Keywords: Error Monitoring, Connectome based Lesion Symptom Mapping, Posterior Medial Frontal Cortex, Aphasia, Speech Error Monitoring

Abstract

Optimal performance in any task relies on the ability to detect and correct errors. The anterior cingulate cortex and the broader posterior medial frontal cortex (pMFC) are active during error processing. However, it is unclear whether damage to the pMFC impairs error monitoring. We hypothesized that successful error monitoring critically relies on connections between the pMFC and broader cortical networks involved in executive functions and the task being monitored. We tested this hypothesis in the context of speech error monitoring in people with post-stroke aphasia. Diffusion weighted images were collected in 51 adults with chronic left-hemisphere stroke and 37 age-matched control participants. Whole-brain connectomes were derived using constrained spherical deconvolution and anatomically-constrained probabilistic tractography. Support vector regressions identified white matter connections in which lost integrity in stroke survivors related to reduced error detection during confrontation naming. Lesioned connections to the bilateral pMFC were related to reduced error monitoring, including many connections to regions associated with speech production and executive function. We conclude that connections to the pMFC support error monitoring. Error monitoring in speech production is supported by the structural connectivity between the pMFC and regions involved in speech production, comprehension, and executive function. Interactions between pMFC and other task-relevant processors may similarly be critical for error monitoring in other task contexts.

1. Introduction

1.1. Error monitoring and the posterior medial frontal cortex

The ability to detect our own errors (i.e., error monitoring) is essential in daily life. The most well-documented neural correlate for error monitoring is the anterior cingulate cortex (ACC) (Botvinick et al., 1999; Carter et al., 1998; Gauvin et al., 2016). Notably, the neural activity associated with errors often extends to ACC-adjacent regions including the posterior superior frontal gyrus (pSFG) and medial precentral gyrus (mPG), which combined with the ACC, encompass a territory called the posterior medial frontal cortex (pMFC) (Ridderinkhof et al., 2007). Functional neuroimaging studies (i.e., using fMRI, EEG, PET) consistently demonstrate pMFC activity when individuals make errors on nonverbal tasks such as the Flanker task (Ullsperger & von Cramon, 2004) and verbal tasks such as tongue twisters (Gauvin et al., 2016). Various proposals have suggested that the pMFC, or parts of it, compute conflict, evaluate predicted outcomes, and compute the expected need to recruit control (Botvinick et al., 2001; Brown, 2013; Shenhar et al., 2013). However, our understanding of the pMFC’s role is limited because functional neuroimaging evidence allows for epiphenomenal explanations (e.g., that the pMFC supports error-related...
processing but not error monitoring per-se). In order to refute such epiphenomenal hypotheses, complementary evidence is needed to demonstrate that perturbation of the pMFC impairs error monitoring. Lesion studies are the most extreme case of perturbation to the pMFC and thus could provide converging evidence for non-epiphenomenal interpretations to this brain region.

To that end, there have been several small lesion studies concerning the ACC, a subregion of the pMFC. These lesion studies include case series that use nonverbal tasks to probe executive functions as well as conflict processing and error monitoring (Lavstad et al., 2012). In sum, the available evidence has not comprehensively supported relationships between damage to the ACC and impairments of any executive functions. While one study (n = 8) found that individuals with ACC lesions were not able to monitor task conflict (di Pellegrino et al., 2007), another study (n = 4) found that individuals with ACC lesions monitored task conflict normally (Fellows & Farah, 2005), and a third study (n = 2) found that a participant with a left ACC lesion did not monitor task conflict but that a participant with a right ACC lesion monitored task conflict normally (Svick & Jovancevic, 2002). There are also inconsistent results as to the consequences of ACC lesions on error monitoring, as measured by post-error slowing. While the participants in di Pellegrino et al. (2007) (n = 8) performing a Simon task did not display post-error slowing, participants in Fellows and Farah 2004 (n = 4) performing Stroop and Go No Go Tasks did display post-error slowing. Intriguingly, an electroencephalography study of 5 individuals with large lesions encompassing the pMFC found an absence of the error-related negativity but intact error monitoring behavior on a Flanker task (Stemmer et al., 2004). In terms of other executive functions, two studies (n = 4; n = 2) found that individuals with ACC lesions had normal performance across a battery of executive functions (Baird et al., 2006; Fellows & Farah, 2005).

These lesion studies have been limited by only considering direct damage to the pMFC, which is relatively uncommon in stroke (Arboix et al., 2009), the predominant human lesion model. If the pMFC serves as a domain general error monitoring system, then it must interact with other brain structures that process the task-relevant information to be monitored. In that way, while the pMFC plays a domain-general role in error monitoring, the pMFC needs to receive domain-specific information to monitor relevant tasks. Thus, we hypothesize that disconnections between the domain general pMFC and task-relevant brain regions due to lesions should reduce error monitoring. We refer to this below as the “Disconnected Monitoring Hypothesis”.

1.2. Critical connections for speech error monitoring

Speech production is an ideal task to investigate the Disconnected Monitoring Hypothesis for two reasons. First, brain regions involved in speech processing are well characterized (e.g., Hickok & Poeppel, 2007; Rauschecker & Scott, 2009). This characterization of speech processing in the brain lays solid groundwork for investigating speech error monitoring in the brain. Second, identifying the effect of brain lesions on speech error monitoring is a feasible endeavor, especially in the context of aphasia, a communication impairment caused by brain damage. People with aphasia tend to commit an increased number of speech errors, however, their ability to monitor speech errors varies depending on the size and location of their lesion (Mandal et al., 2020). Thus, aphasia can be informative as to the effect of lesions on speech error monitoring. Moreover, investigating critical brain structures and connections for speech error monitoring in aphasia also has clinical importance, and can potentially inform prognosis and future therapeutic approaches.

