Generation of hydroxyl radicals by Fe-polyphenol-activated CaO₂ as a potential treatment for soil-borne diseases

Cláudio Kendi Morikawa

An Fe-polyphenol catalyst was recently developed using anhydrous iron (III) chloride and coffee grounds as raw materials. The present study aims to test the application of this Fe-polyphenol catalyst with two hydrogen peroxide (H₂O₂) sources in soil as a new method for controlling the soil-borne disease caused by *Ralstonia solanacearum* and to test the hypothesis that hydroxyl radicals are involved in the catalytic process. Tomato cv. Momotaro was used as the test species. The results showed that powdered CaO₂ (16% W/W) is a more effective H₂O₂ source for controlling bacterial wilt disease than liquid H₂O₂ (35% W/W) when applied with an Fe-polyphenol catalyst. An electron paramagnetic resonance spin trapping method using a 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) assay and Fe-caffeic acid and Fe-chlorogenic acid complexes as models showed that these organometallic complexes react with the H₂O₂ released by CaO₂, producing hydroxyl radicals in a manner that is consistent with the proposed catalytic process. The application of Fe-polyphenol with powdered CaO₂ to soil could be a new environmentally friendly method for controlling soil-borne diseases.

*Ralstonia solanacearum* is one of the top ten most scientifically and economically important bacterial species related to plant diseases. This disease causes bacterial wilt in papayas (*Carica papaya*), potatoes (*Solanum tuberosum*), tomatoes (*Lycopersicum esculentum*), eggplant (*Solanum melongena*), bananas (*Musa spp*) and groundnuts (*Arachis hypogaea*) and causes serious economic losses worldwide. Bacterial wilt in vegetable crops induced by *Ralstonia solanacearum* is especially problematic in tomato plants (*Lycopersicon esculentum* Mill.) cultivated in Japan. Various strategies have been developed to control bacterial wilt, such as grafting, biofumigation and growing resistant crop varieties, but success has been limited due to the high survival capacity of the bacterium in complex environments and the wide variety of suitable hosts. To control this disease, growers often graft seedlings on resistant rootstocks. However, the resistance of the rootstocks is unstable, and the scion grafted on the rootstock of a highly resistant cultivar can be latently infected with the pathogen. The disease has recently been found to occur even on grafted plants. Therefore, effective methods for suppressing bacterial wilt are needed.

Various non-pesticide chemicals can be applied in the field to control bacterial wilt because they are less harmful to the environment; however, economic considerations often influence the selection of the chemicals for application. Expensive chemicals and repeated applications are only feasible for valuable crops that may incur substantial economic losses in the absence of treatments. Since the crop yield and quality are not affected when the disease severity is low or the pathogens are absent, a diagnosis based on an economic threshold is essential for determining whether chemical treatments are needed.

Recently, we developed an Fe-polyphenol catalyst using coffee grounds as raw material, and in a previous study, we demonstrated that this catalyst can be used as an iron fertilizer in agriculture and in the Fenton process to disinfect pathogens such as *E. coli* or to remove methylene blue from water systems. In those works, we proposed that the generation of hydroxyl radicals was responsible for the desired effects. The present study aims to test the application of the Fe-polyphenol catalyst with hydrogen peroxide (H₂O₂) to soil as a new method for controlling bacterial wilt.
for controlling the soil-borne disease caused by *Ralstonia solanacearum* and to test the involvement of hydroxyl radicals in this process.

**Results**

**Soil-borne disease assessment.** The incidence of wilting in the tomato plants during the experimental period differed depending on the material applied. As shown in Fig. 1, the application of Fe-CPP, Fe(III) or Fe(II) with liquid H$_2$O$_2$ did not completely prevent wilt disease. The disease incidence was markedly higher in the (+) CNT (control) treatment, which was inoculated with the bacteria and did not receive any treatment material. On the other hand, a significant ($p < 0.05$) suppression of the incidence of wilt disease was observed for the Fe-CPP and Fe-CPP/H$_2$O$_2$ treatments. In addition, complete prevention was observed in the Fe-CPP/CaO$_2$ treatment. No significant ($p < 0.05$) decreases in the incidence of the disease were found between the H$_2$O$_2$, (+) CNT, Fe(II)/H$_2$O$_2$, Fe(III)/H$_2$O$_2$, CPP and CaO$_2$ treatments. The Fe-CPP/CaO$_2$ treatment significantly reduced ($p < 0.05$) the *R. solanacearum* population to values below the detection limit of $2 \times 10^{-2}$ CFU g$^{-1}$ dry soil for the used selective medium$^{16}$. No colonies of *R. solanacearum* were detected in the autoclaved soil from the (−) CNT treatment. Supplementary Fig. S1 shows a comparison between the two H$_2$O$_2$ sources applied in conjunction with the Fe-CPP catalyst. The Fe-CPP/H$_2$O$_2$ treatment resulted in more plants with visible symptoms of wilt disease than the Fe-CPP/CaO$_2$ treatment, in which no wilted plants were observed. The *R. solanacearum* population in the Fe-CPP/H$_2$O$_2$-treated soil was 24% lower than that of the (+) CNT-treated soil, while that of the Fe-CPP/CaO$_2$-treated soil was 97% lower (Fig. 2). No significant differences were observed between the populations following all other treatments.

