ABSTRACT
We describe the serendipitous discovery of a radio point source in a 618-MHz image of the supernova remnant (SNR) G76.9+1.0. The SNR has a bipolar structure and the point source is located near a faint bridge of emission joining the two lobes of emission. The point source was also detected in follow-up higher frequency (1170 MHz) observations. The spectral index for the point source obtained from the Giant Metrewave Radio Telescope (GMRT) observations is $\alpha = -2.1^{+0.45}_{-0.36}$. The steep spectrum as well as the location of the point source near the centre of the SNR establishes the fact that it is indeed the pulsar J2022+3842 associated with this SNR. The weighted-mean radio position of this point source is $\alpha = 20^h22^m21.69 \pm 0'.11$, $\delta = 38^\circ42'14.8 \pm 1'.7$, J2000. Consistent with this, subsequent analysis of archival Chandra X-ray data shows a point source coincident with the radio point source, as well as diffuse extended X-ray emission surrounding the unresolved source. However, no pulsed emission was detected despite deep searches at both 610 and 1160 MHz, although pulsed emission has been seen at 2 GHz. It appears that the most likely reason for not detecting the pulsed signal at the GMRT is temporal broadening: for the estimated Dispersion Measure (DM) towards this SNR, the pulse broadening time could be as large as tens of milliseconds. The diffuse X-ray emission is elongated along the same direction as the bipolar structure seen in the radio. We interpret the radio lobes as having been formed from an equatorial wind. Although direct detection of pulsed signal has not been possible, we show convincingly that sensitive, high-resolution radio imaging at multiple frequencies is a useful method to search for pulsar candidates.

Key words: radiation mechanisms: general – stars: neutron – pulsars: general – pulsars: individual: J2022+3842 – supernovae: individual: 976.9+1.0 – ISM: supernova remnants.

1 INTRODUCTION
The source G76.9+1.0 was first identified by Wendker, Higgs & Landecker (1991) in a Dominion Radio Astrophysical Observatory (DRAO) survey of the Cygnus X region. Those authors tentatively identified it as a Galactic supernova remnant (SNR), but, because of the limited resolution of their survey, were unable to come to a firm conclusion. From follow-up Very Large Array (VLA) multifrequency observations Landecker, Higgs & Wendker (1993) showed it to have a two-lobed structure, with the lobes themselves joined by a bridge of emission, i.e. morphologically very similar to the pulsar wind nebula (PWNe) DA495 [see e.g. Kothes et al. (2008) for a detailed discussion on DA495].

From the observed rotation measure Landecker et al. (1993) conclude that it is further than 7 kpc. The spectral index they measured for the source was $\alpha = -0.62 \pm 0.04$ where $S(\nu) \propto \nu^{\alpha}$. This is somewhat steep for a filled-centre remnant. None the less, based on its morphological similarity to DA495, both Landecker et al. (1993) and Kothes et al. (2006) suggest that G76.9+1.0 is also a PWNe. For G76.9+1.0, the integrated flux density at the lowest available frequency (327 MHz) is substantially discrepant: Landecker et al. (1993) suggest that this might be because extended emission was resolved out in the 327-MHz image. Here we present a Giant Metrewave Radio Telescope (GMRT) 618-MHz image of this source. This image was obtained as part of a test observation whose original aim was to test a scheme for online system temperature correction of the visibility data. The target was selected from Green (2009a,b) for two reasons: (i) it is located in the Galactic plane, where it would be useful to test our experimental scheme and (ii) the GMRT, being sensitive to both large- and small-scale emission, could settle questions on its unclear morphological type. The
GMRT has a hybrid configuration which allows imaging of both the smooth extended emission and fine scale structure with data taken in a single observing run. The observations and results presented in this paper however provide strong support for the interpretation that G76.9+1.0 is a pulsar wind nebula (PWNe).

The rest of this paper is organized as follows. In Section 2, we describe our 610-MHz GMRT observations and results, which led to the serendipitous detection of the radio point source. In Section 3, we describe a subsequent search for pulsed emission at 610 MHz, unaware that a search had already been carried out (Arzoumanian et al. 2010). Since no pulsed emission was detected, we followed up the 610-MHz observations with 1170-MHz observations, with the aim of both mapping the point source and searching for pulsed emission; the reasons behind this renewed search, its details and results are described in Section 4. In order to better understand the source, we also analysed archival Chandra data for this region. We present in Section 5 the analysis and modelling of Chandra X-ray data. A discussion of the results can be found in Section 6.

