Flooding is an important environmental factor restricting plant growth and productivity throughout the world. Growth, organic solute accumulation and proteolytic activity of *Medicago truncatula* were determined in hydroponically grown plants exposed to hypoxia during 30, 45 and 60 days. Obtained results showed that hypoxia until 45 days have no significant impact on the dry matter production. However, after 60 days of treatment, a decrease in the shoot and root growth was observed. In addition, a development of adventitious roots is shown in the hypocotyle of treated plant. In fact, the water content varied in response to the hypoxia. The soluble carbohydrates content was still stable on the shoot of treated plant until 45 day. Whereas, it was registered that the content of non-reducing soluble sugar present almost all of total soluble sugars, and that the accumulation of this sugars fraction in more important in the roots of hypoxia plants in comparison to the aerial organs. The proline content measured in stressed plants was increased with time over control plants. Contrary, hypoxia decreased the total endopeptidase activity in *M. truncatula* roots. It could be concluded that *M. truncatula* can be support the prolonged hypoxic stress by developing adventitious roots and accumulating proline.

Key words: *Medicago truncatula*, hypoxia, adventitious roots, soluble sugars, proline, endopeptidase activity.

INTRODUCTION

The lack or the excess of the water in the rhizosphere present a critical factor on plant growth. Indeed, drought or waterlogging affect plant characteristics (Iqbal et al., 2009; Ibraheem et al., 2011; Promkhambut et al., 2011). Flooding is one of the most significant abiotic stresses, it causes a slow transfer of dissolved oxygen in the waterfilled pore space of the soil, and plants can have to face to the lack of oxygen during all stage of its growth. Seed imbibitions, flood irrigation, floods and excess of rainfall are examples of natural conditions leading to root hypoxia or anoxia. These conditions can severely disturb plants development (Voosenek and Bailey-Serres, 2013). The oxygen deficiency is thought to be a major determinant in the adverse effects of flooding on crops and other plant species (Mommer et al., 2004). Not all plant species can survive to the waterlogging conditions, only some species are able to adapt to this stress by developing some physiological and morphological mechanisms like adventitious roots and aerenchyma (Vartapetian and Jackson, 1997; Vignolio et al., 1999).
Nevertheless, this adaptive capacity depends on the plant species (Poot and Lambers, 2003). Among species, legumes represent the third largest group of angiosperms and the second largest group of food and feed crops grown globally. They include 670 to 750 genera and 18000 to 19000 species. It regroups varied food and feed crop species, such as clover, chickpea, soybean, pea, alfalfa and mungbean. Grain legumes provide about one-third of all dietary protein nitrogen and one-third of processed vegetable oil for human consumption (Graham and Vance, 2003). Indeed, some varieties such as soybean and *Pongamia pinnata* takes more attention because of their high seed oil content how can be used like a biofuel (Scott et al., 2008). However, Leguminosae are able to evolve a symbiotic relationship with specific soil bacteria, called Rhizobia (de Faria et al., 1989). As a result, many legumes are sensitive to waterlogging, showing reductions in root growth, nodulation process, nitrogen fixation and photosynthesis activity (Linkemer et al., 1998; Bacanamwo and Parcell, 1999). To develop more knowledge on legumes, *Medicago truncatula* get more attention because of its short growth cycle and its small genome (500 to 550 Mbp) (Young et al., 2005). It is a model plant and presents the subject of numerous researches that studying the symbiotic and the mycorrhizal symbiosis (Ané et al., 2004), the abiotic stress tolerance (Narasimhamoorthy et al., 2007), the disease resistance (Ameline-Torregrosa et al., 2008). In this work, we tried to investigate the impact of the prolonged time of hypoxia on the growth of *M. truncatula*. We follow the production of dry matter, the water content, the sugar content, the shoot proline, and the total endopeptidase activity after 30, 45 and 60 days of hypoxia.

### MATERIALS AND METHODS

#### Biological material and growth conditions

Seeds of *M. truncatula* A17 were sterilized with sodium hypochlorite (0.6%), rinsed with distilled water and imbibed during 2 h. Seeds are placed on moist filter paper in a Petri dish and incubated at 25°C. After 5 days, the seedlings were grown hydroponically into glass container. The nutrient solution contained macronutrients: 2.25 mM KNO₃; 0.25 mM Ca (NO₃)₂; 0.35 mM KH₂PO₄ and 0.075 mM MgSO₄, micronutrients: 268.6 μM EDTA-Fe; 8.9 μM MnSO₄; 24.1 μM H₃BO₃; 1.7 μM ZnSO₄ and 3.9 μM CuSO₄ (Saglio and Pradet, 1980).

Hypoxic treatment was applied at the second leaf stage by stopping air bubbling, whereas control plants were continuously aerated. Seedlings were grown in a growth room at 25°C/20°C (day/night) with 18 h/6 h (day/night) photoperiod and 75% relative humidity.

#### Vegetative growth analysis

Growth parameters were evaluated after 30, 45 and 60 days of hypoxia treatment. Plants were harvested, divided into roots and shoots. Roots were washed in distilled water. Fresh weights (FW) were immediately determined for roots and shoots. Dry weights (DW) were obtained by weighing the plant material after drying at 80°C until a constant mass was reached. Water content (WC) was calculated as (FW-DW) / DW.

