Abstract. The trafficking of GLUT4, a facilitative glucose transporter, is examined in transfected CHO cells. In previous work, we expressed GLUT4 in neuroendocrine cells and fibroblasts and found that it was targeted to a population of small vesicles slightly larger than synaptic vesicles (Herman, G.A, F. Bonzelius, A.M. Cieutat, and R.B. Kelly. 1994. Proc. Natl. Acad. Sci. USA. 91: 12750–12754). In this study, we demonstrate that at 37°C, GLUT4-containing small vesicles (GSVs) are detected after cell surface radiolabeling of GLUT4 whereas uptake of radiiodinated human transferrin does not show appreciable accumulation within these small vesicles. Immunofluorescence microscopy experiments show that at 37°C, cell surface–labeled GLUT4 as well as transferrin is internalized into peripheral and perinuclear structures. At 15°C, endocytosis of GLUT4 continues to occur at a slowed rate, but whereas fluorescently labeled GLUT4 is seen to accumulate within large peripheral endosomes, no perinuclear structures are labeled, and no radiolabeled GSVs are detectable. Shifting cells to 37°C after accumulating labeled GLUT4 at 15°C results in the reappearance of GLUT4 in perinuclear structures and GSV reformation. Cytosol acidification or treatment with hypertonic media containing sucrose prevents the exit of GLUT4 from peripheral endosomes as well as GSV formation, suggesting that coat proteins may be involved in the endocytic trafficking of GLUT4. In contrast, at 15°C, transferrin continues to traffic to perinuclear structures and overall labels structures similar in distribution to those observed at 37°C. Furthermore, treatment with hypertonic media has no apparent effect on transferrin trafficking from peripheral endosomes. Double-labeling experiments after the internalization of both transferrin and surface-labeled GLUT4 show that GLUT4 accumulates within peripheral compartments that exclude the transferrin receptor (TfR) at both 15°C and 37°C. Thus, GLUT4 is sorted differently from the transferrin receptor as evidenced by the targeting of each protein to distinct early endosomal compartments and by the formation of GSVs. These results suggest that the sorting of GLUT4 from TfR may occur primarily at the level of the plasma membrane into distinct endosomes and that the organization of the endocytic system in CHO cells more closely resembles that of neuroendocrine cells than previously appreciated.

Many cells adjust the composition of their plasma membranes in response to external signals. For example, in fat and muscle cells after exposure to insulin, the facilitative glucose transporter GLUT4 is redistributed from a predominantly intracellular location to the plasma membrane (Cushman and Wardzala, 1980; Suzuki and Kono, 1980; for reviews see James and Piper, 1994; Stephens and Pilch, 1995; Haussdorff et al., 1996; Holman and Cushman, 1996). In the absence of insulin, GLUT4 resides primarily within tubulovesicular elements and small vesicles (Biber and Lienhard, 1986; James et al., 1987; Blok et al., 1988; Slot et al., 1991a,b; Smith et al., 1991; Rodnick et al., 1992). Different studies have suggested that, in fat cells, the intracellular storage compartment containing the GLUT4 transporter is derived by endocytosis (Slot et al., 1991a,b; Smith et al., 1991; Czech and Buxton, 1993; Satoh et al., 1993), and that this pathway may represent a specialization of the recycling endocytic pathway analogous to the synaptic vesicle recycling system in neurons and in neuroendocrine cells.

The GLUT4 transporter, a protein of ~48 kD with 12 transmembrane domains, is internalized in cardiac cells and adipocytes via clathrin coated pits (Slot et al., 1991a; Robinson et al., 1992). Its endocytosis in fibroblasts, adipocytes, and myocytes is mediated by dileucine and phenylalanine-based motifs (Piper et al., 1993; Corvera et al., 1994; Garippa et al., 1994; Verhey and Birnbaum, 1994; Haney et al., 1995; Martin et al., 1996). GLUT4 has been...
shown to constitutively recycle to and from the plasma membrane (Jhn et al., 1992; Satoh et al., 1993; Yang and Holman, 1993).

We previously analyzed the intracellular distribution of GLUT4. We found that when expressed in neuroendocrine PC12 cells, GLUT4 was not targeted to synaptic vesicles but accumulated in a population of vesicles with diameters of ~70 nm, which were distinct from synaptic vesicles. These homogeneously sized vesicles were also seen in transfected 3T3 fibroblasts and CHO cells, and had physical characteristics resembling those seen in primary adipose cells (Herman et al., 1994). In adipose cells, addition of insulin resulted in the redistribution of GLUT4 from the small vesicles to membranes with the sedimentation properties of endosomes and plasma membranes (Herman et al., 1994). In PC12 cells cotransfected with the polymeric immunoglobulin receptor (pIgR), the small vesicles excluded markers of synaptic vesicles, as well as markers of the conventional endocytotic pathway (transferrin receptor [TIR]) and the transcytotic pathway (pIgR). These findings suggested that GLUT4 was targeted to a unique class of small vesicles that were present in a variety of cell types and might be involved in transient modification of the cell surface. The accumulation of GLUT4 in intracellular compartments resembling those seen in muscle cells and adipocytes has also been described by other investigators for a variety of transfected cell lines (Haney et al., 1991; Hudson et al., 1992, 1993; Piper et al., 1992; Shibasaki et al., 1992; Thorens and Roth, 1996).

