Abstract
We consider the iterative reconstruction of both the internal geometry and the values of an inhomogeneous acoustic refraction index through a piecewise constant approximation. In this context, we propose two enhancements intended to reduce the number of parameters used in reconstruction, while preserving accuracy. This is achieved through the use of geometrical information obtained from a previously developed defect localization method. The first enhancement consists of a preliminary selection of relevant parameters, while the second one is an adaptive refinement to enhance precision with a low number of parameters. Each of them is numerically illustrated.

Keywords: inverse scattering, index reconstruction, inhomogeneous media, defect localization, selective reconstruction, adaptive refinement

(Some figures may appear in colour only in the online journal)

1. Introduction

We are interested in the inverse medium problem consisting of the reconstruction of an inhomogeneous acoustic refraction index from far-field measurements generated through plane waves. This parameter identification problem is non-linear and ill posed, and we investigate two methods to reduce the number of computed parameters while preserving the
reconstruction accuracy. Applications are, for example, non-destructive structure testing or biomedical imaging [1–3].

Following the abundant literature, we write the inverse medium problem as a least-squares problem (see [4] and references therein). In addition, since we are considering discontinuous indices, we look for the index of refraction as a piecewise constant function. In this setting, for its ease of implementation and its efficiency for reasonably sized problems, we consider the Gauss–Newton method, applied to a cost functional involving a Tikhonov regularization [5]. The Gauss–Newton method treats all parameters in the same way. However, during the reconstruction, or even right from the beginning, the values of some parameters can be close to the exact value, while other parameters will need more iterations before reaching a given accuracy. In the absence of any local information, the accurate parameters are then pointless updated at each iteration. Thus, we explore two uses of geometrical information obtained through defect localization to focus the reconstruction and consequently lighten its numerical cost.

By defect localization we mean localizing the support of a perturbation with respect to some known reference. However, in this paper, it is the reconstructed index that we use as the known reference, and it is the exact index that we use as an unknown perturbed state. Thus, defect localization can be used to locate errors in the index reconstruction. In addition, it has recently been proven that the location of the defects in a given refraction index could be established from far-field measurements of the unknown state and computed through a fast numerical method [6, 7]. Shape reconstruction has also already been used jointly with parameter identification by applying the linear sampling method [8–11].

However, the factorization method approach, involved in [6] and [7], provides a more straightforward formulation as an equivalence that is defined at each point. So, we propose here to use this fast local information to reduce the computational effort in the complete refraction index reconstruction process.

More precisely, in this paper we are going to propose two hybridizations between Gauss–Newton and defect localization methods. We first consider the case where a known index has been locally modified. This could happen, for instance, from a local deterioration or a partially incorrect estimation of the actual index. In this case, a preliminary defect localization provides geometrical information that we can use to choose which parameters have to be reconstructed. Then, the reconstruction can be performed straightforwardly on a reduced computational domain. The goal of this strategy is to avoid the useless reconstruction of parameters for which we have a suitable initial guess. Second, we investigate adaptive refinement. Here, defect localization is used to exhibit inaccurate regions in the current reconstruction. This local information allows us to refine the reconstruction mesh in these regions and resume the reconstruction to get better precision while restraining the number of computed parameters. With this strategy, we aim to control the numerical effort by diminishing the number of discrete parameter values with respect to a uniform mesh of the whole parameter space.

This paper is structured as follows: In section 2, we specify the mathematical setting. We then introduce the direct problem in section 2.1, followed in section 2.2 by the description of the inverse medium problem we are interested in. The numerical method on which we will build our enhancements is then described in section 2.3. Afterwards, the defect localization and its applications are presented in section 3. We show how to reduce the reconstruction domain in section 3.1, and the adaptive refinement process is detailed in section 3.2. Finally, we numerically illustrate the sequence of both applications, and furthermore on a non-trivial example, in section 4. We end the paper with our concluding remarks in section 5.
2. Presentation of the problem

We start by introducing the direct problem and the inverse medium problem, followed by its numerical treatment.