**Reactive oxygen species (ROS) assay.** Figure 3 shows the total intensity of luminol during 120 s of reaction in the Fe-CPP/CaO$_2$, Fe(II)/CaO$_2$, Fe(III)/CaO$_2$, Fe-CA/CaO$_2$ and Fe-CGA/CaO$_2$ systems (where CA is caffeic acid and CGA is chlorogenic acid) and the effect of L-ascorbate on the scavenging of the generated radicals. The total intensity of luminol followed the sequence Fe-CPP/CaO$_2$ > Fe-CGA/CaO$_2$ > Fe(III)/CaO$_2$ > Fe(II)/CaO$_2$ > Fe-CA/CaO$_2$. For all systems, the addition of L-ascorbate dramatically reduced the total intensity of luminol.

**Hydroxyl radical assay.** The results of the electron paramagnetic resonance (EPR) experiments are shown in Figs 4–7. The presence of the 5,5-dimethyl-1-pyrroline-N-oxide (DMPO)-OH radical was confirmed by the observed hyperfine coupling constants (hfcc) of $aN = aH = 1.49$ mT$^{17}$. Figure 4 shows the spectra of the DMPO-OH radical after 30 s of reaction in the following systems: (a) CaO$_2$, (b) Fe-CPP/CaO$_2$, and Fe-CPP, (c) Fe(II)/CaO$_2$ and Fe(II), and (d) Fe(III)/CaO$_2$ and Fe(III). Systems that not received liquid or powdered CaO$_2$ or H$_2$O$_2$ no signals of DMPO-OH radical were detected. On the other hand, CaO$_2$ and Fe(III)/CaO$_2$ systems showed DMPO-OH radical signals among the treatments that received liquid or powdered CaO$_2$ as H$_2$O$_2$ source. The signals characteristics of the DMPO-OH radical were also detected in the Fe-CA/CaO$_2$ and Fe-CGA/CaO$_2$ model systems (Fig. 5). When dimethyl sulfoxide (DMSO) was added to the reaction systems, DMPO-CH$_3$ (the spin...
adduct of methyl radical, hfcc: \( aN = 1.64 \text{ mT}, aH = 2.35 \text{ mT} \) was observed, and the intensity of the signals for the DMPO-OH radical decreased (Fig. 6). Figure 7 shows the EPR spectra and the yield of the DMPO-OH radical generated after 30 s of reaction in the powdered CaO₂ systems. Quantitative analysis revealed that the yields of the DMPO-OH radical generated by CPP-Fe/CaO₂ were 1.3-, 1.7- and 3.3-fold higher than those generated by the Fe-CA/CaO₂, Fe-CGA/CaO₂ and Fe(III)/CaO₂ systems, respectively. However, no differences \( p < 0.05 \) were found between the amounts of the DMPO-OH radical generated after 30 s of reaction time in the Fe-CPP/CaO₂ and the Fe(II)/CaO₂ systems. The amount of hydroxyl radical generated after 30 s of reaction time followed the order Fe-CPP = Fe(II) > Fe-CA > Fe-CGA >> Fe(III).

**Discussion**

In previous experiments, the results of an XPS survey revealed that both ferric iron (Fe³⁺) and ferrous iron (Fe²⁺) were present in the Fe-polyphenol catalyst but no zerovalent iron (nZVI) was present. Iron was present in the forms of FeO₃/FeCl₂ and FeCl₃. On the other hand, more than 98% of the iron released from the Fe-polyphenol catalyst was in the Fe²⁺ form as detected by the phenanthroline method. The results of *in vitro* experiments...
showed that the Fe-polyphenol catalyst can be used to supply iron to leaf vegetables\textsuperscript{12} and rice\textsuperscript{13}, and in vitro experiments under laboratory conditions showed that when applied in conjunction with liquid H\textsubscript{2}O\textsubscript{2}, this catalyst could disinfect pathogens such as \textit{Escherichia coli}\textsuperscript{14} and \textit{Ralstonia solanacearum} (see Supplementary Figs S2, S3, and S4) or remove methylene blue from water systems\textsuperscript{15}. We proposed a mechanism involving the generation of hydroxyl radicals by the reaction between the iron catalyst and H\textsubscript{2}O\textsubscript{2}. In the present study, the same Fe-polyphenol catalyst was prepared and applied with two H\textsubscript{2}O\textsubscript{2} sources with different H\textsubscript{2}O\textsubscript{2} release rates to suppress the bacterial wilt disease caused by \textit{R. solanacearum}, which is one of the most difficult soil-borne disease to control because the bacteria can survive in various environments\textsuperscript{19,20}.

