Localization of Wannier functions for entangled energy bands

U. Birkenheuer and D. Izotov
Max-Planck-Institut für Physik komplexer Systeme, Nöthnitzer Str. 38, 01187 Dresden, Germany

A new method for the localization of crystalline orbitals for entangled energy bands is proposed. It is an extension of the Wannier-Boys algorithm [C.M. Zicovich-Wilson, R. Dovesi, and V.R. Saunders, J. Chem. Phys. 115, 9708 (2001)] which is particularly well-suited for linear combination of atomic orbital representations of the Bloch waves. It allows the inclusion of additional bands during the optimization of the unitary hybridization matrix used in the multi-band Wannier transformation. By a projection technique, the proper chemical character is extracted from the Bloch waves and compact localized orbitals are obtained even for entangled bands. The performance of the new projective Wannier-Boys localization is demonstrated on the low-lying unoccupied bands of trans-polyacetylene, diamond and silicon.

I. INTRODUCTION

Localization of Wannier functions (WF) has attracted great attention of scientists in the recent years. Despite the success of describing most of the physical phenomena in crystals in terms of Bloch waves (BW), Wannier functions have obvious advantages. To mention a few: WFs provide a chemically intuitive picture of the electronic structure in crystals, using localized WFs, physical quantities such as effective Born charges and spontaneous polarization can be evaluated in a very simple way, and they play a central role in many post Hartree-Fock electron correlation methods. Several rigorous schemes for the localization of WFs have been proposed so far. They fall into two categories, those which are based on the variational principle and those which are an extension of the Foster-Boys localization criterion for periodic systems. All these methods can only be applied to isolated band complexes, i.e. a group of bands which are separated from the other bands by an energy gap over the entire Brillouin zone. This restriction appreciably confines the possible applications of those methods and only a limited number of systems can be treated. In particular, the energy bands of the unoccupied Bloch waves usually do not exhibit any such band gaps. Thus, none of the localization schemes developed so far can be applied routinely to selectively generate virtual Wannier functions as needed, for instances, in our wave-function-based post Hartree-Fock correlation methods for valence and conduction bands.

Recently, Souza et al. have extended the original Marzari-Vanderbilt localization scheme to systems with entangled bands. The method is based on a pre-selection of optimal Bloch waves having maximal similarity at neighboring \( k \)-points by minimizing a suitable functional. Like the original scheme, the new method is especially designed for a plane wave representation of the BWs and heavily relies on numerical \( k \)-space differentiation.

In this paper, we propose a similar extension for the Wannier-Boys localization scheme developed by Zicovich-Wilson, Dovesi and Saunders. This scheme differs in many aspects from the algorithm proposed by Marzari et al. In particular, it is much better suited for BWs given in a linear combination of atomic-like orbital (LCAO) representation as employed in many widely used program packages for periodic systems such as CRYSTAL, GAUSSIAN, DMOL, NFP-LMTO or BAND (the periodic variant of ADPs).

In Sec. II the details of our algorithm are described. Then, in Sec. III the results from the localization are presented for trans-polyacetylene (tPA), diamond and silicon, and some concluding remarks are drawn in Sec. IV.

II. THE LOCALIZATION PROCEDURE

The new projective Wannier-Boys scheme we want to present here sets out from the original Wannier-Boys (WB) localization procedure which is discussed in detail in Ref. 16. Like all localization schemes for composite bands, it relies on the initial specification of a fixed set of energy bands. These bands determine the space of the Bloch functions which are allowed to participate in the multi-band Wannier transformation, the so-called active space. For example, the valence bands of a system can be chosen as such a set of bands. The WB algorithm is a combination of two steps: the so-called ‘wannierization’ and a Foster-Boys localization of the obtained WFs within the reference unit cell. Recently, the algorithm has been extended to operate with a multi-cell Foster-Boys localization to better preserve the space group symmetry of the system under consideration.