2.1. The direct problem

We consider time-harmonic acoustic waves, with a fixed wave number $k$, modeled by the Helmholtz equation [12]. Inhomogeneous media are then represented by an acoustic refraction index, denoted by $n \in L^\infty(\mathbb{R}^d)$. So, the total field, denoted by $u \in L^2_{\text{loc}}(\mathbb{R}^d)$, is assumed to satisfy

$$\Delta u + k^2 n(x) u = 0, \quad x \in \mathbb{R}^d,$$

where $d$ is the problem’s dimension ($d = 2$ or $3$). We consider compactly supported inhomogeneities, and we denote by $D$ the support of $n$. We also denote by $u' \in L^2_{\text{loc}}(\mathbb{R}^d)$ an incoming wave satisfying (1) with $n(x) = 1$. The total field is then the sum of this incoming wave and the wave scattered by the inhomogeneous medium, denoted by $u^s \in L^2_{\text{loc}}(\mathbb{R}^d)$:

$$u = u' + u^s,$$

where the scattered wave is assumed to satisfy the Sommerfeld radiation condition

$$\partial_\nu u' = ik u' + O\left( |x|^{-d-1} \right).$$

Then, the linear system (1)-(3) defines $u \in L^2_{\text{loc}}(\mathbb{R}^d)$ uniquely from $u'$ [12, Chap. 8].

In addition, the outgoing part of a wave has an asymptotic behavior called the far-field pattern, denoted by $u^m \in C^\infty(\Gamma_m)$, and given by the Atkinson expansion [13, Theorem 6.11]

$$u_m(x) := u'(x) + \frac{e^{ik|x|}}{|x|^d} u^m(\bar{x}) + O\left( |x|^{\frac{d-1}{2}} \right), \quad \bar{x} := \frac{x}{|x|} \in \Gamma_m,$$

where $\Gamma_m$ denotes the set of measurement directions as a subset of the unit sphere $S^{d-1}$ (see figure 1), and where $\gamma$ only depends on the dimension and is defined by

[Figure 1. General setting and notations.]
Furthermore, for practical reasons, we will mainly consider scattered waves having a plane wave source. These plane waves are defined by
\[ u' (\vec{\theta}, x) := \exp(ik\vec{\theta} \cdot x), \]
where \( \vec{\theta} \) is a unitary vector in the set of incidence directions, denoted by \( \Gamma_i \) as shown in figure 1. We then denote the total field with a plane wave source of incoming direction \( \vec{\theta} \) by
\[ u_s (\vec{\theta}, x), \quad \vec{\theta} \in \Gamma_i, \quad x \in \mathbb{R}^d. \]
Lastly, the corresponding far-field pattern in the measurement direction \( \vec{x} \in \Gamma_m \) will be denoted by
\[ u^\infty_s (\vec{\theta}, \vec{x}), \quad \vec{\theta} \in \Gamma_i, \quad \vec{x} \in \Gamma_m. \]

2.2. The inverse medium problem
We are interested in the reconstruction, from far-field data, of an inhomogeneous refraction index that will be denoted by \( n^* \in L^\infty (D) \) throughout this paper. Note that all considered indices will be implicitly extended by 1 outside \( D \), the compact support of \( n^* - 1 \).

Most of the methods used to solve this reconstruction problem are valid for domains that are (subsets of) Hilbert spaces. Thus, we consider an index-to-far-field mapping \( \mathcal{F}: L^\infty (D) \to L^2 (\Gamma_i \times \Gamma_m) \) defined by
\[ \mathcal{F}(n) := u^\infty_s. \]
Data are generally perturbed by noise or measurement errors, so we assume that we only have access to \( u' \in L^2 (\Gamma_i \times \Gamma_m) \), the perturbed version of \( u^\infty_s \) satisfying
\[ \| u' - u^\infty_s \|_{L^2 (\Gamma_i \times \Gamma_m)} \leq \varepsilon \| u^\infty_s \|_{L^2 (\Gamma_i \times \Gamma_m)} \] (5)

The usual approach to this problem is then to find \( n \) by minimizing the difference between \( \mathcal{F}(n) \) and \( u' \). Thus, we define the data misfit by
\[ J (n) := c_1 \| \mathcal{F}(n) - u' \|_{L^2 (\Gamma_i \times \Gamma_m)}^2, \]
where \( c_1 \) denotes a normalization constant (e.g. \( c_1 = \| u' \|_{L^2 (\Gamma_i \times \Gamma_m)}^2 \)).

Even so, this problem is not continuous, as is shown by the following proposition. So, even a small perturbation \( \varepsilon \) can lead to a minimizer very far from \( n^* \).

**Proposition 2.1.** The non-linear problem consisting of ‘finding \( n \) minimizing \( J' \)’ is ill posed in the sense of Hadamard.
Proof. The mapping $\mathcal{F}$ is compact, and thus cannot have a continuous inverse. Indeed, it has been shown in [14, Proposition 2.1.14] that the mapping $n \mapsto u_n$ is continuous from $L^\infty(D)$ into $H^1(D)$; and as such, from $L^\infty(D)$ into $L^2(D)$. As a consequence, the same property holds for the mapping $f: n \mapsto (n - 1)u_n$.