**Figure 4.** Electron paramagnetic resonance (EPR) spectra of the DMPO-OH radical generated after 30 s of reaction in the CaO\textsubscript{2} systems. CaO\textsubscript{2} = calcium peroxide (16%); Fe-CPP = Fe-polyphenol catalyst developed using coffee grounds; Fe(II) = iron (II) sulfate heptahydrate; Fe(III) = anhydrous iron (III) chloride. Reaction conditions: 400\,\mu\text{L} of 100 mmol L\textsuperscript{-1} phosphate buffer (pH 7.4); 200\,\mu\text{L} of 220 mmol L\textsuperscript{-1} DMPO; 100\,\mu\text{L} of 4.42 mmol L\textsuperscript{-1} H\textsubscript{2}O\textsubscript{2} as CaO\textsubscript{2} (16% W/W); 100\,\mu\text{L} of 1.5 mmol L\textsuperscript{-1} of Fe as Fe-CPP, Fe(III) and Fe(II). The reactions were carried out at room temperature. The peaks associated with the presence of the DMPO-OH radical are indicated with ↓. DMPO = 5,5-dimethyl-1-pyrroline-N-oxide.

**Figure 5.** Electron paramagnetic resonance (EPR) spectra of the DMPO-OH radical after 30 s of reaction in the CaO\textsubscript{2} model systems. CaO\textsubscript{2} = calcium peroxide; Fe-CA = Fe-caffeic acid complex; Fe-CGA = Fe-chlorogenic acid complex. Reaction conditions: 400\,\mu\text{L} of 100 mmol L\textsuperscript{-1} phosphate buffer (pH 7.4); 200\,\mu\text{L} of 220 mmol L\textsuperscript{-1} DMPO; 100\,\mu\text{L} of 4.42 mmol L\textsuperscript{-1} of H\textsubscript{2}O\textsubscript{2} as CaO\textsubscript{2} (16% W/W); 100\,\mu\text{L} of 1.5 mmol L\textsuperscript{-1} of Fe as Fe-CPP, Fe(III) and Fe(II). The reactions were carried out at room temperature. The peaks associated with the presence of the DMPO-OH radical are indicated with ↓.
A chemiluminescence method based on luminol was used to verify the presence of ROS by adding L-ascorbate, which can scavenge ROS, decreasing the chemiluminescence intensity. A high chemiluminescence intensity was found for all treatments, and the addition of L-ascorbate dramatically reduced the emission intensity of luminol, indicating the presence of radical species in all systems. The high luminol intensity observed in the Fe-CGA/CaO₂ and Fe-CA/CaO₂ model systems suggests that chlorogenic acid and caffeic acid may be associated with the generation of ROS in the Fe-CPP/CaO₂ system since these acids are the predominant polyphenols found in coffee grounds. Luminol is a good indicator of the presence of ROS but cannot identify specific radicals because it emits chemiluminescence with all kinds of radicals, such as ·OH, ·O₂⁻ and ¹O₂. Hydroxyl radicals are the most reactive and least selective ROS, and they could play a role in the results of this experiment. To test this hypothesis, electron paramagnetic resonance (EPR) was used to detect the presence of specific radicals such as hydroxyl radicals. The EPR spectra and yield of DMPO-OH generated after 30 s of reaction in the powdered CaO₂ systems are shown in Figure 6. The peaks associated with the presence of the DMPO-OH radical are indicated with ▼, and those associated with DMPO-CH₃ are indicated with ○.

