Sparse dimension reduction based on energy and ball statistics

Emmanuel Jordy Menvouta¹, Sven Serneels², Tim Verdonck¹,³,*

Abstract
As its name suggests, sufficient dimension reduction (SDR) targets to estimate a subspace from data that contains all information sufficient to explain a dependent variable. Ample approaches exist to SDR, some of the most recent of which rely on minimal to no model assumptions. These are defined according to an optimization criterion that maximizes a nonparametric measure of association. The original estimators are nonsparse, which means that all variables contribute to the model. However, in many practical applications, an SDR technique may be called for that is sparse and as such, intrinsically performs sufficient variable selection (SVS). This paper examines how such a sparse SDR estimator can be constructed. Three variants are investigated, depending on different measures of association: distance covariance, martingale difference divergence and ball covariance. A simulation study shows that each of these estimators can achieve correct variable selection in highly nonlinear contexts, yet are sensitive to outliers and computationally intensive. The study sheds light on the subtle differences between the methods. Two examples illustrate how these new estimators can be applied in practice, with a slight preference for the option based on martingale difference divergence in the bioinformatics example.

Keywords: (Sufficient) Dimension Reduction, (Sufficient) Variable Selection, Nonparametric Multivariate Statistics, Sparse estimators.

years. The bigger data are, the more difficult it will be to grasp the data by looking at the numbers, or to analyze them visually by plotting fractions of them. That notwithstanding, it can already be a challenge to get a grip on the information contained in small data as well, as soon as dimensionality exceeds what can be visualized. Therefore, dimension reduction has been a mainstay topic of research for the past century and it continues to intrigue researchers up to the present day.

Different approaches to dimension reduction are justified depending on the objectives of the analysis and the structure of the data. Many methods for dimension reduction have been developed to detect structures in one block of data as such, without any external information. A very commonly applied method in that context is principal component analysis (PCA), but sparse variants, or nonlinear methods like autoencoders, will resort under this umbrella as well. However, as soon as there is a dependent variable (or more than one), it becomes more interesting to know which information in the data explains that dependent variable, as opposed to summarizing the data onto a set of latent variables according to a pre-specified criterion, which PCA or autoencoders do. Exactly for this purpose, sufficient dimension reduction (SDR) has been developed. In SDR, one aims to estimate a set of latent variables that are linear combinations of the original variables $T = XW$ in such a way that the subspace spanned by them contains all information relevant to the dependent variable: $Y \perp X \mid T$. 

Here, $X$ is a sample of $n$ cases of a $p$ variate random variable and $Y$ is a sample of the dependent variable, whereas $\perp$ denotes statistical independence. The space that satisfies (1) is called the central subspace. There is over twenty years of literature on how the central subspace can be estimated most efficiently according to a wide range of assumptions. The interested reader is referred to Li (2018) for a recent reference work on SDR. It is not intended to provide a comparison of SDR methods in this article. However, it is noted that some of the most recent approaches to estimate the central subspace are based on maximization of an appropriate nonparametric measure of association. These require no distributional assumptions, and distributional independence (1) follows from absence of association. Because of the latter elegance, that approach will also be the foundational layer for the material developed here, as outlined in Section 2.

Sufficient dimension reduction does identify a subspace whose complement is statistically independent of the predictand. However, SDR is by definition a dense method: when $X$ is $p$ variate, so is $W$ and the elements $w_{ij}$ will generally be nonzero. When all variables can reasonably be assumed to contain information relevant for the predictand $y$, it makes sense that the information contained in them carries through to the latent variables. However, when uninformative variables are present, they should be detected as such and they should not contribute to the model, with the corresponding estimated $\hat{w}_{ij} = 0$ $\forall i \in [1,p]$ $\forall j \in [1,h]$, with $h \in [1, \min(n,p)]$ denoting the dimension
of the central subspace. Such models are sparse dimension reduction models and they are in widespread use, with justifications ranging from a better interpretability to the sparse estimate being less prone to noise, just to name a few. Sparse PCA (Zou et al., 2006) is a well established sparse dimension reduction technique. However, sparse sufficient dimension reduction is still a nascent field of research. When uninformative variables are present, the objective becomes to estimate the central subspace in \( \{1\} \) in such a way that the space estimated does not contain contributions from the uninformative variables. Several approaches have been published to achieve variable selection for SDR, either using hypothesis tests based on the estimated latent variables (Cook 2004), called sufficient variable selection (SVS), or by a sure independence screening (Fan and Lv 2008) procedure prior to the analysis. More recently, a sparse method to estimate the central subspace has been proposed, based on a criterion that maximizes distance covariance (Székely et al. 2007) to the dependent variable in the presence of a sparsity penalty (Chen et al. 2018). This method relies on fewer assumptions than its predecessors, and as it is based on a nonlinear measure of association, will achieve dimension reduction with respect to nonlinear dependencies.

