Abstract. In this paper, we prove that, under Bandt’s finite type condition, a self-similar set is totally disconnected if and only if the $\mathcal{E}$-connected families on every level are uniformly finite.

1. Introduction

Let $\{f_i\}_{i=1}^m$ be an iterated function system (IFS) on $\mathbb{R}^d$, where $f_i$ are contractive similitudes satisfying $|f_i(x) - f_i(y)| = r_i|x - y|$ for any $x, y \in \mathbb{R}^d$ and $0 < r_i < 1$ which are called contraction ratios. Hutchinson [6] proved that there exists a unique nonempty compact subset $K$ of $\mathbb{R}^d$ such that

\begin{equation}
K = \bigcup_{i=1}^m f_i(K).
\end{equation}

We call $K$ a self-similar set. By iteration, for each $k \geq 1$, we have $K = \bigcup_{i \in \Sigma_k} f_i(K)$ where $\Sigma = \{1, \ldots, m\}$ and $i = i_1 \cdots i_k$ means a finite word, $f_i = f_{i_1} \cdots f_{i_k}$ a composition of maps. We write $K_i = f_i(K)$. When the contraction ratios are distinct, we need some modification to make the pieces $K_i$ have approximately the same size.

Let $r = \min_i r_i$. For $n \geq 1$, define the $n$-th level of finite words by

$$\Lambda_n = \{i = i_1 \cdots i_k: r_1 \leq r^n < r_{i_1} \cdots r_{i_{k-1}}\}.$$ 

Then the self-similar set can be written as

$$K = \bigcup_{i \in \Lambda_n} K_i.$$ 

If a word $i \in \Lambda_n$, we denote its length by $|i| = n$. Let $W \subset \Lambda_n$, we call the family of sets $\{K_i: i \in W\}$ an $\mathcal{E}$-connected family if for any distinct $i, j \in W$, there exist $i_1, \ldots, i_k \in W$ satisfying $i = i_1, j = i_k$ and $K_{i_1} \cap K_{i_{k+1}} \neq \emptyset$, $\ell = 1, \ldots, k - 1$.

In 1985, Hata [5] first studied the structure of self-similar sets and showed that a self-similar set $K$ is connected if and only if $\{K_i: i \in \Sigma\}$ is an $\mathcal{E}$-connected family. Since then, the relevant topological questions on self-similar sets have attracted considerable attention. Many researches involve connectedness, local connectedness and disk-likeness of self-similar sets or self-affine tiles (see [8][3][11][12][10] and references therein).

This short paper is about self-similar sets $K$ which are not connected, but may contain connected subsets. The following claim is well-known and easily proved:

If there is a connected subset $S$ with more than one point, then there are $\mathcal{E}$-connected families of arbitrary length.

Indeed, a minimal covering of $S$ by sets $f_i(K)$ from $n$-th level must be $\mathcal{E}$-connected. The by triangle inequality, the sum of the diameters of the sets $f_i(K)$ must be at least the diameter of $S$. Thus the number $N$ of the sets must fulfill $|S| \leq N(r_{\text{max}})E,$ where $r_{\text{max}} = \max_i r_i$ and $|E|$ denotes the diameter of the set $E.$ Therefore, $N$ tends to infinity when $n$ goes to infinity.

However, the reverse of the claim was unknown. In this note we will prove that if Bandt’s finite type condition (see the definition in Section 2) is fulfilled, then the reverse of the claim is true. There is a simple example showing that some separation condition of finite type (here we call Bandt’s finite type). Let collaborators [1, 2] formulated a separation condition of finite type (here we call Bandt’s finite type). Let $K$ be a self-similar set as in (1.1). If there are only finitely many neighbor maps $h := f_i^{-1} f_j$ with $K \cap h(K) \neq \emptyset$ (or equivalently $f_i(K) \cap f_j(K) \neq \emptyset$) and with $i, j \in \Lambda_n$ for any $n \geq 1$, then the self-similar set $K$ is called to be of Bandt’s finite type.

Bandt’s finite type condition is a direct extension of Lagarias’ condition [9] for patterns and tilings which states that a tile should have only finitely many neighborhoods of surrounding tiles. On the other hand, Ngai and Wang [13] have a similar finite type condition, which differs in Kenyon’s example (see [7][4]) and in self-similar sets with incommensurable contraction ratios.

