ABSTRACT

We explain the axisymmetric gaps seen in recent long-baseline observations of the HL Tau protoplanetary disc with the Atacama Large Millimetre/Submillimetre Array (ALMA) as being due to the different response of gas and dust to embedded planets in protoplanetary discs. We perform global, three-dimensional dusty smoothed particle hydrodynamics calculations of multiple planets embedded in dust/gas discs which successfully reproduce most of the structures seen in the ALMA image. We find a best match to the observations using three embedded planets with masses of 0.2, 0.27 and 0.55 M⊙ in the three main gaps observed by ALMA, though there remain uncertainties in the exact planet masses from the disc model.

Key words: planet-disc interactions – protoplanetary discs – dust, extinction – submillimetre: planetary systems.

1 INTRODUCTION

Recent long-baseline observations of the HL Tau protoplanetary disc at mm to cm wavelengths using the Atacama Large Millimetre/Submillimetre Array (ALMA) revealed a striking series of concentric, axisymmetric gaps, thought to indicate the presence of massive protoplanetary bodies caught in the act of forming planets (ALMA Partnership 2015).

While gap carving by planets embedded in discs has been predicted theoretically since at least Lin & Papaloizou (1986), the axisymmetry of the rings in HL Tau is puzzling. First, prominent spiral waves induced by the planet are seen in all theoretical simulations of planets carving gaps in gas discs whenever the planet is massive enough to open a gap (e.g. de Val-Borro et al. 2006). Secondly, prior observational estimates of the relative disc mass in HL Tau suggested a disc of 0.03–0.14 M⊙ around a 0.5–1.3 M⊙ star (e.g. Robitaille et al. 2007; Kwon, Looney & Mundy 2011; Kwon et al. 2015; the latter authors estimated ≲0.1 M⊙ based on fitting disc models to the previous best observations at mm wavelengths). Massive discs should almost certainly show gravitationally instability and hence prominent and large-scale spiral arms (e.g. Lodato & Rice 2004), as seen in the theoretical predictions for HL Tau made by Greaves et al. (2008). Thirdly, HL Tau is in an early phase of star formation (Class I evolving to Class II), emitting a 100–200 km s⁻¹ highly collimated jet (Mundt et al. 1990). The ongoing accretion from the envelope means that the disc is likely relatively thick, massive and hot, yet the clarity of the gaps are more reminiscent of those found in simulations of thin, cold discs (e.g. our most successful attempt to reproduce the gaps in gas-only discs required H/R ≲ 0.02).

This begs the question of whether the gaps seen in HL Tau are genuine signatures of planet formation, or due to some other phenomena such as clumping (Lyra & Kuchner 2013), magnetic or Rossby-wave instabilities (Pinilla et al. 2012) or condensation fronts (Zhang, Blake & Bergin 2015). Then again, the observation that the first four dark rings are located close to what would be resonances between planets orbiting in those locations, together with slight eccentricity observed in the rings are evidence in favour of carving by planets (Wolf et al. 2002; ALMA Partnership 2015).

Key is that the emission seen at the wavelengths observed by ALMA is from dust rather than gas. Dust grains settle and migrate in protoplanetary discs at a rate determined by the Stokes number, Sₜ, the ratio of the stopping time to the orbital time-scale (Weidenschilling 1977; Takeuchi & Lin 2002) with the stopping time depending on the grain size and gas density (equation 1). If mm-grains have settled to the mid-plane in HL Tau then the gap-carving seen by ALMA could be that induced in the thin dust disc rather than the relatively thicker gas disc, since it is easier to carve gaps in the dust (Paardekooper & Mellema 2004). The absence of spiral structure may also be explained by the dust. Simulations of dust grains near gaps carved by planets (Paardekooper & Mellema 2004, 2006; Maddison, Fouchet & Gonzalez 2007; Fouchet et al. 2007; Fouchet, Gonzalez & Maddison 2010; Ayliffe et al. 2012) have demonstrated that dust grains close to Sₜ = 1 form axisymmetric rings, with smaller dust grains more closely following the gas and larger grains trapped in resonances (Ayliffe et al. 2012).