In the present study, a CHO cell line expressing a c-myc epitope–tagged version of GLUT4 was used to determine whether the class of small vesicles containing GLUT4 could be detected by cell surface labeling and, if so, whether the endocytic pathway giving rise to these vesicles differed from the conventional route followed by the transferrin receptor. Antibodies directed against the myc epitope were used to follow the trafficking of GLUT4 labeled at the cell surface. The transferrin receptor was used as a well-accepted marker of the recycling endocytic pathway. Small vesicles enriched in GLUT4 but not in the TIR were detected after cell surface labeling of these molecules. As in the formation of neuroendocrine synaptic vesicles (also referred to as synaptic-like microvesicles) in PC12 cells (Desnos et al., 1995), formation of GLUT4-containing small vesicles (GSVs) was blocked at low temperature (15°C), consistent with GSVs deriving from an endosomal precursor. Kinetic studies of vesicle formation also suggest an endosomal precursor.

The internalization of both transferrin and antibodies directed against the myc-tagged GLUT4 was also examined by immunofluorescence microscopy. At 15°C and at 37°C, peripheral endocytotic compartments enriched for GLUT4 and lacking the TIR were observed. Selective traffic from the cell surface to an endosome that excludes the transferrin receptor is not easily reconciled with the traditional model of membrane trafficking in undifferentiated cells (for review see Mellman, 1996) in which proteins are internalized nonselectively from the plasma membrane into a common endosome from which sorting pathways diverge to different intracellular destinations. The data is consistent with a model where the sorting of GLUT4 from the TIR appears to occur at the plasma membrane at a step that precedes the level of small vesicle formation. The endocytic pathway followed by GLUT4 in CHO cells thus appears to be distinct from that followed by the transferrin receptor, and possesses features similar to those found in the endocytic pathways of neuroendocrine cells.

Materials and Methods

Materials and Antibodies

Cell culture reagents were obtained through the University of California (San Francisco, CA) Cell Culture facility. Iodogen reagent was from Pierce Chemical Co. (Rockford, IL). Enhanced chemiluminescence (ECL) reagents were purchased from Amersham Corp. (Arlington Heights, IL). Human apotransferrin was obtained from Sigma Chemical Co. (St. Louis, MO), Texas red–labeled human transferrin from Molecular Probes (Eugene, OR). Miscellaneous chemical reagents were acquired from Sigma Chemical Co. and Fisher Biochemicals (Santa Clara, CA).

Monoclonal antibody 9E10, directed against the c-myc epitope (Schwab et al., 1986) was provided by Dr. J.M. Bishop (University of California, San Francisco, CA). Rb20, an anti-GLUT4 polyclonal antibody was from East Acres Biologicals (Cambridge, MA). Anti-rab5 monoclonal antibody, anti-rab4 polyclonal sera, and anti-TGN38 polyclonal sera were provided by Drs. I. Mellman, M. Zerial, and A. Wise, respectively. Goat anti-rabbit and goat anti-mouse IgG coupled to HRP or FITC were obtained from Cappel Laboratories (Aurora, OH).

Cell Culture

CHO cells were grown in Ham’s F-12 media supplemented with 10% FCS, 100 U/ml penicillin, 100 µg/ml streptomycin, and 0.25 mg/ml G418 in humidified incubators with 5% CO2 at 37°C. Experiments were performed using cells stably transfected with GLUT4 containing a c-myc epitope tag in the first exofacial domain (Kanai et al., 1993). Some cells were also coexpressing either the human insulin receptor or the mouse PDGF receptor (Kanai et al., 1993; Kamohara et al., 1995). Before experiments, cells were incubated for 1–2 h in serum-free media supplemented with 3% BSA. Under these conditions, no differences could be observed between cells that were coexpressing the insulin or the PDGF receptor, and those that were only expressing GLUT4 myc.

Iodination of Anti-myc Antibodies and Transferrin

Monoclonal antibody 9E10 was purified from serum-free hybridoma supernatant by protein G-Sepharose chromatography. Human apotransferrin was further purified by Sephacryl S-300 gel filtration, and then iron loaded as described (Yamashiro et al., 1984; McGraw et al., 1987). 100-µg aliquots of purified antibody or iron-loaded transferrin were iodinated as described using iodogen-mediated coupling (Grote and Kelly, 1996).

Subcellular Fractionation

Cells were homogenized using a glass–Teflon Potter-Elvehjem homogenizer (Thomas Scientific, Swedesboro, NJ). GSVs were isolated by velocity sedimentation of postnuclear supernatants on glycerol gradients as described previously (Herman et al., 1994) using a modification of the protocol described by Clift-O’Grady et al. (1990). After internalization of radiolabeled antibodies or transferrin (see below), gradients were centrifuged at 60,000 g for 90 min to increase the separation between GSVs and soluble label on top of the gradient. Gradient fractions were analyzed by SDS-PAGE and Western blotting as described previously (Bonzelius et al., 1994), or counted directly in a gamma counter. GLUT4 immunoreactivity was detected using primary polyclonal antibody Rb20 or mAb 9E10 and HRP-coupled secondary antibodies and visualized using the ECL system.

