2} (520 nm) and \textit{4S}_{3/2} (545 nm) excited states upon excitation at 980 nm (c).

Figure 3. Emission spectra of NaYF\textsubscript{4} NCs upon excitation at 980 nm for temperatures ranging from 300 to 600 K recorded with steps of 25 K (a). The linear relation between the natural logarithm of the integrated intensity ratio of the \textit{2H}_{11/2} and \textit{4S}_{3/2} peak vs \textit{1/T} (b). The \textit{r}^2 value for the fit, 0.996, is close to unity, and the steepness of the fit corresponds to a \(\Delta E\) of 714 cm\textsuperscript{-1}. Five spectra were measured at every temperature interval to estimate the error in the measurements; this error is within the dot size of the data points.

\textbf{FLUORESCENCE INTENSITY RATIO NANOTHERMOMETRY}

FIR nanothermometry with luminescent nanoparticles relies on measuring the intensity ratio of emission lines from thermally coupled excited states. The population ratio of two excited states is determined by a Boltzmann distribution, as shown in eq \textit{1}.

\begin{equation}
\frac{\textit{N}_2}{\textit{N}_1} = e^{\frac{-\Delta E}{\textit{kT}}}
\end{equation}

To investigate the NCs as temperature probes, temperature-dependent luminescence measurements were performed on powders of NCs at temperatures ranging from 300 to 600 K with intervals of 25 K. Each temperature interval consisted of 1 min of heating, followed by a dwell time of at least 15 min before measuring spectra to ensure that the sample temperature was the same as that recorded by the thermocouple in the heating stage. Furthermore, the thermocouple allows for monitoring and compensation of heating effects due to the laser heating.

Figure 3a shows spectra recorded from 300 (black) up to 600 K (orange). The spectra are normalized to the maximum intensity of the \textit{4S}_{3/2} \textit{→} \textit{4I}_{15/2} emission peak. Upon excitation at 980 nm, the characteristic luminescence peaks from the \textit{2H}_{11/2} and \textit{4S}_{3/2} excited states can be observed at all temperatures. The energy difference between these peaks is calculated to be 710 cm\textsuperscript{-1}. The intensity ratio between these peaks changes with increasing temperature, as expected for thermally coupled excited states.

To evaluate the temperature-dependent luminescence further, the natural logarithm of the integrated intensity ratio is plotted versus \textit{1/T}, as shown in Figure 3b. The data points can be fitted with a linear fit, as expected from eq \textit{2}. The quality of the fitting was confirmed by the high \(r^2\) value of 0.996. The fitted slopes give the energy difference \(\Delta E\) between the excited states, which is used to calculate the temperature of the sample.
of this fit is high, as shown by the $r^2$ value of 0.996. From the slope of the linear fit, the energy difference between the excited states, $\Delta E$, is calculated to be 714 cm$^{-1}$ in these NCs. This calculated $\Delta E$ closely matches the experimental values of $\Delta E$ of 711 and 710 cm$^{-1}$ determined from Figures 2a and 3a, respectively.

Using the relation between the temperature and luminescence intensity ratio of the $^5S_{1/2}$ and the $^2H_{11/2}$ peaks in Figure 3, it is evident that these NCs can be used as temperature probes from 300 to 600 K. At higher temperatures, the overall luminescence intensity dropped, and it was too low to determine temperatures accurately. The intensity drop above 600 K was accompanied by a brown discoloration of the NC powders. The discoloration is most likely due to the oxidation of the organic ligands capping the NCs. Due to this decrease in luminescence intensity, the NCs could not be used above 600 K for temperature sensing.

**IN SITU STRUCTURAL CHARACTERIZATION**

In situ TEM and XRD measurements were performed in order to investigate the origin of the sudden drop in luminescence intensity above 600 K. TEM micrographs were taken in situ while heating the NCs that were drop-casted on a special TEM heating chip with intervals of 50 K up to 875 K. XRD measurements, taking $\sim$12 min for one XRD pattern, were performed continuously while heating the sample to 825 K in 9 h and afterward cooling down in 45 min.

Figure 4 shows the resulting TEM images of core NCs at 475, 625, and 775 K (panels a–c, respectively). Figure 4d shows three diffractograms taken before heating, during heating, and after heating to 825 K (top, middle, and bottom, respectively) and the corresponding fwhm and peak position of the (201) diffraction peak at 51$^\circ$ vs temperature (e).

Article

Figure 6. Emission spectra of NaYF₄@SiO₂ NCs upon excitation at 980 nm taken at temperatures ranging from 300 to 900 K with steps of 25 K (a). The linear relation between the natural logarithm of the integrated intensity ratio of the $^{2}H_{11/2}$ and $^{2}S_{3/2}$ peak is plotted vs $1/T$ (b). The $r^{2}$ value for the fit, 0.997, is close to unity, and the steepness of the fit corresponds to a $\Delta E$ of 716 cm⁻¹. Five spectra were measured at every temperature interval to estimate the error in the measurements; this error is within the dot size of the data points.

large clusters of material. The temperature at which the coalescence starts, that is, 625 K, matches the temperature at which the decrease in luminescence starts to occur. The XRD diffractograms show the characteristic peaks of hexagonal NaYF₄ shifting slightly upon heating due to thermal expansion of the crystal lattice. No phase transitions are observed, which is in accordance with investigations of Mathews and co-workers. However, the diffraction peaks become irreversibly sharper at around 625 K. The fwhm decreases from 0.6 to 0.2°, corresponding to an increase in crystallite size. To summarize, the results show that the NCs coalesce, starting at temperatures around 625 K.