The wannierization step starts from a set of trial Wannier functions \( \omega_{s}^{(0)}(r) \) which are linear combinations of atomic-like orbitals

\[
\omega_{s}^{(0)}(r) = \sum_{\mu,R} c_{\mu s}^{R} \phi_{\mu}(r - s_{\mu} + R),
\]

We follow the notation from Ref. 14 here. Thus, \( \mu \) runs over all atomic basis functions \( \phi_{\mu}(r - s_{\mu}) \) in the reference unit cell, \( s_{\mu} \) denotes their centers, and \( R \) runs over...
all lattice vectors of the underlying Bravais lattice. To reduce the spacial extent of each of these WFs, the orbital coefficients $c_{s}^{R}$ are set to zero for all sites $s$ at which the atomic Mulliken populations of the given Wannier function falls below a certain threshold (for details see Ref. [16]). The WFs obtained this way, the so-called 'model functions' are transformed to $k$-space, projected onto the active space spanned by the selected BWs, orthonormalized again, transformed back to real space, and moved back into the reference unit cell (if necessary). The resulting (real) WFs, $\omega_{s}^{(1)}$, then enter the Foster-Boys step, where they are subject to an orthogonal transformation

$$\omega_{s}^{(1)} = \sum_{t=1}^{N} \omega_{t}^{(1)} O_{ts}$$

that minimizes the spread $\Omega(\{\omega_{s}^{(1)}\})$ given by the functional

$$\Omega(\{\omega_{s}\}) = \sum_{s=1}^{N} \left( \sum_{t=1}^{N} (\omega_{s}|r^{2}|\omega_{s}) - (\omega_{s}|r|\omega_{s})^{2} \right).$$

Here, $N$ is the number of energy bands involved in the localization. Finally, the optimized functions $\omega_{s}^{(1)}$ are used as new (orthonormal) trial functions for the wannierization and the whole procedure is repeated until convergence is reached. The discarding of orbital coefficients and the subsequent projection onto the active space is the crucial part of the WB algorithm. It is combined with a Foster-Boys localization to ensure localization of the WFs also inside the unit cells.

The described algorithm performs well for isolated band complexes. In the case of entangled bands, however, the selection of proper bands to set up a suitable active space becomes problematic. Avoided and symmetry allowed crossings between the energy bands in mind and other, disturbing energy bands occur, and the orbital character one is looking for is spread over several BWs which in turn exhibit more or less strong admixtures from other, contaminating orbitals. To overcome this difficulties give up the concept of an rigid active space, abandon the constraint that the number of selected Bloch waves per $k$-point has to coincide with the number $N$ of Wannier functions per unit cell, and allow additional BWs to be included in the active space at each $k$-point.

The selection of an appropriate $N$-dimensional active subspace is then done in the projection step during the wannierization. To this end the 'model Bloch waves' $\xi_{sk}(r)$, which are the $k$-space transformed of the model functions $\xi_{s}(r)$, are projected onto the active space via

$$\xi_{sk}^{\prime} = \sum_{n=1}^{N_{k}} \psi_{nk}^{\dagger} \psi_{nk} \xi_{sk}$$

for $s = 1, \ldots, N$ with the number $N_{k}$ of selected BWs $\psi_{nk}$ at each $k$-point being at least as large as the number of WFs per unit cell. The matrices $U_{nk}(k) = \langle \psi_{nk}|\xi_{sk} \rangle$ showing up here establish a generalization of the unitary hybridization matrices used in conventional multi-band Wannier transformations. The new projected functions $\xi_{sk}^{\prime}$ are those functions in the active space which resemble the initial Bloch waves $\xi_{sk}$ most. They span the $N$-dimensional subspace used in the subsequent multi-band Wannier transformation. In this sense, the procedure outlined here is very similar to the one proposed by Souza et al. In particular, our extended projection step during the wannierization can be regarded as an analog to the band preselection scheme used in their method.

As for any hybrid orbitals, the orbital energies

$$\varepsilon_{sk} = \langle \xi_{sk}^{\prime}|F|\xi_{sk}^{\prime}\rangle$$

of the projected model Bloch waves have little in common with the canonical band energies $\varepsilon_{sk}$ they originate from. Yet, by diagonalizing the subblock

$$F_{st}(k) = \langle \xi_{sk}^{\prime}|F|\xi_{tk}^{\prime}\rangle$$

of the Fock operator $F$ of the system, $N$ new, so-called disentangled energy bands $\varepsilon_{sk}$ can be obtained. Where the contamination of the canonical BWs with orbitals of wrong character is small, the disentangled bands will essentially coincide with the canonical ones. Close to band crossings, where the contamination is larger, they will deviate substantially from the canonical bands in order to be able to follow the chemical nature of the underlying BWs. By this the disentangled bands form an effectively isolated complex of $N$ bands with none of them showing any kinks and cones (see Sec. III for more details). The eigenvectors resulting from the diagonalization of $F_{st}(k)$ can be regarded as sort of optimal Bloch wave hybrids with minimal orbital contamination and vanishing off-diagonal terms in the Fock operator. We will refer to these hybrids as disentangled Bloch waves.

