Abstract. The fact that spoolable reinforced plastic line pipe is more flexible and spoolable than steel, and is also much lighter, means that it can be carried and deployed from smaller vessels and managed more easily. It was well known that manganese is an important element in end-fitting of spoolable reinforced plastic line pipe. In this paper, a simple spectrophotometric method was described for the determination of manganese in end-fitting of spoolable reinforced plastic line pipe. The method was based on the oxidation-reduction reaction between ammonium persulfate and manganese(II) producing manganese(VII) in the presence of silver nitrate as a catalyst. The characteristic wavelength of maximum absorption of manganese(VII) was obtained locating at 530 nm. Under the optimum reaction conditions the absorption value was proportional to the concentration of manganese in the range of 0.50\%~1.80\% (\(R^2 = 0.9997\)), and the relative standard deviation was less than 3.0\% (n=5). The proposed method was applied successfully to determine manganese in end-fitting of spoolable reinforced plastic line pipe samples.

1. Introduction

Humanity’s insatiable demand for oil and gas is driving the exploitation of offshore reserves that are ever deeper and harder to bring to the surface. This is subjecting the risers, flowlines, tubulars and other pipe work used to access and work sub-sea locations to greater loads, pressures and environmental challenges. At the same time, pipes need to be as light as possible in order to stay within the payload capacity of floating rigs and storage platforms. The condition of gas and oil wells in the west of China has complex characteristics such as deep, high pressure, and serious corrosive that only corrosion-resistant pipes can be applied to explore. One key feature there is obvious existence of corrosive hydrogen sulfide medium. In order to meet the exploitation requirements of these oil-gas wells with high pressure and high partial pressure of H\textsubscript{2}S and CO\textsubscript{2}, the pipes must adopt new materials with excellent resistance to corrosion. Spoolable reinforced plastic line pipe (Figure 1), also known as flexible composite pipes or reinforced thermoplastic pipes (RTP), contain three layers, among which, neck bush and reinforcement layer are keys to determine mechanical and thermal properties of these pipes. These composite pipes are key to enabling the industry to meet some of the energy security challenges that nations face today. The ability to combine tailored strength with flexibility, low weight, high thermal and pressure tolerance, minimal flow resistance, high resilience and durability in large-bore pipes enables them to surpass the capabilities of current predominantly metal piping - albeit often polymer lined. The Spoolable reinforced plastic line pipe has excellent resistance to corrosion. For example, glass fibre reinforced polyoxymethylene (POM) and polypropylene (PP) performed well.
in saltwater, while carbon fibre reinforced polyetheretherketone (PEEK) proved well suited to a sour oil environment. Carbon in polyphenylenesulphide (PPS) behaved well in a sour oil environment and in hydrocarbon gas condensate at elevated temperature [1].

Figure 1: Spoolable reinforced plastic line pipe

The fact that spoolable reinforced plastic line pipe is more flexible and spoolable than steel, and is also much lighter, means that it can be carried and deployed from smaller vessels and managed more easily. Thus, spoolable reinforced plastic line pipe will be widely used in the exploitation of acid gas and oil wells. End-fitting is a mechanical device that forms the transition from the spoolable reinforced plastic line pipe to the connector. The content of elements in end-fitting of spoolable reinforced plastic line pipe directly influences the properties of materials. In order to control the quality of end-fitting products, the contents of trace impurities and alloy elements in end-fitting should be determined. In making processes, the content of alloyed elements such as nickel, manganese, chromium, molybdenum, vanadium, and so on, is required to be strictly controlled because it fundamentally determines the performance of end-fitting. It is well known that manganese is an important element in end-fitting. Therefore, a rapid and precise analytical method for the determination of manganese is essentially required for the production control of spoolable reinforced plastic line pipe.

Manganese is valuable alloying agents and coexists in a number of industrially important alloys and steels. Owing to their increasing industrial applications of manganese, the determination of trace amounts of manganese is of great interest. Therefore, it was important from the analytical point of view to develop simple, sensitive and reliable methods for the determination of manganese in various complex matrices. Numerous analytical methods were employed for the determination of manganese in different types of matrices including atomic emission spectrophotometry, atomic absorption spectrometry [2, 3], laser induced breakdown spectroscopy [4], ion chromatography [5], electroanalytical method [6] and spectrophotometry [7, 8]. Spectrophotometric methods occupy special position due to their simplicity, less expensive instrumentation and high sensitivity. Similarly, spectrophotometric methods also play an important role in manganese determination. The literatures shows that aromatic amines, azo dyes, oximes, porphyrins and other reagents have been used for the colorimetric determination of manganese. The most significant reagents are permanganate, formaldoxime and 1-(2-pyridylazonaphthol), which is far more sensitive than the other two reagents. This present method was based on the oxidation-reduction reaction between ammonium persulfate and manganese(II). Employing ammonium persulfate as an oxidant, manganese(II) was oxidized to manganese(VII) in the presence of silver nitrate as a catalyst at the room temperature. The characteristic wavelength of maximum absorption was measured at 530 nm. Under the optimum reaction conditions the absorption value (A) was proportional to the concentration of manganese in the range of 0.50%~1.80% (mass fraction), and the relative standard deviation (RSD) was less than 3.0% (n=5). The proposed method was free from the interference from a large number of analytical important elements and has been applied satisfactorily to the determination of manganese...
end-fitting of spoolable reinforced plastic line pipe samples with the improved accuracy and precision. Results were in agreement with those attained by inductively coupled plasma atomic emission spectrophotometry at the 95% confidence level. The satisfactory performance in the determination of manganese in the end-fitting of spoolable reinforced plastic line pipe demonstrated that the method was practical and suitable not only for quality control analysis but also for product analysis, confirming the promise for spoolable reinforced plastic line pipe research.