Contemporary neurocognitive models of speech error monitoring build on our understanding of speech processing. Speech processing broadly encompasses various different stages, spanning from lexical access, to the motoric act of speech, and to the perception and comprehension of the produced speech (Dell and O’Seaghdha, 1992; Levelt, 1983; Levelt et al., 1999). Correspondingly, there are a variety of models of speech error monitoring that differ by which speech processing stages are emphasized (for in-depth reviews see Gauvin & Hartsuiker, 2020; Nozari, 2020; Postma, 2000). It is important to acknowledge that the mechanisms described across speech error monitoring models are not all mutually exclusive: researchers have proposed that there may be distinct error monitoring mechanisms at different stages of speech processing (Postma, 2000). For instance, it has been proposed that monitoring psycholinguistic processes (e.g., lexical access, speech comprehension) might rely on different mechanisms than monitoring sensorimotor processes (e.g., the motoric act of speech and perception of the auditory and somatosensory properties of speech) (Nozari, 2020).

Interestingly, prominent models that emphasize the psycholinguistic aspects of speech processing describe a role of the pMFC, while models that emphasize the sensorimotor aspects of speech processing do not describe a role of the pMFC. For example, Nozari et al., 2013’s Conflict Based Account of error monitoring describes a role of the ACC (a subregion of the pMFC) in monitoring lexical access, particularly during semantic and phonological encoding. Additionally, in their comprehension-based account of error monitoring, Roelofs’ Word Encoding by Activation and Verification (WEAVER++) model also incorporates a role of the ACC (Roelofs, 2014; 2019). The ACC is also responsible for monitoring multiple stages of speech processing in Gauvin and Hartsuiker’s Hierarchical Conflict Model for Self- and Other Monitoring (Gauvin & Hartsuiker, 2020).

Although they concur on the importance of the pMFC, the Conflict-Based Account and WEAVER++ have divergent implications about the regions that critically communicate with the pMFC during speech error monitoring. In their Conflict-Based Account, Nozari et. al. (2011) posits that the pMFC monitors conflict that arises during language production. Since the left lateral frontal cortex is heavily implicated in language aspects of speech production (Mirmier, 2015; Pillay et al., 2017; Wilson, 2017), the Conflict-Based Account would predict that structural connections between the pMFC and left lateral frontal regions are critical for speech error monitoring. Alternatively, in the WEAVER++ model by Roelofs (2014; 2019), the pMFC receives error signals that originate from brain regions underlying speech comprehension. Since the left temporal lobe is thought to support comprehension, WEAVER++ would predict that structural connections between the pMFC and left temporal brain regions are critical for speech error monitoring. Both the Conflict-Based Account and WEAVER++ are broadly consistent with the Disconnected Monitoring Hypothesis because they predict that reduced speech error monitoring in aphasia results from structural disconnections between domain-general pMFC brain regions and brain regions that support speech processing.

On the other hand, prominent contemporary sensorimotor models of speech error monitoring do not describe a role of the pMFC in monitoring. Notable examples include Hickok’s Hierarchical State Feedback Control (HSFC) model (Hickok, 2012), and Guenther and colleagues’ Directions into Velocities of Articulators (DIVA) model (now incorporated into Gradient Order DIVA, or GODIVA in Bohland et al., 2016) also see Guenther, 2006; and Tourville & Guenther, 2011), both of which emphasize monitoring the motoric act of speech via somatosensory and auditory feedback1. Instead, in HSFC and DIVA, error detection results from communication between regions responsible for speech production and speech perception.

However, HSFC and DIVA diverge about whether the brain regions supporting speech perception and speech production communicate directly or via an intermediate processor. In HSFC, the communication between these brain regions occurs through an intermediate processor that translates auditory and motor information (Hickok, 2012). This

---

1 However, note that the DIVA model does describe a role of the preSMA, a subregion of the pMFC, in preparing syllable frames during speech production.
auditory-motor translation is often referred to as coordinate transform and/or sensorimotor integration. The processor that performs sensori-
motor integration in HSFC is referred to as area spt. Area spt is thought
to be located near the temporal-parietal border (Hickok, 2012), and
individual localizations have been found within the planum temporale
(Buchsbaum et al., 2011; Hickok et al., 2009). Some recent lesion-
symptom mapping work supports the role of area spt alongside other
speech processing regions in impaired control of speech production in
aphasia. One study found that impairment in compensation to pitch-
shifted feedback corresponds to lesions near area spt, as well as lesions
in other regions involved in speech production and perception
(Schwartz et al., 2015; Schwartz et al., 2009, 2012; Singh et al., 2018; Stark et al., 2019; and DIVA is consistent with epiphenomenal explanations of pMFC ac-
speech perception. Overall, the absence of a role of the pMFC in HSFC
cortical areas in the temporal lobe (Bohland et al., 2010; Guenther
and Vladusich, 2012). Thus, while HSFC posits that speech error monitoring relies on indirect communication between speech production and speech perception regions as intermediated by area spt, DIVA posits that speech error monitoring relies on direct connections between brain re-
regions that support speech production and brain regions that support speech perception. Overall, the absence of a role of the pMFC in HSFC
and DIVA is consistent with epiphenomenal explanations of pMFC ac-
tivity during error processing.

In sum, theories of speech error monitoring provide at least four distinct predictions about which connections, when lesioned, might reduce speech error monitoring. Consistent with the Disconnected Monitoring Hypothesis, the first two theoretical predictions involve a critical role of the pMFC in speech error monitoring: 1) the Conflict Based Account predicts connections between the pMFC and speech production brain regions; 2) WEAVERT++ predicts connections between the pMFC and speech comprehension brain regions. Alternatively, consistent with epiphenomenal hypotheses of the pMFC in error moni-
toring, the third and fourth theoretical predictions do not involve the pMFC at all: 3) DIVA predicts connections between speech production and speech perception brain regions. 4) HSFC predicts connections involving area spt, either between area spt and speech production brain regions, or between area spt and speech perception brain regions.