Moreover, the asymptotic behavior of the Lippmann-Schwinger equation yields the following relationship [12, Chap. 8.4]:

$$
\mathcal{F}(n)(\vec{\theta}, \vec{x}) = \int_{\partial D} e^{ik\vec{x}\cdot\vec{z}} (n(z) - 1)u_n(\vec{\theta}, z), \quad \theta \in \Gamma_s, \quad x \in \Gamma_n. \quad (6)
$$

It is well known that the linear operator $f \mapsto \int_{\partial D} e^{ik\vec{x}\cdot\vec{z}}f(z)$ is compact.

Hence, the non-linear operator $\mathcal{F}$ is the combination of a compact linear operator with a continuous mapping. Therefore, it is compact itself. $\square$

2.3. Iterative approximation by a piecewise constant index

As stated in the introduction, we try to recover the unknown index $n^*$ with the help of piecewise constant functions. Hence, the indices will numerically be represented by $N$ complex parameters $\eta_{i,j} = 1_{Z_i}(x)$ associated with the same number of zones $Z_i, i = 1, \ldots, N$, so $n(x) = \sum_{i=1}^{N} \eta_{i,j} 1_{Z_i}(x)$, where $1_{Z_i}(x)$ is the characteristic function of $Z_i$ and $\bigcup_{i=1}^{N} Z_i = D$.

Each zone is thus a set of connected elements in the underlying mesh used to solve the Helmholtz equation. Moreover, to avoid any possibility of inverse crime, the reconstruction will be led on a second mesh that is different from the one used to generate the data $u'$.

As a consequence, the zones associated with the unknown parameters will intersect the discontinuities of $n^*$. It is thus strictly impossible to reconstruct $n^*$ exactly. This is illustrated in figure 2, showing the two 2D meshes that will be used in our numerical simulations.

In this setting, we use the well-known Gauss–Newton method applied to the cost function $J$ with a standard Tikhonov regularization term [15]:

![Figure 2. Test case geometry.](a) Data mesh (b) Reconstruction mesh)
\[ \tilde{J}(n) := c_1 \| F(n) - u \|^2_{L^2(\Gamma \times \Omega)} + c_2 \| n - n_0 \|^2_{L^2(D)}, \]

where \( c_1 > 0 \) is a regularization parameter and \( n_0 \in L^\infty(D) \) is an initial guess. The choice of this regularization parameter is discussed in a large number of papers; see for example [16, 17] and references therein. Empirically, it seems that a few percent of the fidelity term \( c_1 \| F(n) - u \|^2 \) is a decent initial guess for \( c_2 \). In addition, assumptions on \( n_0 \) and \( c_2 \) for the convergence of this method are discussed in [18, 19]. Hence, the index \( n^* \) we are looking for is approximated by a sequence \((n_p)_{p \in \mathbb{N}}\) of indices, defined iteratively through algorithm 1.

**Algorithm 1: The Gauss–Newton method for \( \tilde{J} \)**

**Input:** \( n_0 \in L^\infty(D) \)

1. \( p \leftarrow 0; \)

2. repeat
   1. Compute \( n_{p+1} \) by solving the linear system
   \[
   (DF(n_p) + \frac{c_2}{c_1} id)(n_{p+1} - n_0) = -DF(n_p)(n_{p} - n_0),
   \]
   where \( id \) is the identity matrix, and \( DF(n_p)^* \) is the Hermitian adjoint of the matrix \( DF(n_p); \)
   3. \( p \leftarrow p + 1; \)

3. until \( \| n_p - n_{p-1} \|_2 / (1 + \| n_{p-1} \|_2) < \epsilon; \)

**Output:** \( n_{\text{pfinal}} \)

The gradient of the cost function, required for the Gauss–Newton method, has the following integral representation.