Figure 6. Electron paramagnetic resonance (EPR) spectra of DMPO-CH₃ after 30 s of reaction in the CaO₂ systems. CaO₂ = calcium peroxide (16%); Fe-CPP = Fe-polyphenol catalyst developed using coffee grounds; Fe(II) = iron (II) sulfate heptahydrate; Fe-CA = Fe-caffeic acid complex; Fe-CGA = Fe-chlorogenic acid complex. Reaction conditions: 400 µL of 100 mmol L⁻¹ phosphate buffer (pH 7.4); 200 µL of 220 mmol L⁻¹ DMPO; 100 µL of 4.42 mmol L⁻¹ of H₂O₂ as CaO₂ (16% W/W); 100 µL of 1.5 mmol L⁻¹ of Fe as Fe-CPP, Fe(III) and Fe(II); 100 µL of 14.0 mol L⁻¹ DMSO solution. Reactions were carried out at room temperature. The peaks associated with the presence of the DMPO-OH radical are indicated with ▼, and those associated with DMPO-CH₃ are indicated with ○.

Figure 7. Generation of Hydroxyl radicals by different catalysts in the powdered CaO₂ systems. (a) Electron paramagnetic resonance (EPR) spectra and (b) yield of DMPO-OH generated after 30 s of reaction in the powdered CaO₂ systems. Fe-CPP = Fe-polyphenol catalyst developed using coffee grounds; Fe(II) = iron (II) sulfate heptahydrate; Fe(III) = iron (III) chloride anhydrous, Fe-CA = Fe-caffeic acid complex, Fe-CGA = Fe-chlorogenic acid complex. Reaction conditions: 400 µL of 100 mmol L⁻¹ phosphate buffer (pH 7.4), 200 µL of 220 mmol L⁻¹ DMPO, 100 µL of 4.42 mmol L⁻¹ H₂O₂ as powdered CaO₂ (16% W/W) and 100 µL of 1.5 mmol L⁻¹ Fe as Fe-CPP, Fe(III), Fe(II), F-CA or Fe-CGA. 4-Hydroxy-2,2,6,6-tetramethylpiperidine-N-oxyl (TEMPO) was used as the standard to calculate the concentrations of DMPO-OH. Reactions were carried out at room temperature. Peaks associated with the presence of DMPO-OH radical are indicated with ▼. Mean values followed by different letters are significantly different at a p < 0.05 probability level according to a least significant difference (LSD) test. Bars indicate the standard errors.

A chemiluminescence method based on luminol was used to verify the presence of ROS by adding L-ascorbate, which can scavenge ROS, decreasing the chemiluminescence intensity. A high chemiluminescence intensity was found for all treatments, and the addition of L-ascorbate dramatically reduced the emission intensity of luminol, indicating the presence of radical species in all systems. The high luminol intensity observed in the Fe-CGA/CaO₂ and Fe-CA/CaO₂ model systems suggests that chlorogenic acid and caffeic acid may be associated with the generation of ROS in the Fe-CPP/CaO₂ system since these acids are the predominant polyphenols found in coffee grounds. Luminol is a good indicator of the presence of ROS but cannot identify specific radicals because it emits chemiluminescence with all kinds of radicals, such as ·OH, ·O₂⁻ and ¹O₂. Hydroxyl radicals are the most reactive and least selective ROS, and they could play a role in the results of this experiment. To test this hypothesis, electron paramagnetic resonance (EPR) was used to detect the presence of specific radicals such as hydroxyl radicals. The EPR spectra and yield of DMPO-OH generated after 30 s of reaction in the powdered CaO₂ systems are shown in Figure 6. The peaks associated with the presence of the DMPO-OH radical are indicated with ▼, and those associated with DMPO-CH₃ are indicated with ○.
hypothesis, a series of EPR experiments using DMPO as a spin trap were carried out. The results are shown in Figs 4–7. No signals for DMPO-OH radicals were detected in the systems without an added H₂O₂ source (Figs 4 and 5). In addition, as shown in Fig. 6, when DMSO was added to the reaction systems in which the DMPO-OH radical was detected, a signal for the DMPO-CH₃ radical was observed, and the intensity of the DMPO-OH radical signal decreased.

DMPO-CH₃ is produced through the oxidation of DMSO by hydroxyl radicals, indicating that the DMPO-OH radical signal detected by EPR analysis represents the generation of hydroxyl radicals rather than the nucelophilic addition of water. Thus, coffee grounds might contain polyphenols that can contribute to the generation of hydroxyl radicals when bound to iron as a catalyst in the Fenton process. In addition, the hydroxyl radicals generated by the modified Fenton system using the Fe-CPP catalyst might contribute to the lethal oxidative damage to the bacterial cells occurring in the studied soil. These results show that hydroxyl radicals were the major ROS in the Fe-CPP/CaO₂ and Fe(II)/CaO₂ systems and agree with those showing that hydroxyl radicals are the major ROS in Fe(II)/CaO₂ systems.