This article will build on the sparse SDR method in Chen et al. (2018), but will explore different measures of association. Distance covariance is the oldest association measure that belongs to the class of energy statistics (Székely and Rizzo 2013). However, more recently, further measures of association have been proposed. Martingale difference divergence (Shao and Zhang 2014), an energy statistic as well, is a related measure of association that, when zero, ascertains conditional mean independence of two stochastic variables. Ball statistics, introduced in the form of sure independence screening in Pan et al. (2019), on the other hand, comprise an entire different class of statistics, that encompass measures of association as well. While SDR methods based on these more recent measures of association have been developed, sparse variants have not yet been pursued. The latter could be particularly interesting, because the nonsparse variants have been reported to have desirable properties, e.g. SDR based on ball covariance has been reported to be statistically robust and to lead to a straightforward generalization that allows categorical variables as input (Zhang and Chen 2019). Based on this motivation, this paper will introduce sparse SDR based on MDD, as well as based on ball covariance. Section will recapitulate the definitions of the association measures and SDR based on them. Section 3 will introduce sparse SDR based on these measures and will describe how to compute the resulting estimators. Their properties will be investigated in Section 4. Eventually, in Section 5 the practical use will be shown for two data set known to contain uninformative variables. The main findings and suggestions for further research are summarized in the conclusion.

2. Sufficient dimension reduction through energy and ball statistics

As stated in the Introduction, SDR aims to identify a subspace of the original data space by constructing a set of latent variables as linear combinations
of the original variables, such that the complement of resulting space spanned by the latent variables is independent of the predictand \( \mathbf{y} \). There is ample literature on how to estimate the resulting central subspace (see e.g. \( \text{Li} \) (2018)). Some of the most recent developments in this direction estimate the central subspace by maximizing a nonparametric and nonlinear measure of association, as that requires minimal assumptions and works in the context of highly nonlinear dependencies.

To estimate the central subspace using a measure of association \( \Psi \), the following objective is maximized:

\[
\mathbf{W}_h = \arg\max_{\mathbf{B}} \Psi^2 (\mathbf{X} \mathbf{B}, \mathbf{y}),
\]

subject to:

\[
\mathbf{B}^T \mathbf{X}^T \mathbf{X} \mathbf{B} = \mathbf{I}_h,
\]

where \( \mathbf{B} \) is an arbitrary \( p \times h \) matrix, \( h \in [1, \min(n, p)] \). Here, \( \Psi \) can be any statistic that applies to a set of an \( h \) variate and a univariate variable, but of course, in practice, only those statistics estimate a subspace whose complement is independent of \( \mathbf{y} \) make sense in this context. As such, three options have been proposed recently:

- SDR by maximizing squared distance covariance (\( \text{Sheng and Yin} \) (2016));
- SDR by maximizing squared martingale difference divergence (MDD, \( \text{Zhang et al.} \) (2019));
- SDR by maximizing squared ball covariance (\( \text{Zhang and Chen} \) (2019))

Each of these measures of association will briefly be explained in this Section.

**Remark 1.** This optimization objective is, in fact, reminiscent of projection pursuit (\( \text{Huber} \) (1985)), targeting to find directions \( \mathbf{w}_i \) that maximize a certain objective. In the PP literature, the objective would be called the projection index. The difference between criterion (2a) and the typical PP criterion, is that \( \Psi \) is allowed to be a statistic that operates on multivariate variables.

**Remark 2.** Setting \( \Psi \) to the classical covariance in conjunction with a univariate \( \mathbf{b} \) will in fact produce the first latent variable of partial least squares (PLS). Successive PLS latent variables can be obtained by maximizing the same objective on deflated data.

### 2.1. Distance covariance

Distance covariance (DCOV, \( \text{Szekely and Rizzo} \) (2013)) is a measure of dependence between random variables that can detect both linear and non-linear associations. Let random variables \( \mathbf{X} \in \mathbb{R}^p \) and \( \mathbf{Y} \in \mathbb{R} \) such that \( \mathbb{E}[\mathbf{X}] \) and \( \mathbb{E}[\mathbf{Y}] \) are finite. Here, \( p \) is a positive integer and the norm \( |.| \) is defined for complex valued functions \( f(\cdot), a|f| = \overline{ff} \), where \( \overline{f} \) is the complex conjugate of \( f \). The squared distance covariance between \( \mathbf{X} \) and \( \mathbf{Y} \), is defined as:
\[ \mathcal{V}^2(X, Y) = \mathbb{E}|X - X'||Y - Y'| + \mathbb{E}|X - X'|\mathbb{E}|Y - Y'| - \mathbb{E}|X - X'||Y - Y'|. \] (3)

with \((X', Y')\), \((X'', Y'')\), being iid copies of \((X, Y)\). A fundamental reason for using distance covariance in (2a), is that it has the zero equivalence property in Euclidean spaces: \( \mathcal{V}(X, Y) = 0 \iff X \perp Y \). In practice, given the iid observations \((X, Y) = (X_k, Y_k)_{k=1}^n\), and the matrix \(B \in \mathbb{R}^{p \times h}\), the sample version of \( \mathcal{V}^2(XB, Y) \) is given by:

\[ \mathcal{V}^2(XB, Y) = \frac{1}{n^2} \sum_{k,l=1}^n A_{kl}(B)C_{kl}. \] (4)