**Lemma 2.2.** The mapping \( F \) is differentiable and the differential \( DF \) evaluated at \( n \in L^\infty(D) \) and applied to the direction \( dn \in L^\infty(D) \) has the following integral representation

\[
DF(n) \ dn: \left( \tilde{\theta}, \tilde{x} \right) \mapsto \int_{\tilde{x} \in D} k^2 u_n \left( \tilde{\theta}, z \right) u_n \left( \tilde{\theta}, z \right) \ dn (z) \ dz, \quad \tilde{\theta} \in \Gamma_\theta, \ \tilde{x} \in \Gamma_\theta. \tag{7}
\]

**Proof.** Expansion (4) shows that \( u_n^\infty \left( \tilde{\theta}, \cdot \right) \) is linear with respect to the scattered field \( (u_n - u) \left( \tilde{\theta}, \cdot \right) \). Furthermore, it has been shown in [14, Proposition 4.3.1] that the scattered field is differentiable with respect to \( n \) and that the differential of the index-to-scattered-field mapping evaluated at \( n \in L^\infty(D) \), applied to \( dn \in L^\infty(D) \), is the function \( v' \left( \tilde{\theta}, \cdot \right) \in L^\infty_0 (\mathbb{R}^d) \) satisfying

\[
\left( \Delta_n + k^2 n \right) v' \left( \tilde{\theta}, x \right) = -k^2 u_n \left( \tilde{\theta}, x \right) \ dn (x), \quad x \in \mathbb{R}^d, \tag{8}
\]

and the Sommerfeld radiation condition (3). Note that, contrarily to \( n \), the direction \( dn \) is extended by 0 outside \( D \). Thus, \( F \) is differentiable, and its differential is defined on \( C^\infty(\Gamma_\theta \times \Gamma_\theta^\infty) \) by \( DF(n) \ dn = v^\infty \).
Now, let us denote by $\Phi(z, x)$ the Green function of the Helmholtz equation (1). Multiplying (8) by $\Phi(z, x)$, integrating over $D$, and using Green’s formula, yields

$$v^\mu(\bar{\theta}, \bar{x}) = \int_{\partial D} k^2 \Phi^\mu(z, x) u_n\left(\bar{\theta}, z\right) \, d\sigma(z), \quad x \in \mathbb{R}^d.$$ 

The asymptotic behavior is then given by

$$v^\mu(\bar{\theta}, \bar{x}) = \int_{\partial D} k^2 \Phi^\mu(z, x) u_n\left(\bar{\theta}, z\right) \, d\sigma(z), \quad \bar{x} \in S^{d-1}.$$ 

Finally, representation (7) is obtained by applying the mixed reciprocity principle: $\Phi^\mu(z, \bar{x}) = u_n\left(-\bar{x}, z\right)$ (see [20, equation (3.66)]).

Remark 2.3. As described in [18, 19], to ensure the convergence of the regularized non-linear Gauss–Newton method (algorithm 1), one also requires the differential of $F$ to be Lipschitz continuous, which is actually the case. Indeed, the reference [14, Proposition 4.3.1], invoked in the proof of lemma 2.2, gives the twice continuous differentiability of the scattered field with respect to $n$, thus implying that $F$ is twice continuously differentiable too.

Numerical example. Set-up To illustrate our reconstruction schemes in $\mathbb{R}^2$, we consider a disc $D$ of radius 1 centered at the origin. The embedded perturbation $\Omega$ is then chosen as another disc centered at $(0.3, 0.3)$, and of radius 0.3. The mesh corresponding to this geometry can be seen in figure 2(a). The (perturbed) index we are looking for is set to $n^* := 1.3$ in $\Omega \setminus D$ and $n^* := 1.6$ in $\Omega$, whereas the initial guess, corresponding to the last known state, is $n_0 := 1.3$ in $D$.

The Gauss–Newton method is performed with the regularization parameter $c_z := 10^{-2}$ (and $c_l = \|u\|_{L^2(\Omega)}^2$ as previously denoted). Also, solutions to the Helmholtz equation are computed via a $P_1$ finite element method and Cartesian perfectly matched layers [21]. Lastly, the corresponding far fields are evaluated through the representation formula (6). For all these examples, the wave number is set to $k = 5$, and the angles corresponding to incoming/measurement directions are equally distributed over $[0, \pi]$.

Results An example can be seen in figure 3 with a reconstruction mesh of 2672 triangles (see figure 2(b)) divided into $N = 10$, $N = 27$, $N = 75$ and $N = 2672$ zones.

More precisely, the final relative error

$$e_{n_{\text{rel}}} := \frac{\|n_{\text{rel}} - n^*\|_{L^2(\partial D)}}{\|n^*\|_{L^2(\partial D)}}$$

is synthesized as a function of the number of zones $N$ in figure 4.

Moreover, for comparison purposes, we list in table 1 the exact final relative error obtained in several configurations. In addition, we see in this table that the relative error is of the order $10^{-7}$, so we choose the stopping criterion $\|n_n - n_{n-1}\|_{L^2(\partial D)} / (1 + \|n_{n-1}\|_{L^2(\partial D)}) < \varepsilon = 10^{-4}$ for all our reconstructions. In all these test cases, this bound was reached after four iterations.