1.3. Neural correlates of speech error monitoring in aphasia

Although there have been a number of recent studies on lesions
associated with production of speech errors in aphasia (Mirman et al.,
2015; Schwartz et al., 2009, 2012; Singh et al., 2018; Stark et al., 2019;
Wilsnoketter et al., 2019), there have not been many studies on lesions
associated with monitoring speech errors. Only a few studies to date
have systematically investigated the neural correlates of speech error
monitoring in aphasia. One study found an electroencephalographic
signature centered over the pMFC, the error-related negativity, during
incorrect naming trials (Ries et al., 2013), suggesting that the pMFC performs error-related processing in aphasia. In another study, voxel-
based lesion-symptom mapping found that frontal white matter lesions
related to reduced speech-error monitoring (Mandal et al., 2020). The
association of lesioned white matter with reduced speech-error moni-
toring suggests that disconnections between certain brain regions may
be related to poor error monitoring. However, this prior study did not
examine connections directly, which would be critical to determine if
disconnection of the pMFC from speech processing regions reduces speech error monitoring, as predicted by the Disconnected Monitoring
Hypothesis.

1.4. Present study

Here, we evaluated the role of structural disconnections to the pMFC
in error-monitoring in aphasia. We analyzed data from a subgroup of participants in a previous lesion-symptom mapping study (Mandal et al.,
2020) for whom diffusion-weighted images were available. We used support vector regression connectome-based lesion symptom mapping to identify white matter connections in which lost integrity of the connection, compared to controls, is related to reduced error monitoring.

2. Materials and methods

2.1. Participants

Data in this study was compiled from two studies including a clinical
trial on transcranial direct current stimulation for aphasia (Cohort 1),
and an investigation on inner speech in aphasia (Cohort 2). Many par-
ticipants were part of both cohorts (n = 22). The error-monitoring data from the combined cohorts is a subset from those used in the analyses in Mandal et al. 2020. Participants with left hemisphere stroke (n = 51) in the present study were native English speakers, participated at least 6 months after their stroke, had no additional neurological or neuropsych-
iatric disorders, and produced enough errors to be able to measure error detection (see Behavioral Methods below). Controls with no his-
tory of stroke were matched to the stroke group on age and education (n = 37). Controls were included to establish baseline connectome values
to compare to the stroke group. All participants provided written
informed consent. This research was approved by the Georgetown
University Institutional Review Board.

2.2. Behavioral methods

Speech errors and error detections were coded in the participants
with left hemisphere stroke, and not the matched controls. The coding of
speech errors and error detection in this participant pool has been pre-
viously detailed (Mandal et al., 2020) and will be described again below.

2.2.1. Picture naming tasks

Participants with left hemisphere stroke completed picture naming
tasks in which they name aloud black and white drawings presented one
at a time. Participants in Cohort 1 received a 60-item version of the
Philadelphia Naming Test (PNT) (Roach et al 1996). Participants in
Cohort 2 received a total of 120 items across two 60-item naming tasks
across two separate sessions: the 60-item version of the PNT, plus an
additional 60 items which were normed in-house (stimuli available at
https://www.cognitiverecoverylab.com/researchers). The mean inter-
val between administration of 60 item naming tasks in Cohort 2 was 11
days. In sum, participants in Cohort 1 received 60 items, participants
in Cohort 2 received 120 items, and participants in both Cohort 1 and
Cohort 2 received a total of 180 items. In regards to the participants who
were in Cohort 1 and 2, responses on all 180 items were included in this
study. All picture naming responses underwent two types of coding:
first, error coding, and second, error detection coding. The benefits of
pooling error scores and error detection scores across multiple PNT
administrations has been examined in the Mandal et. al. analysis of the
present dataset. There, they compared analyses using trials from only
one PNT administration versus analyses using trials across both PNT
administrations and found that brain-behavior relationships did not
substantially differ, although using both PNT administrations allowed
for more power (Mandal et al., 2020, Supplement).

2.2.2. Error coding for picture naming

All spoken naming responses were recorded on video for offline
coding of error types and error detection. Error coding rules paralleled
those for the PNT (Roach et al., 1996). Errors were coded as phono-
logical when the naming attempt shared either at least two phonemes,
the stressed vowel, or first or last phonemes with the target. Errors were
coded as semantic when the naming attempt was semantically related to
the target. When the naming attempt was both phonologically and
semantically related to the target, then the error was coded as “mixed”
and was not considered as phonological or semantic. Inter-rater reliability of the error coding was demonstrated in the Mandal et al analysis of the present dataset, where two independent scorers both graded 17 participants. In these subjects, the scorers gave the same error codes on 91.7% of the trials (Mandal et al., 2020).

2.2.3. Error detection coding for picture naming

Detection coding was adapted from the protocol used by Schwartz and colleagues (e.g., Schwartz et al., 2016). Only the first naming attempt was considered for detection scoring. Error detection was tabulated separately for each error committed. Trials in which the participant made no response were not considered for detection scoring. Detections were coded when participants verbally indicated awareness of error commission (e.g., “dog….no that’s not right!”) or attempted to self-correct their error (e.g., “dog….cat!”). While participants had the opportunity to detect and correct their errors, they were not explicitly directed to judge the accuracy of their response on each trial. Since individual error detection rates cannot be measured when very few errors are committed, the detection rate for each error type was only analyzed in participants who committed at least 5 of the respective error types. Ultimately, 51 individuals committed at least 5 total errors, 41 in range in square brackets. Values are reported in as averages, with standard deviations in parentheses, Table 1. Total error detection rate was calculated as the total count of errors divided by the count of phonological errors (Table 1).

2.2.4. Other measures

Additional description of the participants is provided in the form of performance on tasks that demonstrate auditory comprehension and speech fluency (Table 1).

Auditory Comprehension: Participants completed the Auditory Verbal Comprehension subtest of the Western Aphasia Battery-Revised (WAB). Scores are reported from the Yes/No Questions task, where participants gave yes or no responses to 20 questions, which were either personal, environmental, or general (i.e., grammatically complex with no context) (Kertesz, 2007).