In (4), the entities \(A_{kl}\) and \(C_{kl}\) are given by:

\[ A_{kl}(B) = a_{kl}(B) - \bar{a}_k(B) - \bar{a}_l(B) + \bar{a}(B), \] (5a)

where:

\[ a_{kl}(B) = |X_kB - X_lB|, \] (5b)

\[ \bar{a}_k(B) = \frac{1}{n} \sum_{l=1}^n a_{kl}(B), \] (5c)

\[ \bar{a}_l(B) = \frac{1}{n} \sum_{k=1}^n a_{kl}(B) \] (5d)

and

\[ \bar{a}(B) = \frac{1}{n^2} \sum_{k,l=1}^n a_{kl}(B). \] (5e)

with \(|.|\) denoting the Euclidean norm. Similarly, define \(c_{kl} = |Y_k - Y_l|\) and \(C_{kl} = c_{kl} - \bar{c}_k - \bar{c}_l + \bar{c}\).

2.2. Martingale difference divergence

Martingale Difference Divergence (Shao and Zhang, 2014) is a measure of conditional mean independence between two random variables. Let \(Y \in \mathbb{R}\) and \(X \in \mathbb{R}^p\) such that \(\mathbb{E}(|Y|^2 + |X|^2) < \infty\) and recall that \((X', Y')\) denotes an iid copy of \((X, Y)\). The squared MDD of \(Y\) given \(X\) is given by

\[ \mathfrak{M}^2(Y|X) = -\mathbb{E}[(Y - \mathbb{E}Y)(Y' - \mathbb{E}Y')|X - X'] \]. (6)

MDD is a particularly useful measure of association between \(Y\) and \(X\) in presence of heteroskedasticity (Zhang et al., 2019). Indeed, in that case, maximizing distance covariance will lead to incorrect estimation of the basis for the central subspace. An attractive property of MDD, which makes it particularly useful in SDR, is that \(\mathfrak{M}^2(Y|X) = 0 \iff \mathbb{E}(Y|X) = \mathbb{E}(Y)\). This is a form of zero equivalence property for the conditional mean. In practice, given the iid
observations \((X, Y) = (X_k, Y_k)_{k=1}^n\), and the matrix \(B \in \mathbb{R}^{p \times h}\), the sample version of MDD, \(\mathfrak{M}^2(Y|X)\), is given by (Park et al., 2015):

\[
\mathfrak{M}^2(Y|XB) = \frac{1}{n^2} \sum_{k,l=1}^n A_{kl}(B)G_{kl},
\]

(7)

where \(A_{kl}\) is defined as in the sample version of DCOV and

\(G_{kl} = g_{kl} - \bar{g}_k - \bar{g}_l + \bar{g}_\ldots\),

(8a)

and the remaining terms can be found analogously to Equations (5c) through (5e), replacing \(a_{kl}\) by \(g_{kl}\).

Equations (5) and (8), show that the sample versions of both DCOV and MDD are based on the matrices of pairwise Euclidean distances of \(Y\) and \(XB\). By consequence, the algorithms are \(O(n^2)\), with a shortcut available for pairs of univariate variables (Huo and Székely, 2016). However, in the context of SDR, at least \(XB\) is typically multivariate and sometimes, so is \(Y\), such that one has to revert to the \(O(n^2)\) algorithm.

2.3. Ball covariance

Ball covariance (Pan et al., 2020) is a general measure of dependence between random variables in metric spaces. It was developed to overcome the fact that distance covariance does not have the zero equivalence property in general metric spaces (Lyons, 2013). It has also been shown that distance covariance can be sensible to outliers (Raymaekers and Rousseeuw, 2019), a disadvantage that ball covariance (BCOV) claims not to have. Formally, let \(X\) and \(Y\) be two random vectors defined respectively in two separable Banach spaces \((X, \zeta_X)\) and \((Y, \zeta_Y)\), where \(\zeta_X\) and \(\zeta_Y\) are norms defined on \(X\) and \(Y\) respectively. Let \(\theta\), \(\mu\) and \(\nu\) be Borel probability measures on \(X \times Y\), \(X\) and \(Y\) respectively. \((X,Y)\) is a Banach-valued random vector defined on a probability space \((\Omega, \mathcal{F}, \mathbb{P})\) such that \((X,Y) \sim \theta, X \sim \mu\) and \(Y \sim \nu\). Denote a closed ball with center \(x_1\) and radius \(\zeta_X(x_1, x_2)\) in \(X\) by \(B_{\zeta_X}(x_1, x_2)\). \(B_{\zeta_Y}(y_1, y_2)\) is then similarly defined in \(Y\).