Comments The low error that can be seen in figure 4 for $N = 19$ is a particular case related to the considered test case. Indeed, it just happens that this choice of zones provides a natural match to our simple geometry, yielding a reconstruction that is better than expected.

3. Enhancements of the Gauss–Newton method via defect localization

In the presented piecewise constant iterative approximation, the possible precision is directly linked to the number of basis functions $N$ which, in turn, is linked to the computational effort.
In the lack of certain geometrical information, all parameters are equally treated and updated at each iteration. However, this can generate more effort than is really needed, and we address two cases where these unnecessary efforts can be reduced.

Figure 3. Gauss–Newton reconstruction with $30 \times 30$ data and $\varepsilon = 2\%$ noise.
(i) For the first case, we consider a bounded perturbation in a known initial state \( n_0 \). So, most of the values of the index have not changed and should not be reconstructed.

(ii) For the second case, we are concerned with focusing on the most inexact constants during the reconstruction. Indeed, to obtain a precise identification, the reconstruction mesh has to be refined in the zones intersected by the discontinuities of \( n^* \). However, if \( n^* \) is constant in large areas, refining the reconstruction mesh everywhere only raises the computational effort for a relatively small precision increment.

To address these aspects of the reconstruction, the useful information in both cases would thus be the localization of the nearly exact constants. Or, to put it otherwise, we look for the localization of the difference between the reconstruction at hand and the exact (unknown) index. We call this defect localization with respect to an inhomogeneous background.

Table 1. Gauss Newton reconstruction

| \( N \) | \( \varepsilon \) | \( e_{15 \times 15} \) | \( e_{30 \times 30} \) | \( e_{60 \times 60} \) |
|-------|-------|----------------|----------------|----------------|
| 10    | 5%    | 5.9%          | 5.9%          | 5.8%          |
| 1%    | 5.9%  | 5.8%          | 5.8%          |               |
| 27    | 5%    | 4.9%          | 4.9%          | 4.9%          |
| 1%    | 4.9%  | 4.8%          | 4.8%          | 4.8%          |
| 75    | 5%    | 5.4%          | 5.0%          | 4.4%          |
| 1%    | 5.4%  | 4.8%          | 4.8%          | 4.8%          |
| 2672  | 5%    | 5.3%          | 4.5%          | 3.9%          |
| 1%    | 5.3%  | 4.3%          | 4.1%          | 2.9%          |

Figure 4. Final relative error with \( 30 \times 30 \) data and different noise levels \( \varepsilon \).
reference. Of course, to enhance the complete reconstruction, access to this specific information should be fast. To this end, it has been shown in [6] that the factorization method for a constant background, as presented in [22], can be extended to an inhomogeneous background with the help of a modified measurement operator.

**Theorem 3.1.** [6, Theorem 6.1]

Assume that \( \Gamma_m = \Gamma_r = S^{d-1} \). Then, define a measurement operator \( W := (I_d + 2ik\Pi \mu_{\Gamma_m} F_r^\ast F_r - F_r^\ast) \), where \( F_r : L^2(S^{d-1}) \to L^2(S^{d-1}) \) denotes the classical far-field operator, defined by \( F \varphi(\mathbf{x}) := (\mathbf{x}, \varphi(\mathbf{x}))\in L^2(S^{d-1}) \). Next, we define the positive self-adjoint operator \( W \) by \( \| \cdot \| = + - \ast \) (\( (\cdot, \cdot) \)), where the notation \( \| \cdot \| \) applied to an operator \( L \) stands for \( \| L^2 \|^2 \). Lastly, assume that \( n \) and \( n^* \) are real valued, and that either \( n = n^* \) or \( n = n^* \) is locally bounded from below in \( \Omega = \text{support} (n - n^*) \).

Then, for each \( z \in \mathbb{R}^d \), we have \( n(z) \neq n^*(z) \) if, and only if,

\[
S_{[n,n^*]}(z) := \sum_j \left[ \frac{\langle u_j(\cdot, z), \psi_j \rangle_{L^2(S^{d-1})}}{\sigma_j} \right]^{-1} > 0,
\]

where \( \left( \sigma_j, \psi_j \right) \) is an eigensystem of \( W \).