Speech Fluency: Mean Length of Utterance (MLU). Participants completed picture description tasks. The Mean Length of Utterance (MLU) was calculated from their description as the mean number of words used per utterance. Participants in Cohort 1 described the picture of a picnic scene in the WAB, whereas participants in Cohort 2 described the picture of a “Cookie Theft” in the Boston Diagnostic Aphasia Examination (Goodglass et al., 2000; Roth, 2011).

Further description of the participants can be found in the Supplement (Table S1). Table S1 provides all participant-level scores summarized in Table 1 as well as motor speech scores, which differed by cohort. In Cohort 1, motor speech scores included the Apraxia of Speech Rating Scale (Strand et al., 2014). In Cohort 2, motor speech scores were acquired from a standard motor speech evaluation (Haley et al., 2012), including Alternating Motion Rate scored as syllables per second, and adequate Sequential Motion Rate scored as a binary outcome of whether the participant accurately produced at least 3 syllable triads (e.g., three productions of /pətʃə/).

2.3. Imaging methods and connectome construction

2.3.1. Image acquisition

All brain images were acquired via a 3 T Siemens Trio scanner at Georgetown via a 12-channel head coil. DWIs were acquired using single shot echo-planar imaging, consisting of 55 axial slices with a slice thickness of 2.5 mm, and voxel size of 2.5 mm by 2.5 mm by 2.5 mm (repetition time (TR) = 7.5 s; echo time (TE) = 87 ms; field of view (FOV) = 240 mm × 240 mm; matrix size = 96 × 96; flip angle = 90°) (Fig. 1). In total, 80 volumes were acquired (60 at b = 1100 s/mm², 10 at b = 300 s/mm², 10 at b = 0 s/mm²).

Single volumes of Magnetization Prepared Rapid Acquisition Gradient Echo (MPRAGE) images were acquired and consisted of 176 sagittal slices with a slice thickness of 1 mm, and voxel size of 1 mm by 1 mm by 1 mm (TR = 1900 ms; TE = 2.52 ms; inversion time = 900 ms FOV = 250 × 250 mm; matrix size = 256 × 256; flip angle = 9°).

2.3.2. Construction of structural connectomes

In preparation for structural connectome construction, each stroke subject’s MPRAGE underwent an imputation process in order to enable tissue segmentation and brain parcellation. Imputation steps included automatic generation of the lesion in native space (Pustina et al., 2016), bias field correction, and skull-stripping of the brain. Lesioned voxels were filled by values from homotopic tissue values in the spared hemisphere. Additional lesion repair benefited from the fusion of T1 images from a group of at least 22 healthy matched controls warped to the lesioned brain via Advanced Normalization Tools (ANTs) (autoJoint-Fusion) (Avants et al., 2011). Stroke and control subject MPRAGEs (imputed in stroke subjects) were submitted to FreeSurfer’s recon-all for cortical reconstruction (https://surfer.nmr.mgh.harvard.edu/). Lusanne atlas parcellations at scale 125 (Daducci et al., 2015) were generated from the output of recon-all with the preprocessed mean b0 image (see below) as the target image.

We derived structural connectomes from diffusion weighted images (DWIs) for stroke and control subjects using MRtrix 3.0 (Tournier et al.,

Table 1

| Table 1 | Participant demographics. |
|---------|---------------------------|
|         | Stroke Survivors: Total Error Detection Group | Stroke Survivors: Phonological Error Detection Group | Matched Controls |

| Total Error Detection (Percent of errors detected) | 41.3% (24.7%) | 41.6% (23.6%) | NA |
| Phonological Error Detection (Percent of errors detected) | 39.6% (26.3%) | 39.6% (26.3%) | NA |
| Semantic Error Detection (Percent of errors detected) | 36.1% (23.3%) | 36.9% (23.4%) | NA |

Values are reported in as averages, with standard deviations in parentheses, range in square brackets.
2017). However, since we are taking a theoretical approach that excludes fiber orientation distributions were computed using multi-shell multi-tissue constrained spherical deconvolution (dwi2fod msmnt_csd) based on a response function computed from the subject’s DWI data (dwi2response d holland). For each individual, 15 million streamlines were generated by probabilistic anatomically-constrained tractography (Smith et al., 2012) on white matter fiber orientation distributions (tckgen -act, algorithm = iOD2, step = 1, min/max length = 10/300, angle = 45, backtracking allowed, dynamic seeding, streamline endpoints cropped at grey matter-white matter interface). The five-tissue-type segmented image of the skull-stripped MPRAGE (imputed in stroke subjects) was warped into DWI space via ANTS and served as the anatomical image for anatomically-constrained probabilistic tractography. Spherical deconvolution informed filtering of tractograms 2 (SIFT-2) (R. E. Smith et al., 2015) was conducted in order to adjust streamline densities to be proportional to the underlying white matter fiber densities. Individual connections in the structural connectome were generated by assigning streamlines to parcels of the brain they connect. The five-tissue-type segmented image of the skull-stripped MPRAGE (imputed in stroke subjects) was warped into DWI space via ANTS and served as the anatomical image for anatomically-constrained probabilistic tractography. Spherical deconvolution informed filtering of tractograms 2 (SIFT-2) (R. E. Smith et al., 2015) was conducted in order to adjust streamline densities to be proportional to the underlying white matter fiber densities. Individual connections in the structural connectome were generated by assigning streamlines to parcels of the brain they connect. 2.4. Experimental design and statistical analysis

2.4.1. Connectome-based lesion-symptom mapping analysis

Support vector regressions (SVR) were run to identify lesioned connections that cause reduced error detection rates. A connection was considered lesioned in a stroke participant when the AFD value was less than all of the control participants’ values at that connection. This binary definition of lesion includes connections with smaller values in stroke participants than controls, as well as those that are absent in stroke participants but detected in controls. This lesion definition permits a simple interpretation as it focuses on connections that were clearly lesioned by stroke.