The temperature at which the luminescence intensity decreases dramatically corresponds to the temperature at which the NCs start to coalesce, as confirmed with TEM and XRD. It is likely that the atomic alignment of the NCs during coalescence/sintering is imperfect, resulting in the introduction of defects in the crystals. These defects can act as quenching sites for luminescence and therefore explain the sudden decrease in luminescence intensity in addition to the ligand oxidation discussed above.

The same in situ measurements were performed on the NaYF₄@SiO₂ NCs, as shown in Figure 5. In contrast to the NaYF₄ NCs, the NaYF₄@SiO₂ NCs remain well separated on the TEM images for all temperatures, showing that no interparticle alloying or intraparticle coalescence occurs. The fwhm of the (201) diffraction peak at 51° is constant during the entire thermal cycle, suggesting that the crystallite size remains unaltered. The overgrowth with silica, resulting in the core/shell architecture, ensures that the NCs are thermally stable up to 875 K and show no luminescence quenching up to at least 900 K.

(Temperature-Dependent) Photoluminescence of NaYF₄@SiO₂ Nanocrystals

To improve the temperature stability and thus extend the temperature range for nanothermometry, the NaYF₄ NCs were coated with a protective silica shell. The SiO₂ shell replaces the organic ligands and can prevent luminescence quenching due to oxidation of ligands and NCs coalescence. To investigate if the silica overgrowth has an effect on the luminescence properties of the NC cores, (time-resolved) room-temperature luminescence measurements were performed similar to those shown in Figure 2. The results, included in Figure S2, reveal that the emission spectra are nearly identical except for a small increase in the relative intensity of the $^{2}F_{9/2} \rightarrow ^{4}I_{15/2}$ emission. Also, the decay time of the $^{2}S_{3/2}$ and $^{2}H_{11/2}$ excited states are slightly shorter (85 µs after silica overgrowth vs 100 µs before). The shortening of the lifetime suggests that nonradiative relaxation to lower-lying $^{2}F_{7/2}$ states has increased, which is consistent with the observed increase in relative intensity of the $^{2}F_{9/2} \rightarrow ^{4}I_{15/2}$ emission. The increase of nonradiative relaxation can be explained by the presence of hydroxyl groups in the silica shell. These hydroxyl groups are present because of incomplete condensation of neighboring silanol groups, Si–OH. These silanol groups condense to form typical Si–O–Si bonds in silica. The high-energy O–H vibration (ca. 3500 cm⁻¹) gives rise to faster multiphonon relaxation.

Although the additional O–H vibrations give rise to faster decay times as a result of multiphonon relaxation, the energy levels of Er³⁺ remain unaltered due to shielding of the f orbitals. The unaltered energy levels dictate that the energy difference, $\Delta E$, between the $^{2}H_{11/2}$ and $^{2}S_{3/2}$ state, and therefore the temperature-dependent luminescence, is not expected to change, which is in agreement with the experimental results.

In order to investigate the temperature-dependent luminescence properties of the silica-coated NCs, emission spectra were measured at different temperatures under 980 nm excitation. Figure 6a shows the spectra taken from 300 (black) up to 900 K (orange), normalized to the maximum intensity of the $^{2}S_{3/2} \rightarrow ^{4}I_{15/2}$ emission peak. The characteristic luminescence peaks from the $^{2}H_{11/2} \rightarrow ^{4}I_{15/2}$ and $^{2}S_{3/2} \rightarrow ^{4}I_{15/2}$ transitions can be observed up to 900 K!

There is a small decrease in intensity, but clearly the temperature stability of the emission is strongly improved in comparison to the NaYF₄ cores. At the temperature limit of our experimental setup (900 K), the emission spectra are still well-resolved, suggesting that significantly higher temperatures can be probing. The emission intensity and signal-to-noise ratio hardly change between room temperature and 900 K. As can be observed in Figure 6a, the signal-to-noise ratio remains high up to the highest temperatures. The temperature limit of 900 K is solely set by the limitations of our instrumentation.

To calibrate the silica-coated NCs as a temperature probe, the natural logarithm of the integrated intensity ratio is plotted versus $1/T$, as shown in Figure 6b. The data points can be fitted with a linear fit, similar to Figure 3b.

The quality of the fit is high, as shown by the $r^{2}$ value of 0.997. From the slope of the linear fit, the energy difference between the excited states, $\Delta E$, can be calculated to be 716 cm⁻¹ and closely matches the experimental value of $\Delta E$ determined from the spectra and from the temperature-dependent emission spectra of the NaYF₄ core particles. The
results show that the maximum temperature range of the core particles can be expanded up to at least 900 K by applying a protective silica shell. The linear fit shows good agreement with the data points over the full temperature range.