**Remark 3.2.** This localization result calls for a number of remarks.

(i) Theorem 3.1 requires full bi-static data \( \Gamma_m = \Gamma_r = S^{d-1} \) and real-valued indices. However, we also recall the conjecture stated in [6, Remark 6.2]: To build the localization function \( S \), the eigensystem of \( W \), denoted by \( \left( \sigma_j, \psi_j \right) \), could be replaced by a right-singular system of \( (F_r^\ast, F_r) \). The main benefit is the possibility of considering \( \Gamma_m \neq \Gamma_r \neq S^{d-1} \) and complex-valued indices. Moreover, we \textit{a priori} need to truncate the sum to avoid overvalued terms, due to perturbations on the smallest eigenvalues. However, in our experience, the computations are stable. So, no truncation is performed for the numerical applications of this paper and all the eigenvalues of the measurement operator’s matrix representation are considered.

(ii) Furthermore, numerical examples in [6] show that this localization is effective for defects bigger than (approximately) one-sixth of the wavelength. Besides, in order to get satisfactory results in the successive resolutions of the Helmholtz equation, we have set the reconstruction mesh size to be about one-twentieth of the wavelength. Thus, we will only consider defects that cover at least four connected mesh elements.

(iii) Moreover, the examples shown in [6] show that defects can be localized even when the surrounding background is not precisely known. Practically, low-amplitude inaccuracies with respect to the exact index do not seem to interfere with the localization of the contrasting defects. Thus, geometrical information gained through the defect localization presented here is expected to focus on the most ‘defective’ zones.

(iv) Finally, it is to be noted that the added computational cost of this localization function within the Gauss–Newton process will be negligible. Indeed, the functions \( u_j(\cdot, z) \) will
already have been computed to evaluate the differential of $\mathcal{F}$, as can be seen on the integral representation (7).

### 3.1. Selective reconstruction

Here we consider the case where the initial guess $n_0$ is exact, except for some perturbation whose support will be denoted by $\Omega$. Thus, we propose to perform a preliminary selection of the parameters, to reconstruct only the perturbed ones. The selection is performed by considering only the parameters associated with zones where the maximal value of the (normalized) defect localization function $S[n_0, n^*]/\max D$ is above some threshold $T$. The whole index $n^*$ is then reconstructed by updating those parameters only. This leads to a reconstruction, described in algorithm 2, using a number of parameters $N_{\text{Sel}}$ that should be significantly less than $N$.

**Algorithm 2: Selective reconstruction.**

**Input:** $n_0 \in L^2(D)$

1. $S_i \leftarrow \max_{x_i} S(n_0, n^*)(x)$;
2. $\Omega_T \leftarrow$ the set of zones for which $S_i > T \max S_i$;
3. $n_{\text{Pre1}} \leftarrow$ Algorithm 1($n_0|\Omega_T$) (all indices are extended by $n_0$ outside $\Omega_T$);

**Output:** $n_{\text{Pre1}}$

**Numerical example Set-up** In the framework of section 2.3, we here consider the smallest possible zones; that is, one parameter for each triangle of the reconstruction mesh. Figure 5 shows which zones are selected with three threshold values $T = 10\%$, $T = 20\%$ and $T = 30\%$.

**Results** We can see that a threshold of $T = 10\%$ yields an accurate selection of the perturbation, and thus provides a satisfactory reconstruction with only $N_{\text{Sel}} = 323$ selected parameters. Thus, we end up with significantly fewer parameters than the 2672 we have initially considered.

**Comments** We can also see in table 2 that the relative error can be lower than what was obtained through a full Gauss–Newton reconstruction over a set of various configurations. This is a consequence of the fact that all the parameters outside the perturbation are equal to the exact value, while they can be miscalculated in the full reconstruction. Identifying the unperturbed parameters can thus clearly enhance the reconstruction. As previously, the stopping criterion was reached after four iterations in all cases.

However, a threshold of $T = 20\%$ seems too high, as the 181 selected zones do not completely cover the perturbation’s support, resulting in a slightly flawed reconstruction. More precisely, the relative error obtained as a function of $T$ with $30 \times 30$ data can be seen in figure 6. Clearly, there is an optimal value for $T$ around $10\%$ when the noise ratio is kept low.

In addition, with more noise (5%), we see in figure 6 that the optimal $T$ is shifted towards 20%. Furthermore, we see that a good estimation of this threshold becomes even more important when the noise level grows. This brings up the problem of how to select a correct threshold, taking at least the measurement noise and the amount of data into account. Unfortunately, for the moment, we do not have a realistic indicator to tell if the selected threshold is acceptable.
Figure 5. Selective reconstruction with $30 \times 30$ data and $\varepsilon = 2\%$ noise.
As stated in section 2.3, we use a reconstruction mesh that is different from the one used to generate the data. Hence, the supports of the basis functions used in the reconstruction will not follow the geometry of $\star n$, especially with a low number $N$ of basis functions. Thus, we propose to iteratively refine the reconstruction mesh with the help of the previously introduced defect localization, in order to provide a satisfying approximation of the unknown index with a small number of parameters. The refinement outline is presented in algorithm 3.