The analyses were run using a method parallel to support vector regression-based lesion-symptom mapping (SVR-LSM) (e.g., DeMarco & Turkeltaub, 2018), where features based on brain imaging are used to predict a behavioral score. The key difference between connectome-based lesion-symptom mapping (e.g., Gleichgerrcht et al., 2017) and SVR-LSM is that brain-based features in SVR-LSM involve the lesion status of each voxel across structural images, whereas the brain-based features in this connectome symptom mapping analysis are the lesion status of each structural connection across connectomes. Since the presence or absence of individual small connections may vary across individuals irrespective of lesions, only connections present in 100% of control subject connectomes (n = 37) were included in the analyses. To avoid spurious relationships based on connections that are only lesioned in one or a few subjects or happen to be smaller than controls based on chance alone, the analysis only considered connections that were lesioned in at least 20% of participants with left-hemisphere stroke.

The dependent variable modeled by SVR is percent detection rate on errors made during picture naming. Lesion volume in voxels was estimated as a proportion of the white matter tracts connecting two brain regions.
phonological errors has stronger lesion-deficit associations than detection across all errors (Mandal et al., 2020), two separate analyses were run for detection across all errors (n = 51) and for only phonological errors (n = 41). Resulting SVR beta weights for each connection were assigned p values using permutation tests, in which error detection rates were randomly assigned to connectomes 10,000 times, and each connection was ranked among the 10,000 permutation-based values for that connection. Statistical thresholding used a continuous familywise error rate (CFWER) method, with a family-wise error rate of 0.05 and v ranging from 1 to 20 (Mirman et al., 2018). In CFWER, the vth most maximal test statistic from each permutation is recorded to form a null distribution, which is then used to provide an adjusted p-value threshold that limits the number of expected false-positive results to v. For example, at v = 20 CFWER produces a p-value threshold at which there is a 5% chance of obtaining 20 significant connections in the entire connectome. Therefore, analyses that result in 20 or more significant connections can be interpreted as non-random. The confidence in individual connection-wise results increases with the number of connections that survive above the v value. Whereas full family-wise error correction provides greater confidence for interpreting the importance of individual connections, it may be overly strict for maps in which loss of individual connections do not produce a dramatic behavioral impairment because the behavior relies on a network involving multiple connections. Analyses were run with v values ranging from 1 to 20 to increase power to detect maps involving over 20 connections.

3. Results

3.1. Behavioral scores

3.1.1. Total error detection group

A total of 51 participants were included in the SVR analysis on detection rate across all errors. Phonological errors accounted for 48.4% of all errors in these participants. On average, detection rate across all errors was 41.3% (SD = 24.7%) (Table 1).

3.1.2. Phonological error detection group

A total of 41 participants were included in the SVR analysis on detection rate across phonological errors. On average, detection rate across phonological errors was 39.6% (SD = 26.3%) (Table 1).

3.2. Tractography

The tractography revealed expected patterns in the connectivity between brain parcels in control participants, including a greater presence of connections between adjacent cortical regions, subcortical-to-cortical connections, and interhemispheric connections that are roughly homotopic (Fig. 2).

As expected, given the broad lesion distribution of white matter voxels (Fig. 3a-3b), stroke survivors had a broad coverage of disconnections within the left hemisphere, and between roughly homotopic regions of the left and right hemisphere (Fig. 3c & d). Disconnections involved a wide range of frontal, temporal, and parietal cortices, as well as subcortical regions (e.g., basal ganglia, and brainstem) (Fig. 3c & d). Connections that were lesioned in at least 20% of stroke participants were included in the analyses examining disconnections associated with reduced error detection (Fig. 3e & f).

3.3. Support vector regressions

3.3.1. Detection rate across all speech errors

Interpretability of Significant Maps. In order to reveal connections that serve a general role in speech error monitoring, the first SVR analysis examined disconnections associated with reduced detection rate across all speech errors, irrespective of the type of error. Maps for detection rate across all errors were significant at thresholds v = 3, 5, 12, and 14. At v = 14, a total of 14 connections survived (Table 2, Fig. 4). Although the maps are statistically significant at these thresholds, the interpretability of the individual connections are limited because the maps barely achieve the required number of connections at each threshold of v = 3, 5, 12, and 14. For example, there is a 5% chance that all 14 of the specific connections at v = 14 occurred by chance. In consideration of this low level of confidence in the individual observed connections, only general trends across the map at v = 14 are described below.

Significant Connections. Twelve of the 14 connections were within the left hemisphere, and the other two were interhemispheric. All 14 connections involved regions of the frontal lobe: with 9 connections within the frontal lobe, 3 connections between the frontal lobe and insula, 1 connection between the frontal and temporal lobe, and 1 connection between the frontal lobe and thalamus. As predicted by the Disconnected Monitoring Hypothesis, connectivity to the pMFC was present in this significant map. In fact, the majority of significant connections involved regions of the pMFC, including the ACC, and pSFG. (9 of 14; 63.4%; Fig. 4b). These pMFC connections mostly connected with the pars triangularis or pars opercularis of the inferior frontal gyrus.

As reviewed in the introduction, four theories of speech error monitoring provide distinct predictions about connections that are important for speech error monitoring. First, the Conflict-Based Account predicts the importance of connectivity between the pMFC and the inferior frontal gyrus. Consistent with the Conflict-Based Account, 7 significant connections were found between the pMFC and regions of the inferior frontal gyrus (Table 2, Fig. 4). Second, WEAVER++ predicts the

![Fig. 2. Mean AFD connection values for control participants (left) and participants with left hemisphere stroke (right). Left Hemi indicates Left Hemisphere, and Right Hemi indicates Right Hemisphere. Cortical regions are indicated on the sides of the matrix, with the empty gray bar indicating the subcortical regions (i.e. basal ganglia and brain stem). Connections between adjacent regions are represented on the main diagonal.](image-url)
importance of connectivity between the pMFC and the temporal lobe. Consistent with WEAVER++, 1 significant connection was found between the pMFC and the anterior temporal lobe (Table 2, Fig. 4). Third, DIVA predicts the importance of connectivity between auditory cortical regions and regions involved in speech production. Despite this prediction by DIVA, none of the significant connections involved auditory cortical regions (Table 2, Fig. 4). Fourth, HSFC predicts the importance of connectivity involving area spt. Despite this prediction by HSFC, none of the significant connections involved area spt (Table 2, Fig. 4).