Whether embedded planets in dusty gas discs can explain the axisymmetric gaps in HL Tau is the focus of this Letter.

2 METHODS

2.1 Dust/gas simulations

We perform 3D global simulations of dust/gas discs with embedded protoplanets using the PHANTOM smoothed particle hydrodynamics (SPH) code written by DP (Lodato & Price 2010; Price & Federrath 2010; Price 2012; Nixon, King & Price 2013).

We assume a single grain size per calculation. For grains of mm-size and larger we employ the two-fluid algorithm described in Laibe & Price (2012a,b). For calculations with smaller grains we employ our new single-fluid algorithm based on the terminal velocity approximation (Laibe & Price 2014; Price & Laibe 2015). This algorithm has been extensively benchmarked on simple test problems including waves and shocks in dust/gas mixtures (Laibe & Price 2011, 2012a; Price & Laibe 2015), but this is our first application to planet formation, allowing us to evolve both small and large grains efficiently.

2.1.1 Drag prescription

We assume a physical drag prescription where the drag regime is chosen automatically depending on the ratio of the grain size to the gas mean free path (Kwok 1975; Paardekooper & Mellema 2006; Laibe & Price 2012b). All of the grain sizes used in this Letter fall into the Epstein regime, meaning that the stopping time is given by

\[ t_s = \frac{\rho_{\text{grain}} s_{\text{grain}}}{\rho_c f s} \sqrt{\frac{\pi \gamma}{8}}, \]

where \( \rho_{\text{grain}} \) is the intrinsic grain density (we assume 1 g cm\(^{-3}\)), \( s_{\text{grain}} \) is the grain size, \( \rho = \rho_g + \rho_d \) is the total density of the mixture, \( c_s \) is the sound speed, \( \gamma = 1 \) is the adiabatic index and \( f \) is a correction factor for supersonic drag given by (Kwok 1975)

\[ f = \sqrt{1 + \frac{9\pi}{128} \frac{\Delta v^2}{c_s^2}}. \]

where \( \Delta v = |v_d - v_g| \) is the drift velocity between the dust and gas. Hence, the Stokes number \( S_t \equiv t_s \Omega \) in the mid-plane is

\[ S_t = 1 \left( \frac{\Sigma}{0.2 \text{ g cm}^{-2}} \right)^{-1} \left( \frac{\rho_{\text{grain}}}{3 \text{ g cm}^{-3}} \right) \left( \frac{s_{\text{grain}}}{1 \text{ mm}} \right) \left( \frac{f}{1} \right)^{-1}. \]

A caveat to the above drag prescription is that it assumes spherical grains. Fractal grain shapes or similar would change the effective Stokes number associated with a particular grain size.

2.1.2 Sink particles

We place three planets, initially located at 13.2, 32.3 and 68.8 au, in the three main gaps observed in HL Tau (ALMA Partnership 2015). We represent the protoplanetary bodies and the central star using sink particles (Bate, Bonnell & Price 1995) with accretion radii of 0.25, 0.25 and 0.75 au, respectively. Dust and gas can be accreted on to the sinks provided that the material is bound to the sink and the velocity divergence is negative. The planets are free to migrate due to planet–disc interactions and the viscous disc evolution. We found migration to be negligible on the time-scales simulated.