The squared ball covariance (BCOV) is defined by

\[
\mathfrak{B}^2(X,Y) = \int \int_{X \times Y} [\theta - \mu \otimes \nu]^2(B_{\zeta_X}(x_1, x_2) \times B_{\zeta_Y}(y_1, y_2)) \theta(dx_1, dx_2) \theta(dy_1, dy_2)
\]

(9)

An interesting property of SDR based on ball covariance is that it is claimed to be robust to outliers (Zhang and Chen, 2019), even though a formal proof to that claim is not provided (e.g. bounded influence function). Ball covariance also possesses the zero equivalence property: \(BCOV(X,Y) = 0 \iff X \perp \!
\!
\!\perp Y\), which makes it a usable statistic in the optimization problem for SDR (2a).
To compute the sample version of BCOV, let \((X, Y) = (X_k, Y_k)_{k=1}^n\), be an iid sample and given the matrix \(B \in \mathbb{R}^{p \times h}\), then:

\[
\mathbb{B}^2(XB, Y) = \frac{1}{n^6} \sum_{i,j,k,l,s,t=1}^{n} \xi_{ij,jklst}^X \xi_{ij,jklst}^Y.
\]

Here,

\[
\xi_{ij,jklst}^X = \frac{1}{2} (\delta_{ij,k} \delta_{ij,l} - \delta_{ij,k} \delta_{ij,l}),
\]

\[
\delta_{ij,k} = \mathbb{P}(X_k \in \bar{B} | (X_i, B, X_j) = (x_i, b, x_j))
\]

and \(\xi_{ij,jklst}^Y\) is similarly defined. Unlike DCOV and MDD, the computation of the empirical BCOV is not based on the matrix of pairwise Euclidean distances and is more time consuming than either of the other measures of association.

To obtain sufficient dimension reduction based on DCOV, MDD or BCOV, it suffices to set \(P\) equal to \(\mathcal{M}\) or \(\mathcal{B}\) in (2a), respectively.

3. Sparse Sufficient Dimension Reduction

The SDR methods presented in the previous section suffer from the fact that all the original variables in \(X\) are present in the linear combination \(XB\). This can be a problem when only a few variables are informative and one would like to select only those variables that are informative. In this section, we consider the extension of the Coordinate Independent Sufficient Variable Selection procedure (Chen et al., 2010) to the distribution free SDR methods proposed in the previous section. To estimate the central variable selection space, consider maximizing the following objective:

\[
W_h = \arg\max_B \mathcal{P}^2(B, X, Y) - \rho(B),
\]

subject to:

\[
B^T X^T XB = I_h,
\]