### 3.3.2. Detection rate across phonological speech errors

**Interpretability of Significant Maps.** In order to identify connections that are specifically involved in monitoring phonological aspects of speech, the next SVR analysis examined disconnections associated with reduced detection of phonological errors. Maps for detection rate across phonological speech errors were significantly non-random at all thresholds from $v = 1$ through $v = 20$. At $v = 20$, 46 connections survived thresholding (Table 3, Fig. 5). Since the map surpasses the required number of connections at $v = 20$, the interpretability for individual connections is strong. There is a 5% chance that 20 of the 46 significant connections occurred by chance. Therefore, we can consider individual significant connections at $v = 20$ with confidence that they are nonrandom.

**Significant Connections.** Twenty-eight of the 46 connections were within the left hemisphere, and the other 14 were interhemispheric. Forty-five of the 46 connections involved regions of the frontal lobe: with 24 connections within the frontal lobe, 5 connections between the frontal lobe and insula, 1 connection between the frontal and temporal lobe, and 15 connections between the frontal lobe and subcortical structures (i.e., thalamus, brainstem, basal ganglia). The only connection that did not involve the frontal lobe connected an area of the parietal lobe to the brainstem. As predicted by the Disconnected

---

**Fig. 3.** Top: Lesion overlap map identifying common locations of brain damage across each participant (a, b). Middle: Overlap maps counting total disconnections across participants included each analysis (c, d). Bottom: Maps of connections included for each analysis (e, f). Right Hemi indicates Right Hemisphere, Left Hemi indicates Left Hemisphere.
Monitoring Hypothesis, connectivity to the pMFC was present in this significant map. In fact, 24 of the 46 significant connections involved regions of the pMFC including the ACC, and pSFG.

All 24 connections involving the pMFC connected the pMFC to regions of the brain’s left hemisphere (Fig. 5b). The region with the most connections from the pMFC implicated in the analysis was the inferior frontal gyrus, with 9 significant connections (8 to pars opercularis, 1 to pars triangularis). Six significant pMFC connections were to subcortical regions (5 to putamen, 1 to brainstem). Five significant pMFC connections were to dorsolateral prefrontal cortex (dIPFC), and two each were to the ventral precentral gyrus and the insular cortex. One pMFC connection was to the anterior superior temporal gyrus.

As reviewed earlier, four theories of speech error monitoring predict distinct patterns of connectivity important for speech error monitoring. First, the Conflict-Based Account predicts the importance of connectivity between the pMFC and the inferior frontal gyrus. Nine significant connections were consistent with the Conflict-Based Account, connecting the pMFC with regions in the inferior frontal gyrus (Table 3, Fig. 5). Second, WEAVER++ predicts the importance of connectivity between the pMFC and regions in the temporal lobe. One significant connection was consistent with WEAVER++, connecting the pMFC with an anterior region of the temporal lobe (Table 3, Fig. 5). Third, DIVA predicts the importance of connectivity between auditory cortical regions and regions involved in speech production. However, despite this prediction by DIVA, none of the significant connections involved auditory cortical regions (Table 3, Fig. 5). Fourth, HSFC predicts the importance of connectivity involving area spt. However, despite this prediction by HSFC, none of the significant connections involved area spt (Table 3, Fig. 5).

### Table 2
Significant connections for detection rate across all speech errors.

| Connection (Parcel 1, Parcel 2) | MNI Coordinates (Parcel 1, Parcel 2) | SVR Beta Value | p Value | Significant CWFER \( v \) Value (min) |

Fig. 4. (a) Map of all significant connections at \( v = 14 \) for detection rate across all speech errors. (b) Map of significant connections involving the posterior Medial Frontal Cortex (pMFC) at \( v = 14 \) for detection rate across all speech errors.
Our whole-brain CLSM analyses confirmed the Disconnected Monitoring Hypothesis, demonstrating that structural disconnections involving the pMFC are associated with reduced speech-error monitoring in aphasia. In the maps for detection rate across both total errors and phonological errors, over half of the disconnections implicated in reduced monitoring involved the pMFC. A growing body of functional neuroimaging evidence suggests that error monitoring recruits activity of the ACC and adjacent regions in the pMFC territory including the pSFG and mPG (Ridderinkhof, 2004). Our findings add complementary lesion-based evidence for this relationship, supporting the existence of an error-monitoring network that relies on the pMFC.

Furthermore, we found an additional network of regions where connections to the pMFC support error monitoring in speech. Specifically, we found a predominance of significant connections between the pMFC and regions known to support speech production including motor regions and the left inferior frontal gyrus (IFG) (Mirman et al., 2015; Pillay et al., 2017; Wilson, 2017). There were also significant connections between the pMFC and the dlPFC, a region canonically involved in executive function. There was one significant connection found between the pMFC and the superior temporal gyrus, a region involved in speech comprehension. This is the first study to present direct lesion-based evidence that structural connectivity between the pMFC and regions involved in speech production and executive function are important for error monitoring in speech.

4. Discussion

4.1. Main findings

Our whole-brain CLSM analyses confirmed the Disconnected Monitoring Hypothesis, demonstrating that structural disconnections involving the pMFC are associated with reduced speech-error monitoring in aphasia. In the maps for detection rate across both total errors and phonological errors, over half of the disconnections implicated in reduced monitoring involved the pMFC. A growing body of functional neuroimaging evidence suggests that error monitoring recruits activity of the ACC and adjacent regions in the pMFC territory including the pSFG and mPG (Ridderinkhof, 2004). Our findings add complementary lesion-based evidence for this relationship, supporting the existence of an error-monitoring network that relies on the pMFC.