![Figure 1. Constraint on the disc scaleheight profile obtained from the gap widths observed in the ALMA image (upper limits; blue points) combined with the lower limit obtained from the dust temperature as a function of radius (red points) along with our best fit \( T \propto R^{-0.7} \) (dashed line).](http://mnrasl.oxfordjournals.org/)

2.2 Initial conditions

2.2.1 Gas

We set up the discs in PHANTOM using the standard procedure outlined in Lodato & Price (2010). The system comprises a central star with mass 1.3M\(_{\odot}\) surrounded by a gaseous disc of 10\(^6\) SPH particles which extends from \( R_{\text{in}} = 1 \) to \( R_{\text{out}} = 120 \) au. We assume a power-law surface density profile given by \( \Sigma(R) = \Sigma_0 (R/R_{\text{in}})^{-q} \), where \( \Sigma_0 \) is the surface density at the inner edge. We assume a radially isothermal equation of state \( P = c_s^2(R) \rho \), where \( c_s = c_{s,\text{in}} (R/R_{\text{in}})^{-q} \), such that the gas temperature power law is \( T(R) \propto (R/R_{\text{in}})^{-q} \). We set the SPH \( \alpha_{\Sigma} \) viscosity parameter to 0.1 giving an effective Shakura & Sunyaev (1973) viscosity \( \alpha_{\Sigma,\text{eff}} \approx 0.005 \).

2.2.2 Constraining the disc model from HL Tau

While Kwon et al. (2011) fit various disc profiles to their previous low-resolution observations of HL Tau to constrain the surface density and temperature profiles, we use the gaps observed in the disc (ALMA Partnership 2015) to directly constrain the aspect ratio.

In particular, while the gap is deeper in the dust (Fouchet et al. 2012), the width is the same. Since a gap cannot be opened with a width less than the disc scaleheight the three prominent gaps observed in HL Tau provide an upper limit on \( H \) as a function of radius. Combining this with the dust temperature profile observed by ALMA, which, assuming that the dust and gas are thermally coupled, provides a lower limit on the gas temperature, we can directly constrain the sound speed profile. Fig. 1 shows the constraint provided by the gap widths together with the lower limit and our best-fitting power law \( q = 0.35 \) (\( T \propto R^{-0.7} \)) with \( (H/R)_{\text{in}} = 0.04 \). This gives \( (H/R)_{\text{out}} \approx 0.08 \).

We choose a shallow surface density profile \( q = 0.1 \) for computational efficiency since it avoids expensive computation of many particles on the shortest orbits. This reproduces the inner disc in our simulations, but gives an outer disc that is overuminous compared to the inner disc in the simulated observations (Fig. 4). While more work is needed on the disc model, our main aim in this Letter is to reproduce the axisymmetry and size of the gaps.
2.2.3 Gas disc mass and dust-to-gas ratio

Hayashi, Ohashi & Miyama (1993) found an H₂ gas mass of 0.03 M☉ contained within 1400 au in HL Tau based on the observed ¹³CO emission. We assume this as our starting point, noting the mass contained with a particular radius depends on the density profile according to

\[ M(< R) = \frac{2\pi}{2 - p} \sum_{n=0}^{\infty} R_n^2 \left[ \left( \frac{R}{R_n} \right)^{2-p} - 1 \right]. \]

(4)

We assume the dust was initially colocated with the gas but has migrated to a radius \( \approx 10 \) times smaller than the initial radius to give the 120 au dust disc visible with ALMA. Assuming an initial dust-to-gas ratio of 0.01 in the undifferentiated material at 1400 au, this gives \( \Sigma_{\text{gas}} \approx \Sigma_{\text{dust}} \) within the smaller radius given our assumed \( p \) index of 0.1. Hence, we assume a dust-to-gas ratio of unity within 120 au and set \( \Sigma_{\text{in}} \) such that \( M_{\text{disc}} = 0.03 M_\odot \) at 1400 au. The total gas mass within 120 au is thus 0.0002 M☉, but this is low mainly due to our assumed shallow surface density profile.