Endocytosis of Surface-labeled GLUT4

Endocytosis of GLUT4 was measured using a modification of the proce-

1. Abbreviations used in this paper: COP, coatomer-associated proteins; GSV, GLUT4-containing small vesicles; pIgR, polymeric immunoglobulin receptor; TIR, transferrin receptor.
dure described by Grote and Kelly (1996). Cells were plated onto poly-
v-lysine-coated dishes 2 d before the experiment. On the day of the
experiment, they were washed for 15 min with PBS/3% BSA, and then incu-
bated with radioiodinated mAb 9E10 (10^10 cpm/ml, ~3.5 μg/ml) in Ham's
F-12/3% BSA/10 mM Hepes, pH 7.4, for 1 h at 4°C. After removal of the
radioiodinated antibody, cells were washed extensively on ice. Cells were
then incubated at 15° or 37°C for various times to allow internalization of
antibody, and then returned to 4°C. After extensive washing with ice-cold
PBS/1 mM MgCl2/3% BSA, cells were resuspended from dishes and pelleted at 400 g. Pellets
were resuspended in ice-cold PBS and subjected to two additional cycles of
washing and pelleting. Antibody remaining at the surface was then re-
moved by resuspending and washing the pellets twice in ice-cold 0.5 N
acetic acid/150 mM NaCl for 15 min at 4°C. The supernatant from these
washes was counted on a gamma counter. The amount of acid-resistant ra-
dioactivity was determined by counting the cell pellets after acid stripping.
For each time point, the fraction of the total cell-associated radioactivity
that was acid resistant was calculated. Approximately 18% of the bound
125I-9E10 was resistant to acid stripping at time zero before warming of the
cells.

**Targeting of Surface-labeled GLUT4 to GSVs**

Cells were incubated with serum-free nutrient mixture Ham's F-12, 3%
BSA, 10 mM Hepes, pH 7.4, containing 10 μM c-myc, for 30 min at either 37
°C or at 15°C, and then labeled with 125I-mAb 9E10 for 80 min at 15°C, washed on ice, and then
incubated with radioiodinated mAb 9E10 for 15° or 37°C for various times. In parallel, cells were incu-
bated with media containing 125I-transferrin. After incubation, cells were
placed on ice and washed extensively with ice-cold PBS/3% BSA. Cells were then scraped in ice-cold buffer A and subjected to three
additional cycles of washing and pelleting before homogenization. Postnu-
clear supernatants were then subjected to velocity sedimentation analysis
as described above. For all experiments, equal amounts of protein were loaded onto each gradient.

Pulse-chase experiments were performed by incubating cells with ra-
dioiodinated mAb 9E10 for 80 min at 15°C, washing extensively on ice, and then rewarmed the cells in media in the absence of labeled antibody
for various periods of time before processing as above. Kinetic data were
obtained by determining the GSV-associated radioactivity for each time
point. The GSV-associated radioactivity was calculated by plotting the
obtained by determining the GSV-associated radioactivity for each time
point. In parallel, cells were incu-
bated with media containing 125I-transferrin. After incubation, cells were
placed on ice and washed extensively with ice-cold PBS/3% BSA. Cells were then scraped in ice-cold buffer A and subjected to three
additional cycles of washing and pelleting before homogenization. Postnu-
clear supernatants were then subjected to velocity sedimentation analysis
as described above. For all experiments, equal amounts of protein were loaded onto each gradient.

The effect of hypertonic media containing sucrose on GSV formation
was assessed as described (Hansen et al., 1993) by placing cells previously
labeled at 15°C into media containing 0.45 M sucrose, 37°C. The supernatant from these
was subjected to velocity sedimentation analysis (Clift-
O’Grady et al., 1990). Western blot analysis of fractions
from the glycerol velocity gradient revealed that the
epitope-tagged version of GLUT4 was present within two
membrane populations: a class of slowly sedimenting
GSVs and a pool of rapidly sedimenting membranes corre-
spanding to endosomes and plasma membrane (Fig. 1). The
disappearance of labeled GSVs was assessed by labeling de novo GSVs and measuring the loss of GSV-associated radioactivity under condi-
tions that prevent the formation of additional GSVs. Cells were incu-
bated with 125I-mAb 9E10 for 80 min at 15°C, washed on ice, and then shifted to 37°C for 30 min to allow formation of labeled GSVs. Cells con-
taining the labeled GSVs were then incubated either in regular media at
15°C or in media containing 0.45 M sucrose to block further GSV forma-
tion for various times before processing as above.

**Antibody-binding Assay for Quantification of Cell Surface GLUT4**

GLUT4 present on the cell surface was assayed using a modification of a
previously described procedure (Kanai et al., 1993). Cells were incubated for
30 min at either 15°C or 37°C in the presence of, or absence of hypertonc media
or at 15°C in regular media. Cells were then placed on ice and fixed in 4%
formaldehyde in PBS for 10 min, followed by 20 min at room temper-
answer. They were then quenched by washing twice with PBS/25 mM gly-
cine and onco with PBS. The cells were blocked by incubation with PBS/
3% BSA for 1 h at room temperature. 125I-mAb 9E10 was bound to the
surface by incubating the fixed cells with radioiodinated antibody (10^7
cpm/ml) for 1 h at room temperature. Cells were then washed extensively
with PBS/3% BSA, scraped, and then centrifuged at 400 g for 5 min. Pel-
lets were resuspended in PBS and subjected to two additional cycles of
washing and pelleting to remove nonspecifically bound antibody. The
amount of antibody bound to the surface was determined by counting the
pellets on a gamma counter. Values obtained were normalized to the amount of total protein in each pellet.