The present study demonstrated that the generation of hydroxyl radicals by the reaction of CaO₂ with an Fe-polyphenol catalyst developed using coffee grounds was associated with the observed bactericidal effects. Hydroxyl radicals have the highest oxidation potential (2.76 V) among ROS and are generated in the reaction between iron (II) as a catalyst and H₂O₂ as an oxidant. The disease incidence was drastically reduced by the Fe-CPP/CaO₂ treatment compared to the Fe-CPP/H₂O₂ treatment. This effect remained until the fruiting stage (see Supplementary Fig. 4S). These results agree with recent studies suggesting that CaO₂ is a more effective source of H₂O₂ than liquid H₂O₂ for in situ chemical oxidation. The chemical oxidation capacity of CaO₂ is dependent on the generation of H₂O₂ (equation (1)) and the subsequent production of hydroxyl radicals from the released H₂O₂ (equation (2)).

\[
\text{CaO}_2 + 2\text{H}_2\text{O} \rightarrow \text{H}_2\text{O}_2 + \text{Ca(OH)}_2
\]

\[
\text{H}_2\text{O}_2 + \text{Fe}^{2+} \rightarrow \cdot\text{OH} + \text{OH}^- + \text{Fe}^{3+}
\]

The advantage of this reaction is that the concentration of released H₂O₂ is autoregulated by the rate of CaO₂ dissolution, which reduces the disproportionation of H₂O₂ in the media since not all the H₂O₂ is available at once, as is the case with liquid H₂O₂. In our experiments, the lower efficacy of liquid H₂O₂ compared with that of powdered CaO₂ as a source of H₂O₂ was obvious and could be explained through the rapid decomposition of liquid H₂O₂ that occurs in soils. These factors limit the applicability of the modified Fenton process for in situ chemical oxidations. The most important limitation of the conventional Fenton reagent is the instability of the large amount of hydroxyl radicals instantaneously produced from liquid H₂O₂. The excess H₂O₂ could act as a scavenger and compete for hydroxyl radicals, inhibiting the oxidation of bacterial cells. In this study, the release of H₂O₂ was autoregulated by the rate of CaO₂ dissolution, which prevented all the H₂O₂ from being available at once, as it is when liquid H₂O₂ is used as the reagent. As a result, the bactericidal effect of the H₂O₂ reaction with Fe-polyphenol increased when CaO₂ was used. On the other hand, the amount of hydroxyl radicals produced by the Fe-polyphenol-activated CaO₂ was estimated to be much higher than that generated by the Fe(II) or Fe(III) catalysts, which was verified by EPR spectroscopy (Fig. 7).

In our experiment, the failure of the Fe(II) and Fe(III) catalysts to reduce the incidence of wilt disease when applied with either source of H₂O₂ was studied (Fig. 1). These results can be explained by the lower total radical concentration produced by the Fe(III)/CaO₂ and Fe(II)/CaO₂ systems than that produced by the Fe-CPP/CaO₂ treatment. The weak effect of the Fe(III)/CaO₂ treatment on wilt disease could be attributed to the low reactivity of Fe(III) with H₂O₂, which results in a lower content of OH radicals produced. Compared to other catalysts, the Fe(III) catalyst produced a lower yield of hydroxyl radicals when reacted with the same amounts of H₂O₂ and powdered CaO₂ (Fig. 7). The Fe(III)-activated CaO₂ exhibited several limitations, such as precipitation of the iron as ferric hydroxide (Fe(OH)₃), which does not readily redissolve and inhibits the oxidation process. The addition of chelating agents such as citric acid, tartaric acid, oxalic acid, and glutamic acid has been proposed as a way to overcome these drawbacks. We believe that the caffeic acid and chlorogenic acid present in coffee grounds probably contributed to the Fenton process by reducing Fe²⁺ to Fe³⁺ and/or served as electron donors binding Fe³⁺ to maintain the activity of Fe in the reduced state in the Fenton cycle.

A single application of H₂O₂ to the soil did not reduce the disease incidence. Usually, a solution containing 588 to 3529.4 mmol L⁻¹ H₂O₂ is used in the in situ chemical oxidation process, but the half-life of H₂O₂ at these concentrations is only minutes to hours. These degradation rates are much higher than that of the 1.5 mmol L⁻¹ H₂O₂ solution used in this experiment.