Furthermore, we found an additional network of regions where connections to the pMFC support error monitoring in speech. Specifically, we found a predominance of significant connections between the pMFC and regions known to support speech production including motor regions and the left inferior frontal gyrus (IFG) (Mirman et al., 2015; Pillay et al., 2017; Wilson, 2017). There were also significant connections between the pMFC and the dlPFC, a region canonically involved in executive function. There was one significant connection found between the pMFC and the superior temporal gyrus, a region involved in speech comprehension. This is the first study to present direct lesion-based evidence that structural connectivity between the pMFC and regions involved in speech production and executive function are important for error monitoring in speech.

### Table 3: Significant connections for detection rate across phonological speech errors.

| Connection (Parcel 1, Parcel 2) | MNI Coordinates (Parcel 1, Parcel 2) | SVR Beta Value | p Value | Significant CWFER (min) |
|--------------------------------|--------------------------------------|----------------|---------|------------------------|
| Right superiorfrontal 4, Left parietal 1 | (16, 31, 50), (–38, 15, 12) | 6.52 | 0.0007 | 15 |
| Right superiorfrontal 5, Left parietal 8 | (8, 12, 51), (–47, –2, 9) | 6.82 | 0.0007 | 15 |
| Left parietal 2, Left superiorfrontal 6 | (–47, 11, 11), (–19, 16, 51) | 6.95 | 0.0008 | 17 |
| Left superiorfrontal 7, Left insula 2 | (–10, 6, 50), (–37, –5, –2) | 6.79 | 0.0008 | 17 |
| Left superiorfrontal 8, Left insula 2 | (–6, –1, 60), (–37, –5, –2) | 6.79 | 0.0008 | 17 |
| Left caudalmiddlefrontal 1, Left thalamus | (–35, 20, 47), (–14, –17, 6) | 6.25 | 0.0009 | 19 |
| Left parietal 1, Left superiorfrontal 5 | (–38, 15, 12), (–7, 29, 54) | 6.66 | 0.0009 | 19 |
| Right caudalmiddlefrontal 2, Left insula 4 | (6, 17, 24), (–30, 12, 7) | 6.66 | 0.0009 | 19 |
| Right parietal 2, Left superiorfrontal 1 | (8, 12, 51), (–38, 15, 12) | 6.68 | 0.0009 | 19 |
| Right superiorfrontal 2, Left caudalmiddlefrontal 1 | (8, 12, 51), (–35, 20, 47) | 6.77 | 0.0009 | 19 |
is partially redundant with the contralateral ACC, or partially redundant with other subregions of the pMFC such as the contralateral or ipsilateral pSFG, then lesion-deficit relationships with the ACC could be subtler. In that case, studies could include some participants with lesions to part of the pMFC that caused subtle changes in their error monitoring behavior and not obvious impairments. Such subtle lesion-deficit associations would require large sample sizes to consistently detect. Thus, partial redundancy between contralateral or ipsilateral pMFC regions in combination with small sample sizes could cause lesion studies on the pMFC to yield mixed findings. It is also notable that prior lesion studies examined error monitoring of cognitive control tasks, which are thought to rely on the bilateral prefrontal cortex (Miller & Cohen, 2001). One could imagine that error monitoring of ‘bilateral’ cognitive control tasks readily recruits bilateral pMFC regions. This bilateral pMFC recruitment may foster partial redundancy that obscures lesion-deficit relationships.

On the other hand, the present study examined monitoring during speech production, a task that relies on the brain’s left hemisphere (Szaflarski et al., 2006). Therefore, the present study may have benefited from extra sensitivity to lesion-deficit relationships by examining monitoring during a ‘unilateral’ task. Our disconnection-based approach may have garnered additional sensitivity because we examined error monitoring during a left-hemisphere task in participants who have disconnections involving the left hemisphere. In other words, we would expect disconnections involving the left hemisphere to strongly impact error monitoring because the left hemisphere contains the task-relevant information being monitored.

Lesions to the dIPFC are well documented to impair a wide range of executive functions (Szczepanski & Knight, 2014). Similarly, here we confirmed that disconnections to the dIPFC reduce error monitoring, which is often considered an executive function. Furthermore, the pMFC and dIPFC have been previously theorized to communicate during error monitoring. For example, conflict monitoring theory proposes that the pMFC generates a conflict-based error signal and then recruits the dIPFC to exert executive control (Carter & van Veen, 2007; Kerns et al., 2004).

Alternatively, the hierarchical error representation model proposes that the pMFC generates a prediction-based error signal that is sent to the dIPFC to hold error prediction representations in working memory (Alexander & Brown, 2015). Under the hierarchical error representation model, the dIPFC also signals to the pMFC in order to refine prediction-based error signaling (Alexander & Brown, 2015). Although the exact information being communicated remains under debate, the present study confirms that structural connectivity between the pMFC and dIPFC is important in error monitoring.

4.3. Connections between pMFC and speech production regions support error detection

A current debate in the field of error monitoring concerns the degree to which the circuitry for error monitoring is specific to the task being monitored. This debate is especially active in the literature for speech error monitoring (Nozari, 2020; Roelofs, 2019). Since functional neuroimaging studies consistently find error-related pMFC activation across task domains (Gauvin et al., 2016; Ullsperger & von Cramon, 2004), we posited that the pMFC plays a domain-general processing role. We predicted that the pMFC would need to communicate with specific brain regions responsible for task-relevant representations in order to support error monitoring. Indeed, we found that speech error monitoring relies on connections between the pMFC and brain structures that process speech, particularly regions canonically associated with speech production.