The canonical Bloch waves $\psi_{nk}$, to be included in the active space, can be selected in various ways, for example, by specifying an energy window and taking all BWs whose band energies $\varepsilon_{nk}$ fall into this window. Alternatively, a so-called 'energy tube' around a given pair of reference bands $(\underline{\varepsilon}, \overline{\varepsilon})$ may be used, i.e. all BWs with band energies

$$\varepsilon_{nk} \in [\varepsilon_{\underline{nk}} - \varepsilon_{\overline{\varepsilon}} \overline{\varepsilon}, \varepsilon_{\overline{\varepsilon}} + \underline{\varepsilon}]$$

are considered where $\underline{\varepsilon}$ and $\overline{\varepsilon}$ are some user-specified energy tolerances.

We have implemented the above projection and rediagonalization scheme as an extension to the original WB localization routine in the Crystal 200x code, a precursor of the most recent public version of the Crystal program package. Its ability to disentangle energy bands properly will be demonstrated in Sec. III where our method is applied to the virtual bands of trans-polyacetylene, diamond and silicon.
III. RESULTS AND DISCUSSION

All band structures shown here are calculated on the Hartree-Fock level of theory. The periodic \textit{ab initio} program package \textsc{Crystal} (version 200x)\cite{crystal} is used for that purpose. The localization of the WFs is performed \textit{a posteriori} with the WB algorithm\cite{wb} as implemented in \textsc{Crystal} 200x\cite{crystal} in conjunction with our extension for entangled bands which has been built into this version of \textsc{Crystal}.

In all cases, we focus on the first few, low-lying virtual bands of our systems. Because of the larger extent of the localized virtual Wannier functions compared to the occupied ones, the former WFs are quite sensitive to the number of \textit{k}-points in the Monkhorst-Pack grid.\cite{monkhorst} We chose the grids sufficiently fine to remove any ambiguities resulting from the discrete \textit{k}-space integration.

A. trans-Polyacetylene

\textit{Trans}-Polyacetylene (tPA), $-[\text{HC=CH}]_{\infty}-$, suits perfectly as illustrative example for band disentanglement, because, in the basis set employed here, it exhibits three low-lying entangled virtual bands which are separated from the rest of the unoccupied band structure (Fig. 1).

![FIG. 1: Virtual Hartree-Fock bands of \textit{trans}-polyacetylene in the energy range from 0 to 10 eV calculated with a cc-pVTZ basis set.\cite{cc-pvtz}](image1)

The computational parameter for tPA are taken from a recent study on the correlated valence and conduction bands of tPA.\cite{tdpa} That is, Dunning’s correlation-consistent polarized valence triple-\(\zeta\) basis sets (cc-pVTZ)\cite{cc-pvtz} for hydrogen and carbon (without \textit{f} functions) are used, the bond distances are $d$($C-C$) = 1.45 Å, $d$($C=\text{H}$) = 1.36 Å, and $d$($C-\text{H}$) = 1.09 Å, and the bond angles are $\angle(C-C=C) = 121.7^\circ$ and $\angle(C-\text{C-H}) = 118.2^\circ$. Two different geometries are considered, flat tPA (the experimental structure) and a distorted configuration with the hydrogens being bent out-of-plane by $20^\circ$ in such a way that the inversion symmetry of the polymer is preserved. The Brillouin zone is sampled by a uniform grid of 100 \textit{k}-points.

The first three virtual bands are selected for the disentanglement (Fig. 1). One is a $\pi^*$ band formed by C=C $\pi$ anti bonds, the other two are of $\sigma$ symmetry and describe C–H anti bonds (not C–C $\sigma$ anti bonds, as one might think at first glance). For the flat polymer the symmetry separation is perfect, for the distorted structure some mixture between $\sigma$ and $\pi$ bonds occurs. Nevertheless, the two types of BWs remain quite different in their orbital character which should facilitate the band disentanglement significantly. In this sense, our first system very much resembles the one chosen by Souza \textit{et al.}\cite{ttonp} They used copper which exhibits a $d$ band manifold which is entangled with a single $sp$ valence band.