### Table 2. Selective reconstruction

| $\mathcal{T}$ | $\varepsilon$ | $N_{\text{sel}}$ | $\varepsilon_{\text{real}}$ | $N_{\text{sel}}$ | $\varepsilon_{\text{real}}$ | $N_{\text{sel}}$ | $\varepsilon_{\text{real}}$ |

### 3.2. Adaptive refinement

As stated in section 2.3, we use a reconstruction mesh that is different from the one used to generate the data. Hence, the supports of the basis functions used in the reconstruction will not follow the geometry of $\star n$, especially with a low number $N$ of basis functions. Thus, we propose to iteratively refine the reconstruction mesh with the help of the previously introduced defect localization, in order to provide a satisfying approximation of the unknown index with a small number of parameters. The refinement outline is presented in algorithm 3.
The number of 16 mesh elements is taken so that, after splitting, each zone still has more than four mesh elements, which is the lower limit for defects to be relevant, as specified in remark 3.2.

Numerical example

Set-up We illustrate our adaptive refinement in figure 7 with the same conditions as in section 3.1.

Results Steps 3 (defect localization) and 9 (reconstruction on the refined set) of algorithm 3 are illustrated alternately in figures 7(a)–(f), and it can be seen how the reconstruction focuses on the support of the contrasting perturbation. Figure 7(g) represents the values of $n_p$, which are obtained with $N = 76$ basis functions chosen during 25 successive adaptive refinements. Also, the relative error $e_p$, obtained in step 10 of the algorithm, is plotted in figure 7(h) as a function of $p$.

Comments First, it can be noted that each refinement adds three parameters to be reconstructed and that each call to algorithm 1 generates about four iterations (see tables 1–2). So, the number of iterations is comparable to the number of parameters.

Then, comparing with the results obtained when using basis functions that are placed randomly, summarized in table 1 or in figure 3(f), we can see lower reconstruction errors when using our guided adaptive refinement. In this example, our results are even comparable to the complete reconstruction (algorithm 1) performed with 20 times more parameters. We thus meet our goal, which is a satisfactory reconstruction with a limited number of well-chosen basis functions.

Moreover, as we can see in table 3, the sensitivities to the noise or data amount in this example are similar to what we observe in section 3.1.

Finally, it cannot be overlooked that the number of total iterations $p_{\text{tot}}$ is now quite high, since each loop in algorithm 3 computes an iterative reconstruction. However, each of those reconstructions is conducted on a very small number of parameters. So, the integral representation (7) for the differential is not cost effective in this case and a suitably tuned evaluation of $n_{p+1}$ in algorithm 1 might thus be able to balance the higher number of iterations.
Figure 7. Adaptive refinement (algorithm 3) with 30 × 30 data and ε = 2% noise.
4. Combining both strategies

The selective reconstruction is presented in section 3.1 as a preliminary step to the reconstruction. Furthermore, the adaptive refinement described in section 3.2 enhances the actual reconstruction step. So, adaptive refinement and selective reconstruction can be used one after the other. This extension of algorithm 2 is described in algorithm 4.

**Algorithm 4: Selective reconstruction followed by adaptive refinement**

**Input**: \( n_0 \in L^2(D) \)

1. \( S_i \leftarrow \max_{x \in \mathcal{D}} S_i(n_0,x) \); 
2. \( \Omega_T \leftarrow \) the set of zones on which \( S_i > T \max(S) \); 
3. \( n_{\text{Ref}} \leftarrow \textbf{Algorithm 3}(n_0|\Omega_T) \) (all indices are extended by \( n_0 \) outside \( \Omega_T \));

**Output**: \( n_{\text{Ref}} \)

Note that the number of parameters selected in step 1 of this algorithm is not directly used in the adaptively refined reconstruction (step 3). Indeed, the iterative refinement described in algorithm 3 starts the reconstruction with only one zone. More precisely, the information retained from the selection step is the shape of the perturbation. Note that the accuracy of this selection is important: this is what allows the adaptive refinement to focus on the reconstruction of the perturbation’s inner geometry instead of focusing on the contrast between the perturbation and the background.