where \(\rho(B) = \sum_{i=1}^p \theta_i |B_i|\), \(B_i\) denotes the \(i\)th row vector of \(B\), and the \(\theta_i \geq 0\), \(i \in [1, p]\), serve as penalty parameters. Note that in practice, the dimension of the central subspace \(h\) needs to be estimated, and to that end the bootstrap method proposed in (Sheng and Yin, 2016) can be applied. As statistic \(\mathcal{P}\), we will consider the three options presented in the previous section, which lead to sufficient variable selection by distance covariance (DCOV—SDR, Chen et al., 2018), Martingale Difference Divergence (MDD—SDR) and Ball Covariance (BCOV—SDR), respectively, the latter two options being introduced in this paper. Note that the sparse sufficient dimension reduction techniques all intrinsically achieve variable selection, and for that purpose, will interchangeably be referred to as sparse variable selection as well, e.g. DCOV—SVS.
To choose the penalty parameters, the approach from Chen et al. (2018) is followed. Consider parameters of the form
\[ \theta_i = \theta |B_i|^{-a}, \] (13)
where \( B_i \) is the \( i \)th row vector of the solution to problem (2) and \( a \) is a real number in \([0,1]\). This strategy is practical, since it turns a \( p \)-dimensional tuning parameter problem into a one-dimensional problem. To choose the tuning parameter \( \theta \), a BIC-type criterion is maximized (Li, 2007):
\[ \text{argmax}_{\theta} \log \left( \mathbb{E}^2(\tilde{X}\tilde{B}_{\theta}, Y) \right) - \frac{\log(n)(p_{\theta} - h)b}{n}, \] (14)
with \( \tilde{B}_{\theta} \) denoting the sparse solution given by \( \theta \) and \( p_{\theta} \) the number of nonzero rows of \( \tilde{B}_{\theta} \). Given that \( \rho \) is not differentiable, the local quadratic approximation (LQA) is applied as in Fan and Li (2001) and the penalty function is approximated by a quadratic function at every step of the iteration. More precisely, if \( B_n = (B_{n1}, \ldots, B_{np})^T \) is the solution to of the optimization problem in (12) at the \( n \)th iteration, then the first derivative of \( \rho(B) \) around \( B_n \) can be approximated as:
\[ \frac{\partial \rho}{\partial B} \approx \text{diag} \left( \frac{\theta |B_{11}|^{-a}}{|B_{11}|}, \ldots, \frac{\theta |B_{p1}|^{-a}}{|B_{p1}|} \right) B := H^n B. \] (15)
Using a second-order Taylor expansion of \( \rho(B) \) about \( B^n \) results in
\[ \rho(B) \approx \frac{1}{2} \text{tr}(B^T H^n B) + C_n, \] (16)
with \( C_n \) a constant with respect to \( B \). This LQA is then plugged in (12a) to obtain the sparse SDR procedure presented in Algorithm 1 below. In practice, \( a \) is set to 0.5, 0.2 and 0.8 for DCOV—SVS, MDD—SVS and BCOV—SVS, respectively. It is practicable to fix the upper bound of iterations \( N \) to 200. The tolerance \( \tau \) is set 0.001 as in Chen et al. (2018) and the starting point \( B^0 \) is taken to be the nonsparse solution from (2) obtained in python through the direpack package (Menvouta et al., 2020). To choose the penalty parameter \( \theta \), values in \([0,0.5]\) spaced by 0.01 are considered in algorithm 1 and the solution to (14) is selected. When the structural dimension \( h \) is unknown, it can be estimated using the bootstrap method of Sheng and Yin (2016) with 200 replications. The subspaceAngle method in algorithm 1 refers to the principal angle between subspaces of Knyazev and Argentati (2002).

4. Simulation study

4.1. Simulation and evaluation setup

This section aims to answer a few questions regarding the properties of different SVS methods in a data driven way. The main question to be investigated is up to which extent the individual SVS methods are able to identify the right
Algorithm 1 SVS algorithm

procedure sparseSDR($X, Y, B^0, h, \theta, \tau, a, N$)
2: $s \leftarrow 0_p,$
    $V^0 \leftarrow B^0,
4: X^0 \leftarrow X$
for $i = 1$ to $N$ do
6: $H^0 \leftarrow \text{diag}\left(\frac{\theta|V^0_{1-a}|}{|V^0_{1}|}, \ldots, \frac{\theta|V^0_{p-a}|}{|V^0_{p}|}\right)$
    $V \leftarrow \text{argmax}_V \Psi^2(X^0V, Y) - \frac{1}{2} \text{tr}(V^T H^0 V)$ s.t. $V^T X^{0,T} X^0 V = I_h$
8: if subspaceAngle($V^0, V) \leq \tau$ then break
    for $j = 1$ to $p$ do
10: if $|V_j| \leq \tau$ then
12: if $s = 1_p$ then break
    $l \leftarrow 1$
14: for $j = 1$ to $p$ do
    if $s_j = 0$ then
16: $V^0_l \leftarrow V_j$
    $X^0_l \leftarrow X_j$
18: $l \leftarrow l + 1$
    $V^\text{sol} \leftarrow 0 \in \mathbb{R}^{p \times h}$
20: $k \leftarrow 0$
    for $j = 1$ to $p$ do
22: if $s_j = 0$ then
    $V^j_\text{sol} \leftarrow V^j_k$
24: $k \leftarrow k + 1$
return $V^\text{sol}$
subset of informative variables, based on data generated according to different mechanisms. As such, the methods from Section 3 will be compared as well to established sparse variable selection tools. For the latter purpose, Sparse NIPALS, also called SNIPLS [Hoffmann et al., 2016], as well as its outlier robust counterpart, sparse partial robust M (SPRM, [Hoffmann et al., 2015], are selected. SPRM is a sparse variant of the older partial robust M-regression [Serneels et al., 2005], a well established robust alternative to partial least squares, which on its turn is proven to estimate the central subspace [Cook et al., 2016]. This will allow to evaluate up to which extent the different methods perform well when the data are generated according to linear and nonlinear models, as well as with or without outliers.

The optimization problem (12) is solved by dint of IPOPT [Wächter and Biegler, 2006], with the MUMPS solver embedded. Setting $n = 120 \ p = 24$, assuming that the dimension $h$ of the central subspace is known, and considering standard normally distributed error terms independent from the predictors, eight different data models are investigated by generating a hundred simulated datasets from each data model. The performance of each of the proposed methods is investigated for the different data models. To assess the quality of the methods, three metrics are reported:

- the True Positive Rate (TPR), defined as the proportion of correctly identified active variables,
- the False Positive Rate (FPR), defined as the proportion of inactive variable identified as active and
- the $F_1$-score, $F_1 = \frac{tp}{tp + 0.5(fp + fn)}$, where $tp$ denotes the number of correctly identified active variables, $fp$ the number of inactive variables identified as active and $fn$ the number of active variables identified as inactive.