The following result was due to Bandt and Mesing [1], which is immediate from the definition. Here we provide a short proof for the sake of completeness.

**Lemma 2.1.** A self-similar set $K$ is of Bandt’s finite type if and only if for any $R > 0$,

$$\#\{f_i^{-1} f_j : i, j \in \Lambda_n, n \geq 1, \text{ and } f_i^{-1} f_j(K) \cap B(0, R) \neq \emptyset\} < \infty.$$  

**Proof.** The sufficiency is trivial since there exists a ball large enough such that $K \subset B(0, R)$. For the converse part, without loss of generality, we assume $0 \in K$. Let $i, j \in \Lambda_n$ and $h = f_i^{-1} f_j$ be a neighbor map of level $n$ if $K \cap h(K) \neq \emptyset$. The neighbor maps can be generated recursively from level $n$ to level $n + 1$ in the sense that if $h = f_i^{-1} f_j$, then the neighbor maps of level $n + 1$ for the pieces $K_{i,1}$ and $K_{j,1}$ of $K_i$ and $K_j$, respectively, is given by

$$g = f_i^{-1} f_i^{-1} f_j f_{j,1} = f_i^{-1} h f_{j,1},$$

where $i_1, j_1$ are finite words such that $i_1, j_1 \in \Lambda_{n+1}$. Hence we can obtain all neighbor maps in this way.

If $K \cap h(K) = \emptyset$, then the distance $d(K, h(K)) := \inf\{|x - y| : x \in K, y \in h(K)\}$ is positive, we set $d(K, h(K)) > \epsilon > 0$. For any $g = f_i^{-1} h f_{j,1}$, it follows that

$$d(K, g(K)) = d(f_i^{-1}(K_{i,1}), f_i^{-1} h(K_{j,1})) = r_i^{-1} d(K_{i,1}, h(K_{j,1})) \geq \epsilon/r_i.$$
For any $R > 0$, the distance can be larger than $R$ by several steps of generating, and $g(K) \cap B(0, R) = \emptyset$. That is, the number of neighbor maps $h$ satisfying both $h(K) \cap K = \emptyset$ and $h(K) \cap B(0, R) \neq \emptyset$ is finite. Suppose Bandt’s finite type condition holds, then the number of neighbor maps $h$ satisfying both $h(K) \cap K \neq \emptyset$ and $h(K) \cap B(0, R) \neq \emptyset$ is finite as well. Consequently, the necessity follows. \qed

**Theorem 2.2.** Suppose a self-similar set $K$ as in (1.1) is of Bandt’s finite type. If $K$ is totally disconnected then the $\mathcal{E}$-connected families on every level are uniformly finite.

**Proof.** Let $R > 3r^{-1}|K|$ where $|K|$ denotes the diameter of $K$. We may assume the origin $0 \in K$. Let $\{g_i\}$ be the collection of maps of the form $f_i^{-1}f_j$ satisfying $g_i(K) \subset B(0, R)$ where $i, j \in \Lambda_n, n \geq 1$. Since $K$ is of Bandt’s finite type, by Lemma 2.1, there are only finitely many of such maps, say, $g_1, \ldots, g_N$. Denote $F = \bigcup_{i=1}^N g_i(K)$, then $F \subset B(0, R)$. Note that if $K$ is totally disconnected, then so is $F$.

We first claim that: for $i' \in \Lambda_p$, $j \in \Lambda_n$ with $p \leq n$, if $f_{i'}^{-1}(K_j) \subset B(0, 2r^{-1}|K|)$ then $f_{i'}^{-1}(K_j) \subset F$. Indeed, let $i' = i_1 \cdots i_p \in \Lambda_p, j = j_1 \cdots j_n \in \Lambda_n$ where $p \leq n$. Clearly

$$f_{i'}^{-1}(K_j) = f_{i_1 \cdots i_p}^{-1}(K_{j_1 \cdots j_n}) \subset f_{i_1 \cdots i_p}^{-1}(K).$$

Since $|f_{i_1 \cdots i_p}^{-1}(K)| \leq r^{-1}|K|$ and $f_{i'}^{-1}(K_j) \subset B(0, 2r^{-1}|K|)$, it follows that

$$f_{i_1 \cdots i_p}^{-1}(K) \subset B(0, 3r^{-1}|K|) \subset B(0, R).$$

Thus $f_{i'}^{-1}(K_j)$ is a subset of $F$ by the definition of $F$.