A steeper surface density profile, e.g. \( p = 1 \) would give a more realistic gas mass of 0.003 M☉. While even this may seem in conflict with earlier fits to much higher disc masses (e.g. Robitaille et al. 2007; Kwon et al. 2011, 2015), these assume that the dust is colocated with the gas, whereas we expect settling and radial inward migration to produce a more compact dust disc, consistent with observations in other systems (Andrews et al. 2012; de Gregorio-Monsalvo et al. 2013). Moreover, Tamayo et al. (2015) found that such a massive gas disc within 120 au would smear out the eccentric features observed in HL Tau since the precession periods of peri-centres would be faster than the time-scale on which planets carve gaps. Our lower disc mass also ensures that the mm grains are close to \( S_t = 1 \) in order to guarantee an efficient migration towards the pressure maxima in the disc induced by the embedded protoplanets. Again, a steeper surface density profile would produce less coupling of the mm grains in the outer disc, giving dynamics similar to those we find with cm grains. Indeed, as we shall see, the spiral waves induced in larger grains by the outer planet do appear to be visible at mm wavelengths in HL Tau.

2.2.4 Dust

The dust disc is setup assuming an initially constant dust-to-gas ratio (equal to unity, see above). Since we simulate one grain size at a time we assume a power-law grain size distribution given by

\[ n(s) \propto s^{-m} \text{ for } s_{\text{min}} < s < s_{\text{max}}, \]

(5)

where we assume \( s_{\text{min}} = 1 \) μm, \( s_{\text{max}} = 10 \) cm and \( m = 3.5 \) and perform six different simulations using \( s = 1 \) μm, \( 10 \) μm, \( 100 \) μm, \( 1 \) mm, \( 1 \) cm and \( 10 \) cm, respectively (Fig. 3). The grain size distribution is appropriate to interstellar dust and particles growing by agglomeration in protoplanetary discs (Draine 2006). While approximate, this is more realistic than assuming a constant dust-to-gas ratio for each grain size, capturing the main idea that small grains are more abundant than large grains.

In our two-fluid simulations we set up the dust disc as a separate set of dust particles. We use one quarter of the number of dust particles compared to gas to prevent dust from becoming artificially trapped below the gas resolution (Ayille et al. 2012; Laibe & Price 2012b). For the calculations employing the single fluid algorithm (Price & Laibe 2015) there is only one set of particles describing the mixture, set up as described above for the gas but with a dust fraction \( \epsilon \) set for each particle to provide an initially constant dust-to-gas ratio (i.e. \( \epsilon = \rho_d/\rho_g/[1 + \rho_d/\rho_g] \)). With both methods the dust is then free to settle and migrate in the disc, and feels gravity from both the central star and the embedded protoplanets.

2.3 Simulated ALMA observations

We perform simulated observations of our model using the RADMC-3D Monte Carlo radiative transfer code (Dullemond 2012) together with the Common Astronomy Software Application (CASA) ALMA simulator (version 4.1), focusing on ALMA band 6 (continuum emission at 253 GHz). The source is located in the position of HL Tau, adopting the disc inclination and position angle given by ALMA Partnership (2015). The procedure is as in Dipierro et al. (2015) except that the dust distribution is used directly from our simulation data rather than being prescribed. The dust model consists of spherical silicate grains with optical constant for magnesium–iron grains taken from the Jena data base.¹ Full-resolution images produced by RADMC-3D simulations are used as input sky models to simulate realistic ALMA observations accounting for thermal noise from the receivers and the atmosphere and assuming a perfect calibration of the visibility measurements. A transit duration of 8 h is used to reach an optimal signal-to-noise ratio. The observation parameters are chosen to match the spatial resolution of the observations (see caption of Fig. 4).

3 RESULTS

Fig. 2 shows the gas surface density, while Fig. 3 shows rendered images of the dust surface density from the disc model with three embedded protoplanets of mass 0.2, 0.27 and 0.55 M☉ initially located at the same distance as the gaps detected in HL Tau, at 13.2, 32.3 and 68.8 au.