**Numerical example 1**

**Set-up** As in section 3, we illustrate algorithm 4 with the selection thresholds \( T = 10\% \), \( T = 20\% \) and \( T = 30\% \). The respective selected mesh elements can be seen in figures 5(a)–(e).

**Results** figures 8(a)–(c) show the reconstructions after 2, 4 and final adaptive refinement loops with a threshold \( T = 10\% \). As expected from the previous results, the reconstruction is very good. In fact, the exact values listed in table 4 show that this reconstruction reaches an accuracy comparable to the one obtained through the initial selective reconstruction; the latter requiring 10 times more basis functions. As in section 3.2, and for the same reasons, the number of parameters for each adaptively refined reconstruction is comparable to the number of iterations.

Similarly to the examples presented in section 3.1, \( T \geq 20\% \) also provides a too small selection, leading to a flawed reconstruction. For example, it can be seen in figures 8(d)–(i) that the reconstruction tends to a crown shape. So, the constraint induced by this too small selection seems to create false local minima, altering the whole convergence process, as we can see in figure 8(j). The corresponding relative error values are detailed in table 4.
Figure 8. Selective reconstruction followed by adaptive refinement, $30 \times 30$ data and $\varepsilon = 2\%$ noise.
Comments Since the selection is performed before the adaptive refinement, the choice of the threshold $\mathcal{T}$ still has a large influence on the final result, even in the case of over-selection. However, in terms of accuracy, the results remain close to the reference listed in table 1 while involving only 0.6% to 2% of the total number of elements used in the full Gauss–Newton reconstruction.

**Numerical example 2**

**Set-up** As a last example, we now consider a more elaborate and complex-valued unknown index $n^*$, shown in figure 9. In addition, we also make this reconstruction more challenging by reducing the measurement aperture. Incoming directions are still taken in $[0, 2\pi]$, but there will be five less, and measurement directions are now taken in $[0, \frac{2\pi}{5}]$. In this situation, the localization function presented in theorem 3.1 cannot be defined. So, we consider the technical modification, recalled in remark 3.2, that is conjectured to cover this case. Furthermore, we assume that $n^*$ was known before the central perturbation. So, we consider the initial guess $n_0$, shown in figure 10.
Finally, to remain in the previously defined context, we present the results of algorithm 4 applied to this new geometry with the same selection thresholds $\mathcal{T} = 10\%$, $\mathcal{T} = 20\%$ and $\mathcal{T} = 30\%$.

**Results** The reference reconstructions obtained with the usual Gauss–Newton reconstruction (algorithm 1) in the special case of $30 \times 25$ data and $2\%$ noise are synthesized in figure 11.

We then present in figure 12 the selected zones and the resulting reconstruction corresponding to each selection threshold. In this case, $\mathcal{T} = 20\%$ now seems to be the best threshold value, and $\mathcal{T} = 30\%$ is still too high. Indeed, in the lines of the previous numerical example depicted in figure 8, $\mathcal{T} = 30\%$ seems again to induce a false local minima, resulting in an altered convergence sequence. This is confirmed in figure 12(j), where we can also see
that, even though $T = 10\%$ allows us to reach a satisfying precision, it requires many more refinements than with $T = 20\%$.

The results obtained in section 3 are thus reinforced by this example, exhibiting reconstructions comparable in precision to the full Gauss–Newton reconstruction, but with a much lower number of parameters.

Figure 12. Selective reconstruction chained with adaptive refinement for the more elaborate example with $30 \times 30$ data and $\varepsilon = 2\%$ noise.
Comments Note that with this less trivial test case, the borders of the supports of the basis functions for the reconstruction do not correspond with the discontinuities of the exact index. This ensures that we avoid this particular case, which was mentioned in the concluding comments of section 2.3.

5. Conclusion

We have used a defect localization method to propose two ways of reducing the number of parameters in the reconstruction of an unknown refraction index. The first method is set in the context of defect identification and uses their localization to reconstruct only the useful parameters of the whole index. The second method is an adaptive refinement based on defect localization to iteratively reconstruct a better approximation with a limited number of parameters. We have obtained good numerical results with both methods.

The reconstruction could however be further enhanced by two automations: some automatic choice of the threshold for the defect localization function and some automatic selection of the regularization parameter. The second issue has been reviewed for example in [16, 17] and is claimed to be less critical when using the so-called multiplicative regularization described in [23]. However, for now, we have not been able to further enhance our results with these techniques. Finally, convergence of the coupled process, hybridizing the Gauss–Newton and factorization methods presented in this paper, remains to be investigated.