Of course, for tPA one could localize the virtual Bloch waves by means of the original WB algorithm. But what we want to demonstrate here, is that it is also possible to localize the $\pi$ and $\sigma$ bands \textit{separately}. We first consider the flat tPA chain. In that case, the BWs come in two different symmetries and the disentanglement could simply be achieved by a proper labeling of the energy bands and the associated Bloch waves. Yet, such symmetry classifications are hard to implement in localization schemes for periodic systems, and thus usually not exploited. Our band disentanglement algorithm, however, is able to recognize the different symmetries and to separate the bands properly.

As an initial guess for the $\pi$-type WFs, anti-phase linear combinations of $2p_z$ atomic orbitals at neighboring carbon atoms are used. For the $\sigma$-type WFs, antibonding linear combinations of $2sp^2$ hybrid orbitals on carbon and $1s$ atomic orbitals on hydrogen are constructed. Because of this choice, the hybridization matrices $U_{ns}(\textit{k})$ become $3 \times 1$ and $3 \times 2$ matrices, respectively, with a maximum-rank subblock and all other entries being exactly zero, as is confirmed numerically.

![FIG. 2: Zoom into the first three virtual bands of \textit{trans}-polyacetylene along the $\Delta$ line (the endpoints of the plot correspond to 1/3 and 2/3 of the $\Gamma$X distance) for the flat (a) and the distorted (b) geometry of the polymer. Solid lines show the canonical bands, symbols represent the disentangled bands: one of $\pi^*$ character (•), two of $\sigma^*$ character (○).](image2)
As seen in the upper panel of Fig. 2 where the canonical band energies $\varepsilon_{nk}$ are compared to the disentangled band energies $\eta_{nk}$, our band disentanglement procedure is perfectly able to describe either the $\pi$ or the $\sigma$ orbitals alone. The crossing of the $\sigma$ bands on the left-hand side is an avoided one (because of the lack of any extra symmetry in the small point group of the $k$-points inside the Brillouin zone). The apparently extremely weak coupling of the two bands is due to ‘soft symmetry selection rules’. That means, the impact of the C-C bond length alternation in tPA on the C–H anti-bond dominated $\sigma^*$ bands is so small that they essentially behave as if there would exist an additional glide plane symmetry in the system (like in equidistant tPA). This concept is corroborated by a detailed analysis of the involved Bloch waves.

A more interesting situation for band disentanglement arises when the symmetry of the system is lowered by moving the hydrogen atoms out of plane. Now, the three energy bands avoid each other and the underlying Bloch waves carry both, $\pi$- and $\sigma$-type atomic orbital contributions. Using band disentanglement we are able to follow this contributions individually. Setting out from an initial guess for $\pi$-type WFs, a single smooth band can be generated starting at the third canonical band at the $\Gamma$ point, passing the avoided crossing in the middle of the Brillouin zone without any kinks and wiggles and ending at the lowest band at the $X$ point (see black dots in the Fig. 2b). The same holds for the two disentangled band of predominantly $\sigma$ character. When going from $\Gamma$ to $X$ they smoothly switch from the lower two bands to the upper two bands without being influenced by the complex structure of the canonical bands close to the multiple avoided crossing.

After having demonstrated that our projective Wannier-Boys scheme is able to separate energy bands appropriately, the effect of the disentanglement on the locality of the resulting Wannier functions should be addressed. For that purpose we turn our attention to the more complex case of bulk materials, diamond and silicon in our case.

B. Diamond

Because of the rather diffuse, atom-optimized basis functions present in the original carbon cc-pVTZ basis set of Dunning[32] (outermost $s$ and $p$ exponents of 0.1285 and 1.2093, respectively) it can not be used for a Hartree-Fock calculation of bulk diamond. Hence, the outermost exponents were reoptimized by minimizing the Hartree-Fock energy per unit cell of diamond. The resulting exponents are 0.2011 for the $s$ function and 0.6256, 0.3243 for the $p$ functions, typical values for diamond[32]. In addition the two $d$ functions of the triple-$\zeta$ basis set were replaced by the single one of the corresponding double-$\zeta$ basis set (with exponent 0.55)[32] and, as for tPA, the $f$ function had to be skipped because CRYSTAL cannot handle them. This basis set, referred to as bulk-optimized cc-pVTZ, has been used very successfully in our embedding studies of wave-function-based correlation calculations for diamond[33]. The experimental lattice constant of 3.57 Å is adopted which corresponds to an interatomic C-C distance of 1.546 Å, together with a $40 \times 40 \times 40$ Monkhorst-Pack grid.