**Immunofluorescence Microscopy**

Cells were analyzed by confocal immunofluorescence microscopy as de-
scribed (Bonzellius et al., 1994). For single-label immunofluorescence, cells were incubated with either mAb 9E10 (10 μg/ml) or Texas red–cou-
pied human transferrin (40 μg/ml) for 30 min at 37°C, or 2.5 h at 15°C. Pulse-chase experiments were performed by internalizing mAb 9E10 or Texas red–coupled transferrin for 2.5 h at 15°C, washing extensively on ice, and then shifting cells to 37°C in regular media, hypertonc media contain-
ing sucrose, or acidified media as above for various times. After exper-
iments with Texas red–coupled transferrin, cells were fixed immediately and prepared for microscopy. After experiments with mAb 9E10, cells were fixed, permeabilized with saponin, and incubated with FITC-coupled
goat anti–mouse antibodies before imaging. For double-label immuno-
fluorescence, mAb 9E10 was coupled to fluorescein succinimidy el ester (Mo-
ecular Probes, Eugene, OR) following the manufacturer’s instructions.
Cells were incubated with fluorescein-treated 9E10 (10 μg/ml) and Texas red–coupled human transferrin (40 μg/ml) for the times and conditions
indicated, fixed, and then processed for microscopy.

**Results**

**GSVs Contain Cell Surface–labeled GLUT4**

To facilitate the study of GLUT4 trafficking, we used a CHO cell line stably expressing a version of GLUT4 containing a c-myc epitope (CHO/G4myc) in the first exofo-
cial domain (Kanai et al., 1993). The GSVs from these
cells were isolated by velocity sedimentation as previously
described (Herman et al., 1994), using a modification of a
procedure for the isolation of synaptic vesicles (Clift-
O’Grady et al., 1990). Western blot analysis of fractions
from the glycerol velocity gradient revealed that the
epitope-tagged version of GLUT4 was present within two
membrane populations: a class of slowly sedimenting
GSVs and a pool of rapidly sedimenting membranes corre-
spanding to endosomes and plasma membrane (Fig. 1). The
sedimentation characteristics of the GSVs containing the
epitope-tagged transporter were indistinguishable from those previously described for GSVs containing un-
tagged transporter (Herman et al., 1994).

To further characterize the nature of the GSVs, we ana-
alyzed the gradient fractions by Western blotting using
anti-rab4, anti-rab5, and anti-TGN38 antibodies (Fig. 1). Neither rab5 nor TGN38 colocalized with GLUT4 in the region of the GSVs, whereas both colocalized with GLUT4 in the region of the rapidly sedimenting membranes. There is a more slowly sedimenting membrane fraction that contains TGN38, but the peak does not coincide with that of the GSVs. Rab4 is found in the region of the GSVs, but is not enriched in those fractions, and is also found
colocalizing with GLUT4 in the rapidly sedimenting peak.

To determine if GSVs in CHO cells are formed along the endocytic pathway, we labeled the glucose transporter on the cell surface, allowed internalization of the label, and then analyzed targeting to intracellular compartments. CHO/G4myc cells were incubated for 30 min at 37°C with a radioiodinated monoclonal antibody directed against the
c-myc epitope (mAb 9E10). Myc epitope–tagged GLUT4

Wei et al. GLUT4 Trafficking in CHO Cells

567
labeled at the surface was targeted to GSVs as well as to endosomal/plasma membrane fractions (Fig. 2 A) in a manner that is analogous to the distribution of the transporter at steady-state (Fig. 1), suggesting that the binding of exogenous antibody does not detectably alter the distribution of GLUT4. Free ligand was also recovered at the top of the gradient (Fig. 2 A, right). Uptake of the anti-myc antibody into CHO cells not transfected with GLUT4 was negligible, showing that there was no significant internalization of antibody by fluid phase endocytosis (data not shown).

In parallel, CHO/G4myc cells were incubated with radioiodinated human transferrin. The majority of the membrane-bound labeled transferrin was recovered in large endosomal/plasma membrane fractions and did not accumulate within a homogeneous population of small vesicles (Fig. 2 A). Note that these gradient conditions do not resolve sorting from recycling endosomes. In contrast to our observations with PC12 cells (Herman et al., 1994), some iodinated transferrin was distributed at low levels throughout the gradient fractions. When cells were incubated with 50-fold excess of cold transferrin in the presence of radioiodinated transferrin, uptake of 125I was nearly undetectable, indicating the specificity of the transferrin internalization (data not shown).

The time-course for the delivery of surface-labeled GLUT4 to GSVs was assessed by incubating cells in the presence of 125I-9E10 for various periods of time and quantifying the GSV-associated radioactivity. After a 5-min lag, surface-labeled GLUT4 began appearing at detectable levels in the GSVs (Fig. 2 B).

Endocytosis of surface-labeled GLUT4 was assayed at both 15°C and 37°C (Fig. 2 C). CHO/G4myc cells were incubated with radioiodinated mAb 9E10 on ice, washed, and then shifted to 15°C or 37°C for various periods of time. After warming, surface-bound antibody was removed by acid stripping. The fraction of acid-resistant, cell-associated radioactivity was then plotted against time. Results were determined by averaging three independent experiments. (C) Cells were incubated with radioiodinated anti-myc antibodies for 1 h on ice, washed, and then warmed for various times at either 15°C or 37°C followed by acid stripping with 0.5 N acetic acid. The fraction of cell-associated, acid-resistant counts for each time point was then determined. □, 15°C; ●, 37°C.