#### Soluble carbohydrates and proline determination

Soluble carbohydrates, total and reduced, were determined as described by Aschi-Smiti et al. (2003). Free proline was quantified spectrophotometrically by the ninhydrin method according to Bates et al. (1973). The plant material was homogenized in 3% (w/v) aqueous sulfosalicylic acid and the homogenate was centrifuged at 14000 rpm. The supernatant was used for the estimation of the proline concentration. The reaction mixture consisted of 2 ml of ninhydrin acid and 2 ml of glacial acetic acid, which was boiled at 100°C for 1 h. After termination of reaction in ice bath, the reaction mixture was extracted with 4 ml of tolulene, and absorbance was read at 520 nm.

#### Proteolytic activity

Proteolytic activity in shoot crude extracts was determined spectrophotometrically by following the digestion of azocasein at 440 nm (Brouquisse et al., 1998).

#### Statistical analysis

Three biological replications were used in this study. Statistical data analysis was made using Student’s t-test. The results are given as means with standard errors of at least 10 samples per treatment. The significance of differences between the control and the treatment mean values was determined at the significance level of p<0.05.

### RESULTS

#### Vegetative growth analysis

In the present study, hypoxia was applied at the second leaf stage of *M. truncatula* growth. In function of time, the biomass production of *M. truncatula* was increased and the differences between control and treated plant were not significant up to 45 days of treatment. At 60 days of hypoxia decreased the growth of shoot and root respectively by 44 and 52% in comparison to control plants (Figure 1).

In fact, hypoxia decreased the water content in shoot respectively by 14, 36 and 33% after 30, 45 and 60 days of treatment (Figure 2A). While, the water content in roots was decreased after 45 and 60 days of hypoxia and an augmentation of the water content was noticed after 30 days estimated by 34% (Figure 2B).

Nevertheless, prolonged root hypoxia (60 days) decreased the development of the whole plant. The picture presents the development of adventitious roots on the hypocotyle of *M. truncatula*. In the present study, compared with the control plant that had no adventitious root, it was observed the petrifaction of the initial root system (Figure 3).
**Soluble carbohydrates**

Data presented in Figure 4 revealed that the content of total soluble sugars (TSS) in shoots still stable up to 45 days of treatment. After 60 days of hypoxic treatment, an augmentation of TSS was observed (Figure 4A). For the underground organ, the sugar content was increased by 50% between 30 and 45 days in control plants, while it decreased at 60 days by 55%. On the other hand, in treated plants, hypoxia increased total root sugar (Figure 4B)

The results of two fractions of soluble sugar: reducing (RS) and non-reducing sugar (NRS) showed that the content on NRS (Figure 4C) is more important in *M. truncatula* organs (Figure 4B). In fact, deficient plant on oxygen presents an elevated content on NRS in their shoots, whereas it was decreased in the root with the treatment. However, at 45 and 60 days the NRS was decreased by 21 and 95% in comparison to the content at 30 days. In parallel to this decreases, it showed an augmentation of RS on stressed roots by 75 and 55% at 30 days.

**Proline and endopeptidase activity**

Proline is uncharged amino acid, it characterize by a neutral pH and a highly water solubility. The results presented in Figure 5A revealed that the proline content of control plant shoots is stable up to 45 days, at 60 days, we showed an augmentation by 40%. However, hypoxia induced synthesize of proline on function of time. The increase estimated by 25 and 30% respectively at 45 and 60 days in comparison to control plant.

The variation of the total endopeptidase activity (Figure 5B) in roots of control plant was increased by 37 and 45% at 45 and 60 days, in comparison to the content obtained at 30 days. On contrary, hypoxia decreased the endopeptidase activity in roots. This reduction estimated by 39, 48 and 55% at 30, 45 and 60 days in comparison to control.

**DISCUSSION**

Waterlogging stress is known to cause a number of morphological and anatomical changes in plants (Sairam...
et al., 2008). For example, the apparition of hypertrophied lenticels on roots, the formation of adventitious roots (Malik et al., 2001), the development of aerenchyma (Evans, 2004; Abiko et al., 2012) were observed under flooding stress. In this work, the application of prolonged hypoxia treatment to *M. truncatula* caused the apparition of adventitious roots on the hypocotyle. In spite this adaptation to the hypoxia; it was noticed a diminution of the plant water content. This decrease in the water status can be the result of the reduction of the stomata conductance. This phenomenon is considered one of the first plant responses to waterlogging (Folzer et al., 2006). In addition the maintenance of elevated content of shoots non-reducing sugar on parallel to its spectacular diminution in root. These results are in agreement with those obtained by Germain and collaborators (1997) on tomato. Moreover, maintaining of elevated quantity of non-reducing sugar in root until 45 days car suggesting the eventual transport of sucrose from shoot to root (Yu et al., 2012).