2. Experimental

2.1. Apparatus
A UV-visible spectrophotometer (Model TU-1901, Beijing Persee General Instrument Co. Ltd.) with 1.0-cm quartz cells was employed for all absorbance measurements.

2.2. General Procedures
Weigh accurately 0.1000 g of drilled low alloy steel samples and dissolve the samples in 20 mL mixture acid solution of sulphuric acid 15% (V/V) and phosphoric acid 15% (V/V) in a 150-mL taper bottle. Continue the treatment with mixture acid till the sample goes into solution and heat to fumes of oxides of nitrogen, sulphuric acid and evaporate almost to dryness. Cool the solution, add 50 mL deionised water to dissolve some materials. Then, add 5 mL of 5.0 mg·mL⁻¹ solution of silver nitrate, 10 mL of 200.0 mg·mL⁻¹ solution of ammonium persulfate in the taper bottle to oxidate manganese(II) to manganese(VII) oxidation states. Boil the solution to no bubble and cool the solution at room temperature. Finally, dilute the solution in a 100-mL volumetric flask, followed make up to the mark with deionised water, mix well and let stand for 10 min. Then, transfer the above mulberry stock solution in 1.0-cm quartz cells. Add 5.0 mg·mL⁻¹ solution of sodium nitrite to the remaining solution reduce manganese(VII) to the lower oxidation states, this transparent solution was employed as the blank solution in subsequent experiments. Measure the absorbance at 530 nm using a UV-visible spectrophotometer with 1.0-cm quartz cells against a reagent blank prepared similarly. Plot the amount of manganese in the sample solution against absorbance to obtain the calibration graph.

3. Results and Discussion

3.1. Spectral Characteristics
The absorption spectra of the reagents blank, manganese(VII) against the reagent blank were tested from 400 nm to 700 nm. It could be seen from Figure 2, the manganese(VII) yields the characteristic wavelength of maximum absorption at 530 nm wavelength. However, the absorption spectrum of the reagents blank under similar conditions shown that it does not absorb at 530 nm. And the experimentation also demonstrated that manganese(VII) increases the absorbance value considerably, resulting in increased sensitivity of the method. Therefore, measure the absorbance of manganese(VII) at 530 nm.

3.2. Select Dissolved Acid for Low Alloy Steel Samples
The effect of the different acids for dissolve the low alloy steel samples was examined. It was found that a solution mixed with 15% (V/V) sulphuric acid and 15% (V/V) phosphoric acid has a good effect for dissolve the low alloy steel samples. Thus, an acid solution mixed with 15% (V/V) sulphuric acid and 15% (V/V) phosphoric acid was recommended for dissolve the low alloy steel samples in subsequent studies.

3.3. Influence of the Amounts of Oxidant
Ammonium persulfate was selected as the oxidant in the proposed method. The effect of the oxidant was examined by measuring the absorbance of solution containing certain amounts of manganese(II) and variable amounts of ammonium persulfate. It was found that 10 mL of 200.0 mg·mL⁻¹ solution of ammonium persulfate sufficed to oxidate the amounts of manganese(II) taken, with higher concentrations the absorbance was essentially constant. Ten millilitres of 200.0 mg·mL⁻¹ ammonium
persulfate solution were recommended as a suitable amount of oxidant.

3.4. Influence of the Amounts of Silver Nitrate

The oxidation-reduction reaction between manganese(II) and ammonium persulfate without a catalyst was slowly and not fully. Selected the silver nitrate as a catalyst for the oxidation-reduction reaction between manganese(II) and ammonium persulfate. It has been further observed that the oxidation-reduction reaction between manganese(II) and ammonium persulfate occurs immediately even at room temperature if silver nitrate was used. Therefore, 5 mL of 5.0 mg·mL⁻¹ solution of silver nitrate was employed in subsequent experiments.

3.5. Influence of the Reductant

Sodium nitrite was selected as the reductant in the proposed method. 5.0 mg·mL⁻¹ solution of sodium nitrite reduce manganese(VII) to the lower oxidation states manganese(II). The transparent solution was employed as the blank solution in subsequent experiments.