**GSV Formation Is Reversibly Blocked at 15°C**

In an effort to dissect the nature of this pathway, we sought to identify whether there were any temperature-sensitive steps in the formation of GSVs. Previous studies have shown that at temperatures <10°C, internalization from the plasma membrane is inhibited (Marsh and Heinli, 1980; Weigel and Oka, 1982; Hopkins and Trowbridge, 1983; Iacopetta and Morgan, 1983; Steinman et al., 1983; Trowbridge et al., 1993). At 15°C, budding of clathrin-coated pits from the plasma membrane takes place (Schmid and Smythe, 1991). At temperatures between 15°C and 22°C, endocytosis and recycling is slowed, while transfer to the degradative pathway appears to be blocked.
steady-state distribution of GLUT4 by immunoblotting shown), no labeling of GSVs was detected. Analysis of the prolonged incubation of up to 3 h at 15°C of GSV formation from the precursor compartment labeled as above. Fractions were counted on a gamma counter (A: ○, 37°C; □, 15°C) or analyzed by SDS-PAGE and Western blotting with polyclonal antibody R820 (B). (In this experiment, repeated washing and pelleting of cells was necessary to lower the background radioactivity. This washing procedure has been observed to cause a preferential loss of GSVs compared with larger GLUT4-containing organelles. [Bonzelius, F., unpublished observations], which may explain the lower yield of GSVs seen here compared with that seen in Fig. 1.) In parallel, cells were incubated with anti-myc antibodies for 80 min at 15°C, and then washed extensively, placed on ice or shifted to 37°C for 30 min in antibody-free media before processing (C: □, 15°C label and then 37°C chase; ○, 15°C label without chase). Note that targeting of surface-labeled GLUT4 to GSVs is inhibited at 15°C but is restored upon rewarming to 37°C. (D) Cells were incubated with radioiodinated anti-myc antibody for 80 min at 15°C, washed extensively, rewarmed to 37°C, and harvested at the indicated times. GSV-associated radioactivity was quantitated, analyzed, and plotted as in Fig. 2 B.

(Dunn et al., 1980; Weigel and Oka, 1982; Hopkins and Trowbridge, 1983; Iacopetta and Morgan, 1983; Harding and Unanue, 1990; Trowbridge et al., 1993). Formation of synaptic vesicles from an endosomal precursor in neuroendocrine PC12 cells is completely inhibited at 15°C (Desnos et al., 1995).

We examined whether GSVs could be formed at 15°C. Cells were incubated with radiolabeled anti-myc antibodies for 40 min at 37°C or 80 min at 15°C, washed, homogenized, and then fractionated as above. Fractions were counted on a gamma counter (A: ○, 37°C; □, 15°C) or analyzed by SDS-PAGE and Western blotting with polyclonal antibody R820 (B). (In this experiment, repeated washing and pelleting of cells was necessary to lower the background radioactivity. This washing procedure has been observed to cause a preferential loss of GSVs compared with larger GLUT4-containing organelles. [Bonzelius, F., unpublished observations], which may explain the lower yield of GSVs seen here compared with that seen in Fig. 1.) In parallel, cells were incubated with anti-myc antibodies for 80 min at 15°C, and then washed extensively, placed on ice or shifted to 37°C for 30 min in antibody-free media before processing (C: □, 15°C label and then 37°C chase; ○, 15°C label without chase). Note that targeting of surface-labeled GLUT4 to GSVs is inhibited at 15°C but is restored upon rewarming to 37°C. (D) Cells were incubated with radioiodinated anti-myc antibody for 80 min at 15°C, washed extensively, rewarmed to 37°C, and harvested at the indicated times. GSV-associated radioactivity was quantitated, analyzed, and plotted as in Fig. 2 B.

Since 125I-transferrin did not accumulate in a homogeneous population of small vesicles, it was difficult to compare the effects of the 15°C block on transferrin receptor trafficking versus GLUT4 trafficking using radioactive labeling techniques. Instead, immunofluorescence microscopy was used to analyze compartments reached by GLUT4 or transferrin after internalization at 37°C or 15°C.

CHO/G4myc cells were incubated with either anti-myc mAb or Texas red–coupled human transferrin at 37°C or 15°C and processed for laser scanning confocal immunofluorescence microscopy. After a 30-min incubation at 37°C, transferrin was found to be distributed in punctate structures throughout the cytoplasm and in the juxtanuclear area (Fig. 4, A and B). Most of the label was concentrated in the perinuclear structures consistent with earlier reports (Trowbridge et al., 1993; Gruenberg and Maxfield, 1995) describing the trafficking of transferrin from peripheral sorting endosomes to juxtanuclear recycling endosomes. When cells were incubated with Texas red–coupled transferrin in the presence of a 50-fold excess of unlabeled, iron-loaded transferrin no internalized fluorescein-treated transferrin was detected (data not shown). Furthermore, when cells were subjected to a prolonged incubation (150 min) at 15°C with Texas red–coupled transferrin, no change from the pattern observed at 37°C was seen, and both peripheral and perinuclear structures were again identified (Fig. 4, E and F).