**THERMAL CYCLING EXPERIMENT**

In addition to having high thermal stability and temperature accuracy, it is important that a temperature sensor can survive multiple thermal cycles without a change in properties. To investigate the durability of the NaYF₄@SiO₂ NCs, the temperature probes were cycled between 300 and 900 K five times. During the heating up and cooling down in each cycle, luminescence measurements were performed at 300, 450, 600, 750, and 900 K.

Figure 7a shows the spectra taken at five different temperatures during the cycle experiment, normalized to the ⁴S₃/₂−⁴I₅/₂ emission peak. The spectra at a specific temperature are very similar. At each temperature, the intensity ratio of the two emission peaks was determined and is plotted in Figure 7b. The data points (black) follow identical trends during the five cycles (cyan line). The average fluorescence intensity ratios for each temperature were calculated from the data (dashed lines). The data points only have small deviations from the average. The thermal cycling experiment shows that the temperature probes are stable and durable up to 900 K.

The standard deviations in temperature are calculated to be 1.1, 1.8, 2.9, 5.2, and 5.3 K for 300, 450, 600, 750, and 900 K, respectively. These values are high compared to the very accurate temperature probes used for bioimaging (<0.5 K)⁴⁷. Temperature accuracies down to 0.2 or 0.3 K have been reported for the Yb–Er and Yb–Tm couple in the biologically interesting temperature window.⁴²–⁴⁵ The smaller standard deviations for temperature measurements in bioimaging are expected based on the smaller temperature range. The probes used are optimized for this temperature range such that the change in intensity ratio with temperature is large.

In the case of FIRT, also the sensitivity S and relative sensitivity of a temperature probe are often used as a quality measure of the performance as a temperature sensor. S is defined as the change of the intensity ratio R with temperature, as shown in eq 3.

\[
S = \frac{dR}{dT}
\]

The relative sensitivity is defined as S/R (in % K⁻¹). For a large temperature range, the change in the intensity ratio with temperature varies with temperature, and thus, the relative sensitivity will be different in different temperature regimes. For the NaYF₄:Er,Yb nanoparticles in the 300–900 K temperature range, the sensitivity, calculated using eqs 2 and 3 (with C = 9.4), shows that the relative sensitivity decreases from 1.02% K⁻¹ at 300 K to 0.13% K⁻¹ at 900 K. The 1.02% K⁻¹ sensitivity is consistent with values typically found at around 300 K for Er³⁺ (between 0.5 and 1.5% K⁻¹).⁴⁶ The variation in relative sensitivity with temperature is inherent to using temperature probes in a wide range. The sensitivity of a temperature probe cannot be optimized for the full temperature window. Most applications that require a broader temperature sensing range do not require a sensitivity of 0.5 K. However, care should be taken that the error in the temperature measurement does not become too large. In our case, a measurement error of ~5 at 900 K is sufficient for most applications.

The present results demonstrate for the first time the use of ~50 nm NCs for high-temperature nanothermometry using a silica coating to stabilize the NCs. Silica-stabilized NCs of other host materials (e.g., oxides) and also other Ln³⁺ dopants with a different ΔE between levels can be developed to realize other high-temperature nanoprobes with potentially higher sensitivity in the high-temperature range.

In summary, we have reported NaYF₄:Er³⁺,Yb³⁺ NCs coated with a SiO₂ shell as stable nanoprobes for high-temperature nanothermometry, up to 900 K. The temperature-dependent intensity ratio of emission from the ⁴H₁₁/₂ level (520 nm) and the ⁴S₃/₂ level (545 nm) follows a Boltzmann distribution. From the intensity ratio, temperatures can be measured accurately (1–5 K accuracy) using remote sensing techniques. The temperature stability of the probes is confirmed by in situ TEM and XRD. The temperature-dependent luminescence remains unaltered in multiple cycling experiments between 300 and 900 K. On the basis of these observations, the NaYF₄:Er³⁺,Yb³⁺ nanoprobes provide a noninvasive temperature probe that is dispersible in liquids and has a broad range for temperature sensing. It can therefore be used for high-resolution temperature sensing in a wide range of applications, including chemical reactors and nanoelectronics. The reported method of strongly improving the thermal stability of nanoprobes by silica coating can be generally applied to enhance the performance of other nanoprobes.

ACKNOWLEDGMENTS

The authors acknowledge the assistance of J. Meeldijk and M. Verslujs-Helder, both from Utrecht University, with TEM and XRD measurements, respectively. This work was supported by the Netherlands Center for Multiscale Catalytic Energy Conversion (MCEC), an NWO Gravitation programme funded by the Ministry of Education, Culture and Science of the government of The Netherlands. The authors acknowledge financial support from the European Research Council under the European Unions Seventh Framework Programme (FP-2007-2013)/ERC Advanced Grant Agreement 291667 HierarSACol.