Beyond reporting the $F_1$-score for each method, the Kruskal-Wallis non parametric ANOVA [Kruskal and Wallis, 1952] and the Conover [Conover, 1999] post-hoc tests are performed. This allows to take into account the uncertainty and error in the estimates when comparing different methods. Methods perform similarly if the $p$-value of the corresponding pairwise post-hoc test is greater than 0.05.
4.2. Data generating models

Table 1 shows the distribution of \(X\), the structure of the covariance matrix \(\Sigma\), the basis for the central subspace \(B\) and the expression for \(Y\) for each of the eight simulation study setups. The error terms \(\epsilon, \epsilon_1\) and \(\epsilon_2\) follow independent standard normal distributions and are independent from \(X\). For studies A, B and E we have \(\Sigma_{i,j} = 0.5^{|i-j|}\) and for studies C and D \(\Sigma\) is taken to be the identity matrix. The setup in Study A was taken from Chen et al. (2018), in study B from Zhang et al. (2019), in Study C from Sheng and Yin (2016), in Study D from Yin and Hilafu (2015) and in Study E from Zhang and Chen (2019). Studies F, G and H are set up as Study E, but 10% of some variables are replaced by outliers \(2 \cdot t_1\), where \(t_1\) is a Cauchy distributed random variable. The aim is to investigate which method performs best when outliers are present in the informative and/or uninformative variables, or both. In study F, outliers are added in the informative variables alone, which presumably should still lead to those variables being detected as informative and contributing to the model. Study G investigates the effect of outlying cells in the uninformative variables, which should not be selected as informative. Study H generates casewise outliers in both informative and uninformative variables.

4.3. Results

The simulation results for the eight studies are presented in Tables 2 through 4. One cannot expect a specific method to have better performance than all the other ones across all simulation studies. However, the SVS methods obtained from solving (12) are superior to the linear dimension reduction methods SNIPLS and SPRM as they return a better \(F_1\)-score than the linear methods across all 8 studies.

Studies A, B and C illustrate that increasing the level of non-linearity in the expression of \(Y\) favors DCOV—SVS and BCOV—SVS over MDD—SVS. Effectiveness with respect to nonlinearity is reflected in their \(F_1\)-scores and FPRs, which are consistently better than those of MDD—SVS. The fact that MDD—SVS performs worst is to be expected as DCOV and BCOV can detect more general forms of associations than MDD. Accounting for the mean and standard deviation of the estimated \(F_1\)-score, DCOV-SVS and BCOV-SVS perform similarly.

In the sparse categorical setting (Study D) DCOV—SVS, MDD—SVS and BCOV—SVS perform similarly in terms of \(F_1\)-score. This is an indication that although these non-linear methods are more general and are able to detect general forms of associations, they perform better when the dependent variable is continuous.

Studies E through H assess the effect outliers have on the resulting sufficient variable selection. In the absence of outliers (Study E), DCOV-SVS performs best as it is able to correctly detect the nonlinear associations between \(X\) and \(Y\). Study F presents the case where outliers are added to the active variables.
In this case, DCOV—SVS and BCOV—SVS perform similarly with an average $F_1$-score of 0.921 and 0.923, respectively. This implies that both methods show similar sensitivity to outliers in the active variables. When outliers are added to the inactive variables (Study G), DCOV—SVS performs best with an $F_1$-score of 0.896, showing that it is less sensitive to outliers in the inactive variables than both other variants. When outliers are added to all variables (Study H), the 3 nonlinear methods and SNIPLS perform similarly. This indicates that all the nonlinear methods under consideration are the most sensible to outliers when these outliers occur on a casewise basis.

Tables 5 and 6 show the average penalty parameter and the average time taken for one simulation run in seconds. Regarding the penalty parameter $\theta$, on average BCOV—SVS selects a lower penalty parameter than both other options. Howbeit, in 6 of the 8 studies considered, BCOV—SVS takes longer to fit. That said, when outliers are present in the active variables, MDD—SVS takes longer to fit. Expectedly, SPRM and SNIPLS are much faster to fit than the other methods, since they do not rely on a numerical nonlinear optimization.

5. Real data application

5.1. Boston housing data

The Boston housing data (Harrison and Rubinfeld, 1978) present a well studied data set in regression and dimension reduction analysis, which allows to compare the results to prior literature. Many reports have been published on the data, but generally an objective of interest when analyzing these data, is to understand how median house prices are impacted by a set of predictors in each of the 506 census tracts that the Boston Standard Metropolitan Statistical Area was composed of. This list of properties describing each census tract, is listed in Table 7.