¹ http://www.astro.uni-jena.de/Laboratory/Database/databases.html

Figure 2. Rendered image of dust surface density for a disc containing three embedded protoplanets of mass 0.2, 0.27 and 0.55 M☉ initially located at the same distance as the gaps detected in HL Tau, at 13.2, 32.3 and 68.8 au.
the grain size (e.g. Fouchet et al. 2007; Ayliffe et al. 2012), or more specifically on the Stokes number. The density distribution of μm-sized particles (top left and centre) are similar to the gas distribution due to the stronger coupling. The micron-sized grains (top left) capture the spiral density wave launched by the protoplanets. Millimetre-sized particles (bottom left) are most affected by the density waves induced by the protoplanets, exhibiting the largest migration towards the gap edges. Interestingly, the dust density distributions of 10 mm and cm-sized particles (bottom centre and right) show axisymmetric waves launched by the planets propagating across the whole disc. The gaps carved by protoplanets in cm grains ($S_t \approx 10$) show the formation of horseshoe regions. As expected, the formation of the horseshoe region in planetary gaps depends on the dust–gas coupling, since poorly coupled large particles tend to have frequent close encounters with the planet. We stress that the important parameter is the Stokes number rather than the actual grain size, so equivalent dynamics can be produced in different grains by changing the gas density or with different assumptions about the grain composition (see equation 3).

An intriguing possibility is to infer the disc viscosity from the morphology of the gaps. Since our results show that the planets are not massive enough to open gaps in the gas or, equivalently, the viscosity is high enough to effectively smooth the density profile, we can only evaluate a lower limit for $\alpha_{\text{SS}}$ below which planets are able to carve gaps in the disc model adopted here. Using the criterion in Crida, Morbidelli & Masset (2006) we infer $\alpha_{\text{SS}} \gtrsim 0.0002$.

Fig. 4 compares the ALMA simulated observation of our disc model at band 6 (right) with the publicly released image of HL Tau.

(iii) We can reproduce all the major features of HL Tau observations with three embedded planets at 13.2, 32.3 and 68.8 au with planet masses of 0.2, 0.27 and 0.55 \( M_J \), respectively, though there is uncertainty in the exact masses from the assumed disc model. This supports the conclusion that embedded protoplanets are responsible. Our masses are similar to the 0.2 \( M_J \) suggested for all three planets in Dong, Zhu & Whitney (2014) and consistent with a 10 \( M_J \) upper limit for the third planet given by Testi et al. (2015).

(ii) In agreement with previous authors, we find it is easier to carve gaps in dust than in gas. Hence gaps observed in the continuum at mm-wavelengths do not necessarily indicate gaps in gas.

(iii) We can reproduce all the major features of HL Tau observations with three embedded planets at 13.2, 32.3 and 68.8 au with planet masses of 0.2, 0.27 and 0.55 \( M_J \), respectively, though there is uncertainty in the exact masses from the assumed disc model. This supports the conclusion that embedded protoplanets are responsible. Our masses are similar to the 0.2 \( M_J \) suggested for all three planets in Dong, Zhu & Whitney (2014) and consistent with a 10 \( M_J \) upper limit for the third planet given by Testi et al. (2015).

(iv) The dust density structures for grains with \( S_\lambda \gtrsim 10 \) (cm-
size and larger in our simulations; bottom centre and right-hand panels of Fig. 3) show axisymmetric features that can be identified as waves excited by the embedded protoplanets (Goldreich & Tremaine 1980). These waves can freely propagate across the dusty disc without being damped by dissipative phenomena (Rafikov 2002). The lower drag makes these waves more visible since the drag effect on the radial dust motion is negligible. We therefore suggest that the axisymmetric perturbations in the ALMA images in the outer part of the second and third planet orbits are generated by the lower coupling of mm-particles. Further simulations with a steeper surface density profile should be able to reproduce this.

There are many caveats to our results, and these are preliminary investigations. Nevertheless they illustrate that the ALMA observations of HL Tau can be understood from the interaction between dust, gas and planets in the disc.

ACKNOWLEDGEMENTS