For the in situ chemical oxidation process, iron can be added as Fe²⁺ or Fe³⁺ salts or as native iron-containing minerals such as goethite and ferrihydrite. The low solubility of Fe³⁺ at neutral pH necessitates the use of chelators to increase the Fe³⁺ concentration in the aqueous phase. Citric acid, oxalic acid, ethylenediaminetetraacetic acid, 1,4-benzenedicarboxylic acid, N,N-dimethylformamide and tartaric acid have been successfully applied as Fe³⁺ chelating agents for the Fenton process. If insufficient Fe²⁺ is added or if only Fe³⁺ is present initially, Fe²⁺ is regenerated through various reactions.

Our results are consistent with those of other studies. The detected EPR signals together with the results of the scavenging tests with L-ascorbate indicated that hydroxyl radicals were the major ROS in the Fe-CPP/CaO₂, Fe-CA/CaO₂, Fe-CGA/CaO₂, and Fe(II)/CaO₂ systems but not in the Fe(III)/CaO₂ system, as no DMPO-OH radical signal was detected in this system. The peaks of O₂⁻ were not confirmed in the EPR analyses of all the treatments, indicating that low concentrations of O₂⁻ were generated in the systems studied.
Figure 8 shows the proposed mechanism for the treatment of soil-borne disease by the CAF-Fe activation of powdered CaO₂. First, Fe³⁺ is reduced to Fe²⁺, and then the Fe²⁺ forms a complex with the coffee polyphenols. The Fe²⁺-polyphenol species react with the H₂O₂ from the calcium peroxide to generate -OH radicals. Finally, the -OH radicals oxidize the bacterial cells in the soil. We proposed that the coffee polyphenols such as chlorogenic acid and caffeic acid used in our study reduced and chelated the iron, creating conditions that favour the oxidation of bacterial cells in the soil environment by the Fenton process. Generally, hydroxyl radicals are generated from electron transfer between the complex of H₂O₂ and iron sites. The electron-rich organic ligands could donate electrons to the Fe ions. Coffee polyphenols probably contributed to the Fenton process by reducing Fe³⁺ to Fe²⁺ and/or served as electron donors to maintain the activity of Fe in its reduced state in the Fenton cycle. Reduction of Fe³⁺ generates Fe²⁺, which can participate in the Fenton reaction and generate ROS (i.e., H₂O₂).

Regardless of the investigated Fe-polyphenols and CaO₂, as an advancement in soil-borne disease control, further investigations are required to evaluate the injection mode of these particles in soils. The developed method could reduce the dependence on high-risk chemicals for disease management, and this method is ecologically sound and environmentally friendly. Evaluating the effectiveness of CPP-Fe/CaO₂ for controlling soil-borne disease on a large scale is difficult because few controlled studies on the rate of dissolution of CaO₂ and the yield of H₂O₂ in different types of soil and on the stability of the CPP-Fe material in soil have been reported. The efficiency of the treatment will significantly depend on the contact between the bacteria and the catalyst with the CaO₂ particles. Therefore, particles with a high mobility must easily reach the contaminated target soil layers. Other factors such as soil pH, natural scavengers, soil texture, and water content could alter the effectiveness of Fe-polyphenol-activated CaO₂ for controlling soil-borne disease in field conditions. The release rate of H₂O₂ from CaO₂ is autoregulated by the rate of CaO₂ dissolution, which can be controlled by adjusting the pH. Carbonate and bicarbonate buffer species act as radical scavengers in the Fenton process. Thus, the soil pH could certainly alter the effectiveness of the CPP-Fe/CaO₂ treatment. The carboxylate or phenolic functional groups in natural organic substances could act as a ligand for Fe(III), scavenge hydroxyl radicals, or reduce ferric oxides altering the effectiveness of Fenton or Fenton-like reactions. Humic acid can act as a free-radical scavenger, as a radical chain promoter, and as a catalytic site inhibitor. Fenton oxidation and -OH production were enhanced in the presence of peat by one or more peat-dependent mechanisms. The Fe concentration and availability in the peat, the reduction of Fe³⁺ to Fe²⁺ by the organic matter, and the reduction of organic-complexed Fe³⁺ to Fe²⁺ were probable causes of this enhancement. In addition, microbial activity may also be responsible for hydrogen peroxide decomposition.

The presence of inorganic components in the soil could affect the generation of -OH. Ammonium sulfate and monobasic sodium phosphate have been used to stabilize hydrogen peroxide. Of the four inorganic stabilizers (i.e., monobasic potassium phosphate, dibasic potassium phosphate, sodium tripolyphosphate, and silicic acid) for hydrogen peroxide, monobasic phosphate was found to propagate hydrogen peroxide over the longest distance in soil columns; however, monobasic phosphate was depleted by adsorption and may also function as a radical scavenger. Those stabilizers could increase the effectiveness of the CPP-Fe/CaO₂ treatment. The mobility of the Fe-CPP and CaO₂ particles in soils (i.e., saturated and unsaturated zones) should be investigated prior to in situ applications. The effect of Fe-CPP/CaO₂ treatment on soil quality and native microbiota should be investigated. Prior to field or in situ applications, feasibility studies are necessary to determine the extent and rate of bacterial oxidation on a batch scale.