Concentrations of free proline in the leaves of *M. truncatula* increased synchronously with time of hypoxia treatment. Proline accumulation is known to have multifunctional role on the defense mechanisms developed by plants grown under various stress (Nanjo et al., 2003). It’s related also to the non-enzymatic detoxification of free radicals (superoxide, peroxide or hydroxyl) that are generated excessively under stress (Radyukina et al., 2008). It plays an important role of osmolyte for osmotic adjustment and contributes to the stabilization of cell structures, protection of membranes and proteins against reactive oxygen species (Steffens et al., 2012). The authors explain such ability of this amino acid by the presence of tertiary carbon which can form stable radical tearing off free radical reactions induced by ROS (Radyukina et al., 2008). In roots of *M. truncatula* the proteolytic activity was increased with time but still fewer that obtained in roots of control plant. In fact, the increase of the proteolytic activity is explained by the nature and the development of tissues. Indeed, roots of control plants are much vacuolated and the endopeptidase activity quantified with the azocasein characterizes vacuole. These results are similar to those found by Aschi-Smiti and collaborators (2003) on *Trifolium subterraneum*.

Another adaptation road of plant to survive under hypoxia is the shifting of the energy metabolism from aerobic to anaerobic mode since the energy requirements of the tissue is greatly restricted as very few ATPs are generated per molecule of glucose (Jackson and Drew, 1984). Thus, maintaining adequate levels of readily fermentable sugars under oxygen deficient in roots is one of the adaptive mechanisms to hypoxia (Xia and Saglio, 1992; Sairam et al., 2009). Moreover, waterlogging, in tolerant genotypes, induces to increase the content of reducing sugar through increased activity of sucrose synthase by increasing the level expression of its mRNA (Sairam et al., 2009). Therefore, the availability of sufficient sugar reserves in the roots with the increased activity of TSS to provide reducing sugars for anaerobic respiration is one of the important mechanisms of waterlogging tolerance. In our results, *M. truncatula* present more non-reducing sugar than reducing form. Therefore, sucrose represents almost all of the total soluble sugars in this legume. The concentration of soluble carbohydrate in *M. truncatula* was increased during the prolonged long-term oxygen deficit, and we register an augmentation of the root and shoot content on reducing sugar on function of time (Kumutha et al., 2008). In addition the maintenance of elevated content of shoots non-reducing sugar on parallel to its spectacular diminution in root. These results are in agreement with those obtained by Germain and collaborators (1997) on tomato. Moreover, maintaining of elevated quantity of non-reducing sugar in root until 45 days car suggesting the eventual transport of sucrose from shoot to root (Yu et al., 2012).

Concentrations of free proline in the leaves of *M. truncatula* increased synchronously with time of hypoxia treatment. Proline accumulation is known to have multifunctional role on the defense mechanisms developed by plants grown under various stress (Nanjo et al., 2003). It’s related also to the non-enzymatic detoxification of free radicals (superoxide, peroxide or hydroxyl) that are generated excessively under stress (Radyukina et al., 2008). It plays an important role of osmolyte for osmotic adjustment and contributes to the stabilization of cell structures, protection of membranes and proteins against reactive oxygen species (Steffens et al., 2012). The authors explain such ability of this amino acid by the presence of tertiary carbon which can form stable radical tearing off free radical reactions induced by ROS (Radyukina et al., 2008). In roots of *M. truncatula* the proteolytic activity was increased with time but still fewer that obtained in roots of control plant. In fact, the increase of the proteolytic activity is explained by the nature and the development of tissues. Indeed, roots of control plants are much vacuolated and the endopeptidase activity quantified with the azocasein characterizes vacuole. These results are similar to those found by Aschi-Smiti and collaborators (2003) on *Trifolium subterraneum*. 

---

**Figure 3.** Morphological aspect of *M. truncatula* (A) and roots (B) after 60 days of hypoxia treatment. Ad: Adventitious roots; In: initial.
The lowest proteolytic activity was found in hypoxic’s root can be the result of the purification and the necrosis of root under hypoxia. Since that adventitious roots ensure survive and nutrition of *M. truncatula*; this roots are physiologically young and haven’t important vacuoles. These results are consistent with those obtained on maize under dark stress by Brouquisse et al. (1998) and on *Trifolium subterraneum* grown in hypoxia by Aschi-Smiti et al. (2003).

**Conflict of Interest**

The authors have not declared any conflict of interest.

**Conclusion**

*M. truncatula* seem supporting the prolonged hypoxia stress. Its capacity to develop adventitious roots, accumulating proline and getting an elevated content of sugar help it to achieve its biological cycle. Indeed, it is important to study the molecular and the genetic basis of this adaptation to oxygen deficiency of this model plant.

**ACKNOWLEDGEMENTS**

The authors thank Dr Hela Ben Ahmed for help. They are indebted to the eco-physiological team members for
Figure 5. Shoot’s proline (A) and root’s proteolytic activity (B) of control (grey) and hypoxia treatment (black) of M. truncatula after 30, 45 and 60 days. Values are the mean ± S.E. from ten measurements. The significance of differences between the control and the treatment mean values was determined by the Student’s t-test at the significance level of p<0.05 in comparison to the control.

numerous harvests.