Now suppose there is an $\mathcal{E}$-connected family $\{K_{i(j)} : j = 1, \ldots, k\}$ in level $n$. Without loss of generality, we let $\{K_{i(j)} : j = 1, \ldots, \ell(k)\}$ be the maximal subset of the $\mathcal{E}$-connected family such that any two consecutive elements meet and non-consecutive elements do not intersect. From Bandt’s finite type condition, it is trivial to see that if $k$ tends to infinity then $\ell(k)$ also tends to infinity. Let $i^{(1)} = i_1 \cdots i_n \in \Lambda_n$. For $0 \leq p \leq n$, we define a set

$$G_p := \bigcup_{j=1}^{\ell(k)} f_{i_1 \cdots i_p}^{-1}(K_{i^{(j)}}).$$

Then one part of $G_p$, i.e., $f_{i_1 \cdots i_p}^{-1}(K_{i^{(j)}}) = K_{i_p+1 \cdots i_n} \subset K \subset B(0, |K|)$. Especially, $G_0 = \bigcup_{j=1}^{\ell(k)} K_{i^{(j)}} \subset K \subset B(0, |K|)$. The diameter of $G_p$ is a monotonic increasing function about $p$. Moreover, if we take $\ell(k)$ large enough (i.e., $\ell(k) > N + 1$) then $G_n$ will be not contained in $B(0, R)$ by the argument in the first paragraph. Hence we can choose a suitable $p$ such that $G_p$ is contained in the ball $B(0, 2r^{-1}|K|)$ but not contained in $B(0, 2|K|)$. The first restriction guarantees $G_p$ is a subset of $F$ by the above claim. The second restriction implies there is a $\delta_k$-path in $F$ from $x$ to $y$, where $x \in K \subset B(0, |K|), y \notin B(0, 2|K|)$ (see Figure 1) and $r^{n-p+1}|K| \leq \delta_k \leq r^{n-p-1}|K|$. Denote this $\delta_k$-path by $\Gamma_k$.

Next we argue that $n - p$ tends to infinity when $k$ goes to infinity. Otherwise, if $n - p$ is bounded by a number $q$, then the diameters of the sets $f_{i_1 \cdots i_p}^{-1}(K_{i^{(j)}}), 1 \leq j \leq \ell(k)$ are larger than $r^{q+1}|K|$. This implies that $B(0, R)$ will contain arbitrarily many cylinders of size $r^{q+1}|K|$, which is impossible.
Hence we have a sequence of $\delta_k$-paths $\{\Gamma_k\}$ in $F$, which starts from a point in $B(0,|K|)$ and ends at a point out of $B(0,2|K|)$. Let $\Gamma$ be a convergent point of $\Gamma_k$ under the Hausdorff metric $d_H$ [6]. Then $\Gamma \subset F$ and $\Gamma$ is connected. Indeed, for any $x \in \Gamma$ and any $\epsilon > 0$, the ball $B(x,\epsilon)$ must intersect some $\Gamma_k$ and hence $B(x,\epsilon) \cap F \neq \emptyset$. That is, $x$ is an accumulation point of $F$, and then $x \in F$ by the compactness of $F$. Secondly, if $\Gamma$ is not connected, then $\Gamma$ has a separation $\Gamma = A \cup B$ where $A$ and $B$ are nonempty closed sets and thus are compact sets, and

$$
\epsilon := \inf \{|a-b|; a \in A, b \in B\} > 0.
$$

Let $\Gamma_k$ be a $\delta$-path such that $d_H(\Gamma_k, \Gamma) < \epsilon/3$ and $\delta < \epsilon/3$. Then $\Gamma_k$ is contained in an $\epsilon/3$-neighborhood of $A$ and $B$, and $\Gamma_k$ cannot be a $\delta$-path. That completes the proof. \qed