Because the first four low-lying virtual bands of diamond are separated from the rest of the virtual bands by a small gap, it is possible to use the original WB algorithm to generate localized Wannier functions $\omega_\ast$. The energy bands obtained from the Wannier representation $F_{n\ell}(\mathbf{R}) = \langle \omega_\ast(\mathbf{r}) | F | \omega_\ast(\mathbf{r} - \mathbf{R}) \rangle$ of the Fock operator — or equivalently from $F_{n\ell}(\mathbf{k})$ as defined in Eq. 4 — exactly reproduces the canonical bands (see Fig. 3a). Nevertheless, the resulting localized Wannier functions possess rather substantial tails at the second nearest neighbor carbon atoms as seen in Fig. 3b. These tails can very well spoil the performance of any scheme which relies on the locality of virtual WFs (like the one having been used in Ref. [17]).

Extending the active space used in the WB algorithm opens the possibility for making the Wannier functions more compact. Switching to an energy window of $0 - 38$ eV the spread of the virtual Wannier function, as measured by the Foster-Boys functional [40], reduces by more than a factor of two (see table I) and the undesired orbital contributions at the second nearest neighbor carbon atoms disappear in the contour plot shown in Fig. 3b.
FIG. 4: Contour plots of the virtual Wannier function of diamond shown in the (110) plane of a C–C zig-zag chain as obtained by the original WB algorithm (a) or by band disentanglement with an energy window of \(0 - 38\) eV (b). The values of the contours are \(\pm 0.046, \pm 0.10\) and \(\pm 0.22\) bohr\(^{-3/2}\) (a geometrical progression with \(q = 10^{1/3}\)).

No shrinking of the virtual WF around the central bond is discernible in Fig. 4 compared to the WF obtained by the original WB localization. Apparently, the reduction in the spread is solely due to the fading of the tails in the localized Wannier function, precisely what we are aiming for.

The price to pay, is an overall upwards shift of the disentangled bands with respect to the canonical ones, more pronounced at the X point than at the \(\Gamma\) or L point, a phenomenon we also hit on for silicon in Sec. III C. It is a feature one often observes when Foster-Boys-like schemes are used to localize virtual orbitals. The localization functional \(\Omega\) tries to minimize the extent of the orbitals as much as possible, regardless of the chemical nature of the orbitals and, in particular, their orbital energies. But compactness of orbitals usually implies high kinetic energies. Thus, it can easily happen that the WFs pick up more and more kinetic energy during the iterative procedure of the projective WB localization algorithm as soon as the BWs spanning active space allow so. In practice, a compromise has to be found between tracing the proper orbital character in BWs energetically far away from the bands in mind and the risk of opening channels for spurious orbitals compression.

### C. Silicon

Silicon is the last and most interesting example which is discussed here, because local virtual Wannier functions can not be generated at all for silicon without band disentanglement.

The relativistic energy-consistent Ne-core pseudopotential from Stuttgart\(^{36}\) together with a decontracted [3s3p] version of the corresponding optimized valence double-\(\zeta\) basis set are used here. The basis set is augmented by a single \(d\) polarization function with an exponent of 0.4. The Si-Si distance is set to 2.352 Å which corresponds to a lattice constant of 5.432 Å. These computational parameters originate from the first pioneer study on a rigorous determination of the correlation energy of silicon by means of an incremental expansion\(^4\) and has successfully been used from that time on in all \(ab\) \(initio\) study of correlation effects in bulk silicon performed with the incremental scheme\(^{37,38}\) or its extension to valence and conduction bands. Like for diamond, a very dense \(40 \times 40 \times 40\) Monkhorst-Pack grid is used here to resolve the subtle details of the silicon conduction bands to be discussed below.