Uptake of anti-myc mAb at 37°C for 30 min resulted in a pattern similar to that of transferrin internalized under the same conditions, demonstrating that GLUT4 trafficked through heterogeneously sized peripheral and perinuclear structures (Fig. 4, C and D). However, when cells internalized anti-myc antibody at 15°C, the labeling of perinuclear structures could no longer be seen. Instead, labeled GLUT4 accumulated in a population of large peripheral endosomes (Fig. 4, G and H). Many of these structures appeared to be localized very close to the plasma membrane. Acid stripping of cells with 0.5 M acetic acid after allowing antibody internalization did not alter the labeling of the peripheral structures, suggesting that they do not communicate with the cell surface. As a control, the steady-state distribution of GLUT4 was determined in cells that were preincubated at 15°C. Large peripheral structures were predominantly labeled, with a diminution in labeling of the perinuclear structures (data not shown), indicating that antibody internalization did not significantly perturb GLUT4 trafficking. Thus, although incubation at 15°C appears not to arrest transferrin trafficking, the reduced temperature limits the distribution of GLUT4 to large, peripheral endosomal compartments.

Formation of perinuclear structures containing GLUT4 could be restored by shifting cells, previously fluorescently labeled at 15°C, to 37°C. Cells were incubated with either...
human transferrin was for 30 min at 37°C, washed extensively on ice, and then chased in label-free media at 37°C. After a 10-min chase at 37°C, GLUT4 label was again detected in juxtanuclear structures as well as in heterogeneous sized cytoplasmic structures (Fig. 4, K and L). By 30 min, most of the label was localized to juxtanuclear structures (data not shown), and resembled the pattern seen after uptake of antibody at 37°C alone. Large, peripheral endosomes could no longer be easily identified. In the case of transferrin, after 10 min at 37°C, most of the internalized transferrin was localized to juxtanuclear structures (Fig. 4, I and J). By 30 min, staining was almost undetectable suggesting that most of the transferrin had recycled back to the surface and was released into the media (data not shown), as has been demonstrated earlier.

These experiments suggest that GLUT4 traffics between two separate populations of endosomes: large peripheral endosomes and perinuclear endosomes. GLUT4 movement between these two compartments appears to be directional, with traffic from peripheral to perinuclear endosomes blocked at 15°C.

The large peripheral GLUT4-containing compartment observed at 15°C was further characterized by double-labeling immunofluorescence assays. Cells were incubated at 15°C for 2.5 h with both Texas red-coupled transferrin and fluoresceinated anti-myc antibody. Cells were then either processed immediately (Fig. 5, A–F) for confocal microscopy or shifted to 37°C for 10 min in label-free media (Fig. 5, G–I), and then processed. At 15°C, large peripheral compartments containing GLUT4 but not transferrin were identified. The perinuclear structures containing transferrin were less apparent in these images because of the plane of sectioning, which was chosen to optimize the visualization of the GLUT4 structures. After shifting to 37°C, GLUT4 and TfR did appear to be colocalized to some extent in the perinuclear region, although the possibility of distinct GLUT4- and transferrin-containing compartments in very close apposition is not eliminated. In the periphery, many structures enriched for GLUT4 but not for the TfR were apparent, suggesting that GLUT4 sorts away from the TfR at 37°C as well. This latter pattern (Fig. 5, G–I) is identical to that seen in cells which have been incubated with both labels at 37°C for 30 min, without a prior incubation at 15°C (data not shown).

Exit of GLUT4 from Peripheral Endosomes and Formation of GSVs Are Inhibited by Hypertonic Sucrose or Cytosol Acidification

The above experiments suggested that sorting mechanisms are involved in the traffic of GLUT4 and TfR in CHO cells. Previous studies have noted the presence of clathrin and COP-related coat proteins on endosomal membranes (Gruenberg and Maxfield, 1995; Whitney et al., 1995;
Aniento et al., 1996; Stoorvogel et al., 1996), and suggest these proteins may play a role in the sorting of membrane proteins. In addition, subjecting cells to either incubation in media containing sucrose (Daukas and Zigmond, 1985) or cytosol acidification with acetic acid (Davoust et al., 1987; Sandvig et al., 1987) has been shown to inhibit clathrin–adaptor interactions (Hansen et al., 1993), or by altering the structure of clathrin itself (Heuser, 1989; Heuser and Anderson, 1989; Hansen et al., 1993). We tested the effect of sucrose and cytosol acidification on GLUT4 trafficking from peripheral endosomes and on GSV formation.

TfR was analyzed under the same conditions, no obvious differences between the sucrose-treated and untreated cells could be detected (Figs. 4, I and J; and 6, C and D). By 30 min, nearly all of the internalized transferrin had exited the cells despite the presence of sucrose (data not shown), indicating that the presence of sucrose had not nonspecifically blocked all vesicular traffic.

Parallel experiments were performed to test the effect of cytosol acidification on GLUT4 distribution. Peripheral endosomes were labeled as above at 15°C, cells were then incubated with acidified media containing 10 mM acetic acid, pH 5.0, to acidify the cytosol, and then shifted to 37°C for 10 or 30 min in the acidified media. As with sucrose, labeling of juxtanuclear structures was not evident (Fig. 6, E and F). Most of the label appeared to be restricted to the large peripheral endosomes.