Conclusion
From the results obtained in this work, we conclude that the polyphenols in coffee, such as caffeic acid and chlorogenic acid, play an important role in the generation of hydroxyl radicals in the Fe-polyphenol catalyst developed using coffee grounds. The developed catalyst is low-cost, has a low toxicity and could be used as an environmentally friendly method for suppressing the incidence of soil-borne diseases. However, the feasibility of this method on the field scale needs to be verified.
Material and Methods

Chemicals. 2,3,5-Triphenyl tetrazolium chloride and 5,5-dimethyl-1-pyrroline-N-oxide (DMPO) were purchased from Tokyo Chemical Industry Co., Japan. Anhydrous iron (III) chloride was obtained from Kanto Chemical, Japan. H$_2$O$_2$ (35% W/W), agar (powder), chloramphenicol, crystal violet, cycloheximide, polymyxin B sulfate, calcium peroxide (CaO$_2$), caffeic acid (CA, 3,4-dihydroxycinnamic acid), chlorogenic acid (CGA), liquid H$_2$O$_2$ (Fe(III)/H$_2$O$_2$); and 12. anhydrous iron (III) chloride and powdered CaO$_2$ (Fe(III)/CaO$_2$). Both the models to clarify the role of these Fe-polyphenol complexes in the activation of CaO$_2$ and the generation of hydroxyl radicals. The Fe-CGA and Fe-CA complexes were prepared with deionized water. A total of 252.2 mg of CA and 496.0 mg of CGA were individually mixed with 227.1 mg L$^{-1}$ of anhydrous iron (III) chloride (Fe(III)). Iron (II) sulfate heptahydrate (Fe(II)) and Fe(III) chloride (Fe(III)) catalysts were used as pure salts.

Synthesis of iron catalysts. Eighty-eight grams of coffee grounds was mixed with 12 g of anhydrous iron (III) chloride (Fe(III)) and 300 mL of water. The mixture was heated to 98°C for 24 hours and then dried at 82°C for 48 hours. The coffee grounds-iron mixture was subsequently ground before the experiments. To investigate whether the observed DMPO-OH radical originated from hydroxyl radical generation, an additional experiment was performed: no inoculation of an R. solanacearum population; the soil moisture level does not affect R. solanacearum populations except in instances of severe drought. To minimize the effect of drought on the bacterial populations, water was continuously provided by placing the pots in a tray in which the water level was maintained at 5 mm from the bottom by frequent watering.

Soil-borne disease assessment. Tomato cv. Momotaro was used as the test specie. For the inoculum, Ralstonia solanacearum MAFF301487 (see Supplementary Fig. S5) was cultured in 1 L of casamino acid-peptone-glucose medium (CPG medium) (0.1% casamino acid, 1% peptone, and 0.5% glucose, pH 7.0) in a sealed 500 mL Erlenmeyer flask at 32°C for 3 days in the dark with continuous shaking. All treatments, except for the negative control treatment (-(−) CNT), were inoculated with this bacterial solution. Two hundred and fifty grams of previously sterilized gardening soil (NIPPI, Nihon Hiyoro Co., Tokyo, Japan) was placed in a polyethylene plant pot (9.2 cm × 8.2 cm, Asahikasei, Tokyo, Japan) and inoculated with the bacterial solution to a final R. solanacearum population of 5.0 log CFU g$^{-1}$ dry soil. Then, the following treatments were applied: no inoculation of an R. solanacearum treatment; 1. negative control: no application of any material (-(−) CNT); inoculation of R. solanacearum treatments: 2. positive control: no application of any material (+(+) CNT); 3. 300 mL of 1.5 mmol L$^{-1}$ liquid H$_2$O$_2$ (H$_2$O$_2$); 4. powdered CaO$_2$ (16% W/W); 5. coffee polyphenols from coffee grounds (CPP); 6. Fe-polyphenol catalyst developed using coffee grounds (Fe-CPP); 7. Fe-CPP and liquid H$_2$O$_2$ (Fe-CPP/H$_2$O$_2$); 8. Fe-CPP and powdered CaO$_2$ (Fe-CPP/ CaO$_2$); 9. iron (II) sulfate heptahydrate and liquid H$_2$O$_2$ (Fe(II)/H$_2$O$_2$); 10. iron (II) heptylheptahydrate and CaO$_2$ (Fe(II)/CaO$_2$); 11. anhydrous iron (III) chloride and liquid H$_2$O$_2$ (Fe(III)/H$_2$O$_2$); and 12. anhydrous iron (III) chloride and powdered CaO$_2$ (Fe(III)/CaO$_2$). Both the liquid H$_2$O$_2$ (35% W/W) and powdered CaO$_2$ (16% W/W) treatments were applied at the same final concentrations (4.42 mmol L$^{-1}$ H$_2$O$_2$ kg$^{-1}$ dry soil). The catalysts Fe-CPP, iron (II) sulfate heptahydrate (Fe(II)) and iron (III) chloride anhydrous (Fe(III)) were applied at the same final concentrations (1.5 mmol kg$^{-1}$ dry soil) in their respective treatments. Each treatment was repeated three times (twelve pots per replicate) with one plant per pot. The disease incidence was assessed by counting the wilting plants at weekly intervals for 42 days postinoculation. The populations of R. solanacearum in the soils at the end of the experiment were estimated using a selective medium. Tomato seeds were sown in a tray, and the seedlings were transplanted when they reached 10 cm in height. The soil moisture level does not affect Ralstonia solanacearum populations except in instances of severe drought. To minimize the effect of drought on the bacterial populations, water was continuously provided by placing the pots in a tray in which the water level was maintained at 5 mm from the bottom by frequent watering.