The Boston Housing data are known to be skewed, particularly with respect to crime rate, which can be mitigated by removing observations greater than 3.2 for that variable, as was also suggested in Chen et al. (2018). Upon trimming, 374 observations out of the original 506 census tracts, remain.

To understand how the variables listed in Table 7 bear relation to the median house price per census tract, the central subspace can be estimated, which by definition contains all information relevant to describe the dependent variable. However, in this analysis, one cannot rule out that not all of the predictors originally considered, should contribute the central subspace, as was surmised by Chen et al. (2018) as well. These authors proceeded to apply sparse DCOV—SDR in order to obtain a sparse estimate of the central subspace and report the resulting coefficients. These results will now be compared to sparse MDD—SDR and sparse BCOV—SDR.

Following Zhou and He (2008), the dimension of the central subspace of the Boston Housing data is $h = 2$. The coefficients of the loading vectors of the SDR central subspace estimates, are presented in table 8. The optimal penalty parameters for DCOV—SVS, MDD—SVS and BCOV—SVS, were estimated to be 0.49, 0.48 and 0.17, respectively.
Due to the trimming of the crime rate variable, it makes sense that that variable no longer significantly contributes to the central subspace. Furthermore, further variables that do not contribute to explaining the median house prices are: Charles river proximity, nitric oxide concentration in ambient air, the average number of rooms per dwelling, weighted distances to employment centers, as well as radial highways. Up to some extent, one can interpret why these variables could be less important than the other ones set forward. The BCOV and DCOV based variants add two additional variables to the list: the proportion of nonretail business area and the pupil—teacher ratio, whereas the MDD based variant does capture these, which illustrates that conditional mean independence does not have the same practical implications as distributional independence. MDD does add both variables with a negative sign, which corresponds to what one would, maybe subjectively, expect. Finally, it is noted that BCOV estimates some variables with an opposite sign compared to both other techniques. These are the proportion of African Americans in the population, which as hard to interpret as this may be in 2020, may have been seen as a negative factor back in the seventies. Also, BCOV estimates the proportion of poorer residents to be a positive instead of a negative. It is hard to say what this should be on an average basis. A high ratio of low status residents may indicate disrepair, but on a local level it may correspond to an "up-and-coming" redeveloping neighbourhood as well. The BCOV measure of association being a more local estimate, based on a $n$-ball around each point, can yield a different overall outcome.

5.2. Riboflavin data

To illustrate a high dimensional setting ($n < p$), a genomics example will be put forward. The study, originally published by Bühlmann et al. (2014), aims to model riboflavin production as the single real-valued response variable from 4088 variables that measure the logarithm of the expression level of the corresponding genes. Roboflavin production is reported as the logarithm of the riboflavin production rate. The data consist of $n = 71$ samples that were hybridized repeatedly during a fed-batch fermentation process, in which different engineered strains and strains grown under different fermentation conditions were studied. The data were split randomly into a training set of 49 samples and a test set of 22 samples. Next, in order to reduce the dimensionality to tractable levels, the training set was subjected to marginal variable screening based on the distance correlation $t$-test of independence (Szekely and Rizzo, 2013) on a pairwise basis between the predictors and the response. Variables that yield a $p$-value lower than 0.01 were retained, effectively reducing the number of variables from 4088 to 854. Sparse SDR was applied to the dimension reduced training set, and the central subspace dimension was set to $h = 1$, as previously reported by Hilafu and Yin (2017). Figure 1(a) illustrates that the absolute correlation between the predictors is high, which further complicates the task of estimating the sparse central subspace. Figures 1(b), (c), (d) show the predicted and actual response for DCOV—SVS, MDD—SVS and BCOV—SVS, respectively. The predicted responses are obtained by fitting a linear regression to the latent...
variables that span the central subspace. This approach is analogous to e.g. principal component regression and can be used to predict the responses in the test set. Table 9 confirms that all sparse solutions produce a better fit to the data than the non-sparse solutions and are more parsimonious, hence justifying the need for sparse variable selection. MDD—SVS produces a better fit to the data than DCOV—SVS and BCOV—SVS. This is further illustrated in table 9 below, where MDD—SVS has the lowest Median Absolute Error (MAE). Note that the same pattern was present in the simulations of section 4: BCOV—SVS selects the lowest penalty parameter and the lowest number of predictors. Again, conditional mean independence presents a dimension reduction strategy different from distributional independence. From this example, as well as from the simulation study, it seems that MDD—SDR tends to lead to a less sparse central subspace than BCOV—SDR. In bioinformatics, a phenomenon like riboflavin production is rarely caused by the expression of a single gene, which in this case, seems to advocate for the MDD based approach from a practical perspective.