If radioactively labeled GSVs form from the peripheral endosomes identified by the internalization of fluorescent label at 15°C, treatment with either hypertonic medium or cytosol acidification should also inhibit the biogenesis of GSVs. GSV formation was assayed using velocity sedimentation, after cells were labeled with radioiodinated anti-myc mAb for 80 min at 15°C, washed to remove free antibody, and then shifted to 37°C in the presence or absence of sucrose or acetic acid. Both sucrose (Fig. 7A) and acetic acid (Fig. 7B) inhibited the formation of GSVs compared to control cells. This effect was not due to nonspecific toxicity, as the percentage of cells that incorporated the internalized label was similar in all experiments.
Figure 6. Effect of hypertonic sucrose and cytosol acidification on the endocytic trafficking of GLUT4 and transferrin. Cells were incubated with either anti-myc mAb 9E10 (A, B, E, and F) or Texas red–coupled transferrin (C and D) for 2.5 h at 15°C, and then shifted to 37°C for 10 min in either hypertonic medium containing 0.45 M sucrose (A–D) or in regular medium acidified with acetic acid (E and F). Processing for laser confocal microscopy was as in Fig. 4. Note that in the presence of sucrose and acetic acid, GLUT4 labeling of the juxtanuclear structures is lacking, whereas the distribution of transferrin in sucrose is unaffected. Bars, 10 μm.

Newly Formed GSVs Are Dynamic

We next examined the fate of newly formed GSVs. To do so, we labeled GSVs, then measured their rate of disappearance under conditions that prevented additional GSV formation. CHO/G4myc cells were incubated with radiolabeled GLUT4 and transferrin, washed to remove free antibody, and then warmed for 30 min at 37°C to allow formation of labeled GSVs. Cells were then shifted to conditions that would block further GSV formation: to 15°C or to media containing hypertonic sucrose at 37°C. The amount of GSV-associated radioactivity was determined over time.

Figure 7. Formation of GSVs is inhibited by treatment either with hypertonic medium containing sucrose or with cytosol acidification. Cells were incubated with radiiodinated anti-myc mAb for 80 min at 15°C, washed extensively, and warmed in regular media, in media containing 0.45 M sucrose (A: □, control; ●, sucrose) or in media acidified with 10 mM acetic acid (B: □, control; ●, 10 mM acetic acid). Cells were fractionated by velocity sedimentation as above.

(data not shown). Vesicle disappearance was also apparent during the 15°C incubation (Fig. 8 B). When the steady-state distribution of GLUT4 was analyzed by Western blotting after incubating the cells either at 15°C (Fig. 3 B), or with hypertonic medium (data not shown), disappearance of GSVs was also observed.

We then examined the distribution of GLUT4 under these conditions that inhibit formation of GSVs but allow for their disappearance. Specifically, we compared cell surface levels of GLUT4 on control versus treated cells (Fig. 8 C). Cells were incubated for 30 min either at 37°C in the presence or absence of hypertonic media, or at 15°C in regular media. Control and treated cells were then fixed and incubated with radiiodinated anti-myc antibody to determine the level of antibody binding to the cell surface. After 30 min in hypertonic media, the level of cell surface GLUT4 was increased more than fivefold as compared to untreated cells. After 30 min at 15°C, a threefold increase in cell surface GLUT4 was observed. These results are consistent with a redistribution of GLUT4 from GSVs to the plasma membrane. The large increase in cell surface GLUT4 seen with sucrose treatment suggests that endocytosis of GLUT4 from the surface is also efficiently blocked by sucrose. Less pronounced redistribution is seen at 15°C, consistent with our observation that at 15°C, GLUT4 can be reinternalized, albeit at a slowed rate, into peripheral endosomes. These experiments do not address whether GSVs fuse directly with the plasma membrane or must first fuse with an endosomal intermediate that subsequently delivers GLUT4 to the plasma membrane.

Discussion

We have previously demonstrated (Herman et al., 1994) that in fat cells, a subset of the intracellular GLUT4 storage pool is in small uniformly sedimenting vesicles (GSVs). We also showed that GSVs can be found in fibroblasts, PC12, and CHO cells transfected with the GLUT4 cDNA, thus raising the possibility that the intracellular storage of selected proteins such as GLUT4 can be a general property of cells.

Glut4 Trafficking in CHO Cells

In this study, we further characterize the GSVs in CHO cells and present two types of data comparing the trafficking of GLUT4 with that of the TIR. In the first set of data, biochemical experiments using radiolabeling and velocity sedimentation analysis demonstrate that GSVs, enriched in GLUT4 but not the TIR, can be detected by internalization of surface-labeled GLUT4. In the second set of data, morphological studies using confocal immunofluorescence microscopy demonstrate that internalized GLUT4 and transferrin label distinct endocytic structures.

The GSVs found at steady state were characterized. The distribution of the small GTP-binding proteins, Rab4 and Rab5, which are associated with early endosomes and are proposed to have a role in the regulation of endocytosis (Mellman, 1996), were examined. It was found that Rab5 did not colocalize with the GSVs, consistent with findings in 3T3-L1 adipocytes (Cormont et al., 1996; Livingstone et al., 1996), and suggesting that the GSVs are not produced by fragmentation of the endosomes during the cell homogenization process. Rab4, which has been reported to be associated with GLUT4-containing membranes (Cormont et al., 1993, 1996; Sherman et al., 1996), was seen on the gradient in the region of the GSVs but was not enriched within GSV gradient fractions. Definitive colocalization requires immunosolation of the GSVs. Another marker, TGN38 (which labels the trans-Golgi network), also did not significantly colocalize with the GSVs. This is in agreement with compartment ablation studies done in 3T3-L1 adipocytes (Martin et al., 1994; Livingstone et al., 1996) and further suggests that the GSVs are not formed by fragmentation of the trans-Golgi reticulum during cell homogenization.