Our finding of the importance of connections between the pMFC and regions supporting speech production is consistent with Nozari et al.’s Conflict Based Account which proposes that error-monitoring relies on the interplay between speech production regions and general error monitoring machinery. The IFG is thought to support speech production, and was prominently involved in significant disconnections with the pMFC in our results. It is worth noting that the IFG has also been proposed to support a wide range of general executive functions that aid in
language processing (Fedorenko et al., 2012; Fedorenko & Kanwisher, 2011; Lambon Ralph et al., 2017; Nozari et al., 2016; Thompson et al., 2018). Thus, an alternative interpretation of our results is that the connections between the IFG and pMFC are part of the general executive function circuitry that supports error monitoring across task domains. However, connections between the pMFC and other regions thought to support speech production, including the ventral motor cortex, the basal ganglia and the anterior insula, were also implicated by our results (Dronkers, 1996; although see Fedorenko et al., 2015 regarding the role of anterior insula in speech production; Jürgens, 2002), strongly supporting the role of connections between speech production machinery and pMFC in speech error monitoring.

According to some models of speech error monitoring, representations of speech perception and comprehension are critically relevant during monitoring. Indeed, we found a connection between the pMFC and the anterior superior temporal gyrus, a region implicated in speech comprehension (Crinion et al., 2003; DeWitt & Rauschecker, 2012; Mesulam et al., 2015; Xing et al., 2017; Yi et al., 2019). This also was the only significant connection between the pMFC and the temporal lobe across all of the considered thresholds, this connection was significant at the strictest threshold $v = 1$ in the map for detection of phonological errors. Therefore, we have relatively high confidence that this connection is important for speech error monitoring.

Ultimately, the task-specificity of the connections found in our study remains unclear because we did not compare speech error monitoring to error monitoring in other domains (e.g., nonverbal tasks). Within the context of speech error monitoring, the Disconnected Monitoring Hypothesis would predict that connections between the pMFC and different cortical regions might support monitoring of different types of errors. Unfortunately, we did not have enough semantic errors to directly compare disconnections that affect monitoring of phonological and semantic errors. Thus, our results do not provide clear evidence for the specificity of neural connections for error monitoring in specific task contexts. However, our results may indirectly imply such specificity because the results were stronger when we examined one specific error type (i.e., phonological errors) than when we examined all errors together. If error-monitoring relies on connections between the pMFC and processors specific to the signals being monitored, one would expect an analysis that mixes multiple error-types to yield relatively weaker results since individual connections may only be important for monitoring certain error types and not others. For example, connections that are only important for monitoring phonological errors might strongly relate to monitoring phonological errors, but weakly relate to monitoring across all error types. Consistent with this prediction, the pattern of connections observed for all errors was similar to that observed for phonological errors, likely reflecting the predominance of phonological errors in our sample, but the results were less robust when all error types were examined together. Further research is needed to dissect the task-specificity of neural substrates that support error-monitoring.

4.4. A role of the PMFC in monitoring the motor execution of speech?

As reviewed in the introduction, two sensorimotor models predicted different connections would support speech error monitoring. First, DIVA predicted connections between auditory temporal cortex and regions involved in speech production, which were not found in the present analysis. Second, HSFC predicted connections to the area spt, which were also not found in the present analysis. Overall, the present findings do not support the neural predictions of these sensorimotor models in their current forms. However, it is worth noting that internal sensorimotor feedback mechanisms of error monitoring may serve primarily to prevent errors during articulatory preparation. Our measure of error detection, which requires the overt production of an error, would be insensitive to mechanisms of internal monitoring that prevent commission of errors before they occur. Moreover, although they did not confirm the specific predictions of the sensorimotor models, the present findings may still be informative about monitoring sensorimotor aspects of speech. Many of the significant pMFC connections were to speech production regions implicated in motor-speech processing. These pMFC-motor speech connections are consistent with a role of the pMFC in monitoring the motor execution of speech. Future neurocognitive models of speech error monitoring might benefit from considering a role of the pMFC in monitoring sensorimotor stages of speech processing.

4.5. Limitations

This study utilized a naturalistic measurement of error monitoring in the sense that participants were not explicitly directed to monitor their errors. The scoring of error monitoring therefore relied on participants spontaneously monitoring their errors. This study’s measurement method is standard in the field of speech error monitoring in aphasia, and is often used in research on the relationship between error monitoring and clinical outcomes (Marshall et al., 1982, 1994; Nozari et al., 2011; Schwartz et al., 2016). However, we cannot preclude the possibility that participants successfully monitored some errors but chose not to display spontaneous error monitoring behavior. The inclusion of explicit instructions to monitor all responses for accuracy could reduce this possibility, but may affect the strategies and processes participants use to monitor their errors (e.g., Grützmann et al., 2014).

4.6. Clinical considerations

The present study suggests that speech error monitoring relies on the integrity of connections between the pMFC and brain regions responsible for executive function as well as brain regions responsible for speech production and comprehension. Thus, impairments in monitoring speech errors could arise from deficits in speech production, comprehension, executive function, or their interplay. Since error monitoring in speech aids in effective communication, understanding whether it is intact after stroke can be informative for tailoring therapies for individuals with aphasia. Additionally, in clinical settings involving brain damage of any etiology (e.g., stroke, trauma, neoplasm, etc.) it can be informative to consider not only the damage to grey matter regions, but also the damage to white matter tracts connecting these regions. Ultimately, understanding the neural mechanisms of error monitoring may lead to brain-based treatments (e.g., brain stimulation) to enhance error monitoring ability. Our findings suggest that such treatment studies should consider designing stimulation methods to enhance connectivity between pMFC and speech production and comprehension regions.

4.7. Conclusions

This connectome-based lesion analysis demonstrated that damage to connections involving the pMFC reduces the monitoring of speech errors. Specifically, damage to structural connections between the pMFC, other structures involved executive functions, and speech production and comprehension regions were associated with a reduction in error detection, particularly for phonological errors. These findings are consistent with the notion that error monitoring critically relies on structural connectivity between task-specific cortical regions and domain-general control regions, including the pMFC. These results align with models of speech error monitoring that emphasize a role of the pMFC during lexical access stages of word production (e.g., Gauvin & Hartsuiker, 2020; Nozari et al., 2011), as well as those that emphasize comprehension of one’s own produced speech (Roelofs, 2019). In clinical settings, damage to fiber tracts that connect to the pMFC may predict reduced error monitoring.