Reactive oxygen species (ROS) assay. A chemiluminescence assay was carried out to determine the total amount of ROS generated in the reaction of CaO$_2$ with the Fe-CPP, Fe(II), Fe(III), Fe-CA and Fe-CGA catalysts. Fifty microlitres of each iron catalyst solution containing 1.5 mmol L$^{-1}$ of Fe was transferred to a tube and placed in a luminometer (AB 2270, ATTO, Tokyo, Japan), and then, 50 µL of a solution containing 0.13 mol L$^{-1}$ of NaOH, 4.42 mmol L$^{-1}$ H$_2$O$_2$ in the form of CaO$_2$ and 2.8 mmol L$^{-1}$ luminol was injected into the system via a pump through the upper injection port. Fifty microlitres of 10 mmol L$^{-1}$ L-ascorbate was added to the reaction to verify the presence of radicals. The intensities of the signals were recorded for 120 s. The H$_2$O$_2$ in the samples was analysed by a spectroscopic method using a UV spectrophotometer (UV-1800, Shimadzu, Tokyo, Japan).

Hydroxyl radical (·OH) assay. An EPR assay was carried out to identify the presence of hydroxyl radicals in the systems. To follow the hydroxyl radical generation in the modified Fenton reaction using the iron catalysts, a spin trapping method using DMPO was employed. In the spin trapping experiment, 400 µL of phosphate buffer (pH 7.4) was mixed with 200 µL of 220 mmol L$^{-1}$ DMSO, 100 µL of 4.42 mmol L$^{-1}$ H$_2$O$_2$ in the form of liquid H$_2$O$_2$ (35% W/W) or CaO$_2$ (16% W/W) and 100 µL of 1 mmol L$^{-1}$ Fe in the form of Fe-CPP, Fe(III) and Fe(II). To investigate whether the observed DMPO-OH radical originated from hydroxyl radical generation, an additional assay was performed in which 100 µL of 14 mol L$^{-1}$ DMSO, an authentic hydroxyl radical scavenger, was added to each reaction system. Furthermore, the reactions of Fe-CGA and Fe-CA with CaO$_2$ were performed as models. The EPR spectra were recorded 30 s after the addition of the respective iron catalyst using an X-band EPR spectrometer (MS 5000, Magnetec, Berlin, Germany). The measurement conditions for EPR were as follows: magnetic field, 337.5 mT; field modulation frequency, 100 kHz; field modulation width, 0.16 mT; sweep time, 60 s; microwave frequency, 9.463 GHz; and microwave power, 5 mW.
Statistical analyses. Completely randomized designs were used in all the experiments. Statistical significance \((p < 0.05)\) for the wilt disease assay, population of \(R.\ solanacearum\) in the soil and total ROS generated were each assessed by one-way analysis of variance (ANOVA) followed by Fisher’s least significant difference (LSD) post hoc test for multiple comparisons at a significance level of \(p < 0.05\).

Data availability. All data generated or analysed during this study are included in this published article (and its Supplementary Information files). The data sheets generated and/or analysed in the current study are available from the corresponding author on reasonable request.