The likelihood that GSVs arise by fragmentation of tubular endosomes or of Golgi stacks is further reduced by the observation that GLUT4-containing vesicles with the same sedimentation properties as GSVs are detected in the homogenates of multiple cell types (Herman et al., 1994), and when different homogenization conditions are used (Bonzelius, F., and G.A. Herman, unpublished observations). Furthermore, GSVs can also be generated in vitro from precursor membranes under conditions in which no shearing forces are applied (Scully, R.M., and G.A. Herman, unpublished observations).

Antibody binding to surface GLUT4 did not appear to significantly perturb its intracellular targeting since the distribution of surface-labeled GLUT4 seen on gradients was identical to that observed for GLUT4 by Western blotting. Kinetic and temperature studies (Fig. 2B versus Fig. 3, D and A) suggest that GLUT4 internalized from the cell surface traffics initially through the 15°C compartment before being targeted to the GSVs, i.e., that the GSVs may be formed from an endosomal precursor.

This study demonstrates that GLUT4 is sorted from the TIR during its endocytic processing. The currently favored model for membrane trafficking proposes that internalized membrane proteins enter a common early endosome and are then sorted to pathways leading to other cellular compartments such as the plasma membrane, the lysosome, the trans-Golgi network, and to storage vesicles such as synaptic vesicles. In this study, however, GLUT4 is shown by confocal immunofluorescence microscopy to accumulate in peripheral endocytic compartments distinct from those containing the TIR, at both 15°C and 37°C (Fig. 5). To explain this result according to the above model, in which GLUT4 and TIR are sorted from one another at a common early endosome, it is necessary to hypothesize that the TIR traffics through the peripheral endosomes labeled by GLUT4 at 15°C at a rapid rate and at low receptor number, precluding detectable accumulation of transferrin ligand. Alternatively, the data are consistent with a model whereby most of the sorting of GLUT4 from TIR occurs at the level of the plasma membrane.

Recent work by Schmidt et al. (1997) is also consistent with a model in which some sorting of recycling membrane proteins occurs at the level of the plasma membrane. The synaptic vesicle protein, synaptophysin, is shown in PC12 cells to be segregated from the TIR at the level of the plasma membrane, both at 18°C and 37°C, with internalization of biotinylated synaptophysin into peripheral compartments distinct from those containing the TIR. These data and ours suggest that the conventional model of a single endosome generated by fusion of vesicles derived from the plasma membrane may need to be refined to one in which endosomes of different composition that subserve different functions can be generated in parallel fashion from the plasma membrane.

Also consistent with our results are studies in neuroendocrine cells and neurons that demonstrate the existence of separate populations of early endosomes based on the topographical separation of internalized ligands to differ-
ent regions of the cells (Parton et al., 1992; Mundigl et al., 1993; Bonzelius et al., 1994). Endocytic trafficking in neuroendocrine cells has also previously been shown to display temperature sensitivity that resembles that reported here for GLUT4 in CHO cells. The formation of synaptic vesicles from an endosomal precursor is inhibited at 15°C in undifferentiated PC12 cells (Desnos et al., 1995). Similarly, we observed that formation of GSVs as well as the exit of GLUT4 from peripheral endosomes was inhibited at 15°C. Thus, the endocytic trafficking pathway described here for GLUT4 has characteristics similar to pathways for synaptic membrane proteins in neuroendocrine cells: segregation from transferrin, temperature sensitivity, and sorting to homogeneously sized vesicles.

Wilson and Colton (1997) recently described evidence in fibroblasts for an early endosomal compartment that has characteristics of an apical or axonal endosomal compartment and that largely excludes transferrin. Data from Yoshimori et al. (1996) suggest that apical and basolateral transport routes to the plasma membrane along the biosynthetic pathway also exist in CHO cells. Recent work also suggests that fibroblasts are capable of some level of regulated exocytosis (Kanai et al., 1993; Morimoto et al., 1995; Chavez et al., 1996; Coorssen et al., 1996; Ninomiya et al., 1996). Collectively, these recent data suggest that specialized membrane trafficking pathways may arise by adaptation and differentiation of preexisting pathways found in all cell types.

What would be the function of multiple populations of early endosomes and of postendocytic organelles such as the GSV in CHO cells? The function may be to provide a reserve pool of selected plasma membrane proteins that can be rapidly mobilized to the cell surface in the appropriate physiological context thereby controlling the cellular distribution of some plasma membrane proteins independently of others. Such regulation may be as important in undifferentiated cells as it is in such cell types as fat and muscle cells. Validation or disproof of this concept may require characterizing the protein composition of GSVs, identifying the cellular compartment with which they fuse, determining if fusion mechanisms are regulated, and comparing GSV biogenesis with that of storage vesicles in fat and muscle cells.

We thank Drs. K. Mostov, V. Faundez, J. Roos, J.-T. Horng, (all UCSF) L. Nagy (Case Western Reserve, Cleveland, OH), and S. Marullo (Hôpital Cochin, Paris, France) for critical reading of the manuscript, and L. Specor (UCSF) for excellent administrative support. We thank Drs. Y. Ebina and H. Hayashi (University of Tokushima, Japan) for their generous gift of the CHO cell lines transfected with the myc epitope–tagged GLUT4.