---

**TABLE I**: The spread \(\Omega\) (per orbital) of the virtual Wannier functions of diamond and silicon (in bohr\(^2\)) as a function of the energy window (in eV) used for the band disentanglement. For comparison, the scaled spreads \(\Omega/a^2\) with \(a\) being the lattice constant are given as well.

|          | diamond | silicon |
|----------|---------|---------|
| window   | \(\Omega\) | \(\Omega/a^2\) | window | \(\Omega\) | \(\Omega/a^2\) |
| none     | 10.10   | 0.792   | 0 - 15 | 33.03   | 1.120   |
| 0 - 38   | 4.94    | 0.388   | 0 - 31 | 15.45   | 0.524   |

---

FIG. 5: The fourth and fifth conduction band of silicon in the vicinity of the two symmetry-allowed crossings on the \(\Sigma\) line drawn as a 2-dimensional function in the \(\Gamma X \Gamma'\) plane. The canonical bands are shown as energy surfaces, the uppermost disentangled band (whose energies are only available on the Monkhorst-Pack grid) as dots. An energy window of \(0 - 15\) eV is used for the disentanglement.

The reasons why band disentanglement is absolutely crucial for silicon are the two symmetry-allowed crossings of a fourth and fifth conduction band on the \(\Sigma\) line from X over \(U = K\) to \(\Gamma'\) (the \(S + \Sigma\) line to be precise) which prevents a direct application of the WB algorithm (see Figs. 4 and 7). The localization simply fails because the active BWs exhibit symmetries different from the ones of the model Bloch waves \(\xi_{sk}\) and the projec-
tion step yields linear dependent projections $\xi'_s$. A $d$ band is involved, one might speculate, but closer inspection of the corresponding BWs reveals that the fifth conduction band is an $sp$ band, formed — in contrast to the other four conduction bands — by $s$ and $p$ orbitals of the next atomic shell following the $3s/3p$ valence shell, at least in the basis set employed here.

Sometimes it is argued that the band crossing problem discussed above can simply be solved by a proper relabeling of the energy bands. This is not the case. Energy bands of bulk materials are three-dimensional functions of the crystal momentum $k$ and the two critical bands exhibit an interesting topology around the symmetry allowed crossings. They only touch, twice, like the tips of two cones, as is clearly seen in Fig. 5 where the band energies are plotted as 2-dimensional energy surfaces over the $\Gamma X \Gamma'$ plane. The symmetry-allowed crossings are singularities. No band crossing occurs anywhere else in the neighborhood of these points. Nevertheless, the character of the associated Bloch waves still switches from one band to the other when passing from the left-hand to the right-hand side of the plot plane precisely as in conventional avoided crossings.

**FIG. 6:** Contour plots of the virtual Wannier function in silicon shown in the (110) plane of a Si–Si zig-zag chain as obtained from band disentanglement with an energy window of $0 - 15$ eV (a) or $0 - 31$ eV (b). The value of the contours are $\pm 0.022$, $\pm 0.046$ and $\pm 0.10$ bohr$^{-3/2}$ (see Fig. 4).

Band disentanglement is the only way around. Two different energy windows are considered, one being sort of minimal with the upper edge at 15 eV which is closely above the top of the fourth conduction band, the other being big enough to follow the BWs with proper $sp$ character up to the 12-th unoccupied band at $\Gamma' = \frac{2\pi}{a}(1, 1, 1)$. In both cases, the localization could be performed without any problems. As clearly seen in Fig. 6 the different symmetry of the fourth and fifth conduction band along the $\Sigma$ line is perfectly recognized by the band disentanglement algorithm — like for the flat tPA chain discussed in Sec. III A — and the uppermost disentangled energy band exclusively follows the flatter of the two canonical bands without any kinks. Leaving the high-symmetry line, the disentangled bands start to interpolate between the two canonical bands and form a smooth and well-behaved energy surface.

The resulting localized virtual WFs of silicon are depicted in Fig. 6. Compared to diamond which exhibits typical $sp^3$ hybrid character around the nuclei the virtual WF of silicon is more symmetric and $p$-like in the vicinity of the nuclei. The same holds for the maximally localized virtual WF of silicon shown in Ref. 19. Expectedly, the larger energy window yields the more compact WF, and like for diamond, the reduction in the spread is impressive, from 33 down to 15 bohr$^2$ (table I). Yet, all together, the virtual orbitals of silicon remain more diffuse than those of diamond even if the difference in the lattice constants is accounted for, as done by the scaled spreads listed in Table I. This is not surprising, because of the much smaller (direct) band gap of silicon (7.3 eV at $\Gamma$, experimentally$^{39}$) compared to diamond (3.4 eV$^{39}$).