The 17 predictors selected by MDD-SVS are: 'ASD_at', 'DACA_at', 'ECSC_at', 'FLIJ_at', 'FLIY_at', 'FLIZ_at', 'FRUB_at', 'FTSE_at', 'GSIB_at', 'GUAB_at', 'ASD_at', 'DACA_at', 'ECSC_at', 'FLIJ_at', 'FLIY_at', 'FLIZ_at', 'FRUB_at', 'FTSE_at', 'GSIB_at', 'GUAB_at',...
The variables selected by the two other methods are ‘GUAB_at’, ‘HEMA_at’, ‘PKSD_at’ for DCOV-SVS and ‘MRAY_at’ for BCOV-SVS.

6. Conclusion and Outlook

In this article, sparse sufficient dimension reduction methods have been presented based on energy and ball statistics. The advantage of these methods is that they are essentially nonparametric: they can be applied with little distributional assumptions. Three approaches were investigated: sparse sufficient dimension reduction that maximizes distance covariance, martingale difference divergence, or ball covariance. Whereas the first of these approaches had been reported before (Chen et al., 2018), the two remaining approaches have been put forward in this article. The paper has presented an extensive investigation of how these approaches compare, both in a simulation setting that compares different scenarios: linear and nonlinear dependencies, with clean data and data that contain outliers, as well as in two real data examples. The approaches are based on different statistical assumptions, each of which have their pros and cons. Therefore, one cannot expect a clear winner from these investigations. However, some take home messages are that ball covariance tends to lead to a more sparse estimate of the central subspace and may account for local variations in the data. On the contrary, zero martingale difference divergence guarantees conditional mean independence, which is an overall location property, and therefore looks at the data as a whole. MDD tends to report less sparse solutions, which can be an advantage when it makes sense to interpret an interplay of variables, such as in the riboflavin production example shown. However, some statement can be made across the different methods. All SDR methods investigated have been shown to be able to detect nonlinear dependencies. The DCOV and BCOV based options proved to lead to more accurate SVS in highly nonlinear contexts. They do work with little distributional information, yet are still sensitive to outliers. To their advantage, each of the methods can be applied equally well to data with more variables than predictors and the other way around. Howbeit, while the implementations described here and in Chen et al. (2018) may be the most efficient algorithms available, all three methods tend to be computationally involved. Therefore, we see the methods find immediate application in data sets of moderate sizes. Yet further research may bring an even more efficient algorithm, such that the methods may find more widespread adoption. Future research could focus as well on more robust optimization algorithms for solving problem (12) and different statistics that could be used in Algorithm 1.

| 10        | full-value property-tax rate                                                            |
| 11        | pupil-teacher ratio by town                                                             |
| 12        | proportion of African Americans per town                                                |
| 13        | percentage of lower status of the population                                            |

Table 7: Description of predictors in the Boston Housing data set

| Method     | DCOV—SVS | MDD—SVS | BCOV—SVS |
|------------|----------|---------|----------|
| \( x_1 \)  | 0        | 0       | 0        |
| \( x_2 \)  | 0.268    | 0.040   | 0.310    | 0.198    | 0.006    | -0.0002 |
| \( x_3 \)  | 0        | 0       | -0.044   | -0.028   | 0        | 0        |
| \( x_4 \)  | 0        | 0       | 0        | 0        | 0        | 0        |
| \( x_5 \)  | 0        | 0       | 0        | 0        | 0        | 0        |
| \( x_6 \)  | 0        | 0       | 0        | 0        | 0        | 0        |
| \( x_7 \)  | -0.240   | -0.037  | -0.246   | -0.157   | -0.001   | 0.001    |
| \( x_8 \)  | 0        | 0       | 0        | 0        | 0        | 0        |
| \( x_9 \)  | 0        | 0       | 0        | 0        | 0        | 0        |
| \( x_{10} \) | -0.874   | -0.131  | -0.687   | -0.438   | 0.001    | 0.001    |
| \( x_{11} \) | 0        | 0       | -0.017   | -0.011   | 0        | 0        |
| \( x_{12} \) | 0.159    | 0.024   | 0.179    | 0.114    | -0.392   | 0.047    |
| \( x_{13} \) | -0.162   | -0.024  | -0.175   | -0.112   | 0.132    | 0.572    |

Table 8: Estimated SVS basis of the central subspace.

| Method     | DCOV—SVS | MDD—SVS | BCOV—SVS |
|------------|----------|---------|----------|
| Sparse MAE | 0.376    | 0.316   | 0.532    |
| Non Sparse MAE | 0.378   | 0.447   | 0.666    |
| \( \theta \) | 0.22     | 0.10    | 0.01     |
| Number of predictors | 3         | 17      | 1        |

Table 9: Median Absolute Error(MAE), penalty parameter \( \theta \) and number of selected variables for SVS methods.