3.6. Sequence of Addition of Reagents

From experiments in which sulphuric acid, phosphoric acid, ammonium persulfate and silver nitrate were added in all possible orders. It was found that there was no appreciable change in the colour of the solution and the variations in the absorbance values. These phenomena demonstrate that the oxidation-reduction reaction between manganese(II) and ammonium persulfate was independent of the order of addition.

3.7. Preparation of the Calibration Graph

Under the optimal conditions, a series of standard solutions of manganese were prepared by the different steel certified reference materials in a 100-mL volumetric flask. Add 5 mL of 5.0 mg·mL⁻¹ solution of silver nitrate, 10 mL of 200.0 mg·mL⁻¹ solution of ammonium persulfate followed make up to the mark with deionised water, mix well and let stand for 10 min. Measure the absorbance at 530 nm using a UV-visible spectrophotometer with 1.0-cm quartz cells against a reagent blank. The absorbance of the solution was proportional to the concentration of manganese in the range of 0.50%~1.80% (mass fraction). Plot the amount of manganese in the sample solution against absorbance to obtain the calibration graph. The linear regression equation for manganese was \( A = 0.41837C - 0.01073 \), \( R^2 = 0.9997 \), and the relative standard deviation (RSD) was less than 3.0% (n=5).

3.8. Interference Studies

![Figure 2 Absorbance-wavelength profile](image_url)
The extent of interference by diverse ions was determined by measuring the absorbance of solutions containing manganese and various amounts of diverse ions. The criterion for interference was an absorbance value varying by more than $\pm 2\%$ from the expected value of manganese alone. The results show that a large excess of cations and anions which are usually associated in the determination of manganese do not interfere. The colorless metal ions do not interfere. The tolerable amounts of foreign species with respect to manganese for interference at $+2\%$ level were over 200~300 for the colored metal ions. When the colored metal ions contents of not more than 200~300 times manganese, it can be in some color solution adding a few drops of EDTA solution or sodium nitrite solution to fade the color, this solution as the measured reference solution to eliminate the interference. There was not obvious interference ions exist in end-fitting of spoolable reinforced plastic line pipesamples.

4. Applications

4.1. Determination of Manganese in End-Fitting

The recommended procedure has been applied satisfactorily to the determination of manganese in end-fitting of spoolable reinforced plastic line pipe samples. The samples were dissolved according to the following procedure: Dissolve 0.1000 g of drilled end-fitting of spoolable reinforced plastic line pipe samples in 20 mL mixture acid solution of sulphuric acid 15% (V/V) and phosphoric acid 15% (V/V) in a 150-mL taper bottle. Continue the treatment with mixture acid till the sample goes into solution and heat to fumes of oxides of nitrogen, sulphuric acid and evaporate almost to dryness. Cool the solution, add 50 mL deionised water to dissolve some materials. Then, add 5 mL of 5.0 mg·mL$^{-1}$ solution of silver nitrate, 10 mL of 200.0 mg·mL$^{-1}$ solution of ammonium persulfate in the taper bottle to oxidate manganese(II) to manganese(VII) oxidation states. Boil the solution to no bubble and cool the solution at room temperature.Finally, dilute the solution in a 100-mL volumetric flask, followed make up to the mark with deionised water, mix well and let stand for 10 min. Then, transfer the above mulberry stock solution in 1.0-cm quartz cells. Add 5.0 mg·mL$^{-1}$ solution of sodium nitrite to the remaining solution reduce manganese(VII) to the lower oxidation states, this transparent solution was employed as the blank solution in subsequent experiments. Measure the absorbance at 530 nm using a UV-visible spectrophotometer with 1.0-cm quartz cells against a reagent blank. The results were summarized in Table 1 with the good accuracy and precision. To verify the results obtained by the proposed method, inductively coupled plasma atomic emission spectrophotometry method was applied to determine the samples according to the literature and the results obtained by the proposed method agreed well with that from the reference method.

5. Conclusions

Based on the oxidation-reduction reaction between manganese(II) and ammonium persulfate, a simple and accurate spectrophotometric method for determination of manganese in the end-fitting of spoolable reinforced plastic line pipe was proposed. The purple-red colored manganese(VII) solution exhibits absorption maximum at 530 nm. The proposed method was free from the interference from a large number of analytical important elements and has been applied satisfactorily to the determination of manganese in end-fitting of spoolable reinforced plastic line pipe samples. Compared with other methods for the determination of manganese, this method offers advantages of simplicity, less expensive instrumentation and high efficient. The satisfactory performance in the determination of manganese in end-fitting of spoolable reinforced plastic line pipe demonstrated that the method was practical and suitable not only for quality control analysis but also for product analysis, confirming the promise for spoolable reinforced plastic line pipe research.