**FIG. 7:** Virtual Hartree-Fock band structure of silicon (solid lines) and the energies of the disentangled bands (dots) using either a $0 - 15$ eV energy window (a) or a $0 - 31$ eV energy window (b) for the band disentanglement.

As already discussed above, the disentangled conduc-
tion bands have the tendency to shift upwards with increasing size of the energy window, a trend which is also found for silicon (Fig. 4). Therefore, a further increase of the energy window is not very helpful anymore, although even more compact virtual Wannier functions can be generated this way.

There exist a couple of further interesting features in the disentangled conduction bands of silicon. One is, that the second disentangled conduction band along the Σ line climbs up to the upper part of the avoided crossing in the middle of the Σ panel. Apparently, close to this crossing the contaminating 4s/4p orbital character is solely sitting on the energetically more stable second Bloch wave while the corresponding valence 3s/3p contributions form the fourth BW, an interpretation which is corroborated by a detailed analysis of the involved BWs.

The second point is the unexpected discontinuity in the uppermost disentangled band along the Σ line discernible in Fig. 4 for the 0 – 15 eV window. Its position coincides with the position of the avoided crossing between the sixth and eighth conduction band which shows up in the middle of the Σ panel between 15 and 18 eV. During the band disentanglement, the BWs from the upper part of this crossing are excluded from the active space while those of the lower part are present, and it seems that there is still a substantial part of the necessary orbital character present in this upper BWs to cause the abrupt change in the uppermost disentangled band. Obviously, the 3s/3p valence orbital character moves up much higher into the unoccupied band structure of silicon than one might expect at first glance.

This is the reason why we switched to the larger energy window of 0 – 31 eV, though a non-negligible upwards shift of the disentangled virtual bands arises. Nevertheless we consider the disentangled bands and Bloch orbitals from the enlarged energy window to be the more appropriate ones.

IV. CONCLUSIONS

An extension of the Wannier-Boys localization algorithm for periodic systems\textsuperscript{15,16} is developed which allows to generate localized Wannier functions in the case of entangled energy bands. The method has been implemented into the localization routine of the Crystal program package.\textsuperscript{46} Its main feature is the use of an enlarged set of active Bloch waves during the optimization of the unitary hybridization matrix for the multi-band Wannier transformation. This allows the inclusion of all Bloch waves which contain noticeable admixture from orbitals with the same chemical character as the localized Wannier functions one is looking for. The proper identification of these admixtures is done by a simple projection technique.

The efficiency of our projective Wannier-Boys algorithm is demonstrated for the virtual bands of three different systems, trans-polyacetylene, diamond and bulk silicon. Localized virtual Wannier functions could be generated in all three cases. The spatial extent of them is found to be controllable by the size of the active space, i.e., the number of selected Bloch waves per \( k \)-point. The more Bloch waves are considered, the more compact the localized Wannier functions become. Yet, at the same time, an increasing tendency for an overall upwards shift in the energies of the disentangled bands is observed.

The same trend is discernible in the Kohn-Sham energies of silicon discussed by Souza et al.\textsuperscript{8} though, because of the tight energy window employed there (up to \(~\)11 eV), the effect is not very pronounced. The spread of the maximally localized virtual Wannier function of silicon reported there is 30.13 bohr\(^2\) (based on a \( 10 \times 10 \times 10 \) Monkhorst-Pack grid) which is quite close to the value of 33.03 bohr\(^2\) we found for the 0 – 15 eV energy window.

The choice of the systems considered here was not accidental. Subsequent use of the localized Wannier functions in wave-function-based post Hartree-Fock correlation methods for periodic systems which explicitly exploit the local character of virtual Wannier functions was the driving force of this work, for example the method used in our study of the valence and conduction bands of trans-polyacetylene\textsuperscript{47} or in analogue investigations of the band structure of bulk materials like diamond.\textsuperscript{48} The more compact the Wannier functions are the better these local correlation methods perform.

V. ACKNOWLEDGEMENTS

We thank the Crystal group in Torino for making available to us the source code of the Crystal 200x code without which the present study would not have been possible.