2 GMRT 610-MHz OBSERVATIONS

2.1 Observing and analysis details

The SNR G76.9+1.0 was observed on 2009 June 24 using the GMRT hardware correlator. Flux and bandpass calibration were based on scans of the standard calibrators 3C286, 3C48 and 3C147; the VLA calibrator 2052+365 was used for phase calibration. Although the GMRT correlator produces 128 spectral channels across each of two 16-MHz wide sidebands, only the upper sideband data were used for analysis because of problems with the data in the lower sideband. The centre frequency of the resulting image is hence 618 MHz. Throughout the observation, the Automatic Level Control (ALC) was kept switched off. Data reduction was done using AIPS. Bad data were flagged; data calibrated on a single channel and solutions were applied to all channels by bandpass calibration. The strong source 4C39.61 at the edge of the field of view was first imaged and subtracted out. The rest of the field was then imaged (and self-calibrated) using 37 facets.

2.2 Results

The low-resolution 618-MHz continuum map is shown in Fig. 1. The GMRT has a hybrid configuration (Swarup et al. 1991) with roughly half the antennas in a central region approximately 1 × 1 km² across. The remaining antennas are spread along three ~14 km long arms, giving a maximum baseline length ~25 km. This image is made using essentially only the data from antennas in the central square of the GMRT (i.e. using a Gaussian ultraviolet taper with the 30 per cent level at 2.5 kλ) and has a resolution of 54 × 51 arcsec². The morphology matches well with the double-lobed structure joined by a diffuse bridge of emission noted in earlier studies (Landecker et al. 1993; Kothes et al. 2006). The total integrated flux density from the remnant, uncorrected for foreground contribution or absorption, is 2.36 ± 0.28 Jy. The rms noise on the integrated flux is 45 mJy; however, we have folded in a 10 per cent error (0.236 Jy) to account for possible systematics (for this observing mode with the GMRT, from similar observations in the past) in the calibration. The GMRT 618-MHz flux measurement is plotted along with other previous measurements (from Landecker et al. 1993) in Fig. 2. The earlier spectral index measurement obtained by Landecker et al. (1993) excluded certain measurements. Their reasons included possible under-representation of large-scale emission due to poor υ-coverage in the measurements they excluded for spectral fitting. Including the new GMRT flux measurement, but following Landecker et al. (1993) in excluding the discrepant measurements at 327, 1408, 1490 and 4850 MHz, the spectral index we measure is α = −0.62 ± 0.04. We used the same 618-MHz data to search for compact sources by making an image after excluding all baselines shorter than 10 kλ. A point source with a peak flux density of 680 ± 58 μJy at α = 20°22′21″71, δ = 38°42′15″0, J2000, near the bridge of emission joining the two lobes is clearly detected. This is shown in Fig. 3, with the 618-MHz contours of Fig. 1 overlaid. Its location makes it a very promising candidate for the central pulsar associated with this PWNe. The error on the position is half of the synthesized beam – in this case ~2.5 arcsec. The error on the position as returned by a Gaussian fit to the

Figure 1. The 618-MHz continuum map of G76.9+1.0 obtained with the GMRT. The contours are at 5 per cent levels, the lowest contour is 20 per cent and the peak contour is 102 mJy beam⁻¹. The restoring beam used is 54 × 51 arcsec² so as to image the extended emission. The cross marks the position of a point source discovered in these data.

Figure 2. Spectrum of G76.9+1.0, with the GMRT 618-MHz measurement shown in blue. Integrated flux densities at 408 MHz, 618 MHz, 2.695 GHz and 4.8 GHz give a power-law fit with an index α = −0.61 ± 0.03 shown in green.

Figure 3. A diffuse source with a position uncertainty of 1.5 arcsec discovered in 618-MHz GMRT data. The peak integrated flux density is 4.83 ± 1.67 mJy beam⁻¹. The error is 70 per cent. The Chandra contour is overlaid. The position of the point source is marked by a cross.

bad channels and sections of the pulsar search data corresponding

to the presence of intermittent RFI. Therefore, the centre frequency

of the resulting image is ~1160 MHz.

4 GMRT L-BAND OBSERVATIONS

The lack of pulsation was puzzling, since the location of this source made it highly likely to be the central pulsar in this SNR. The fact that radio continuum emission was detected also ensures that this putative pulsar is beamed towards us. Possible causes for this include the following: (i) the rotation and magnetic axes of the pulsar are aligned; (ii) the pulse is significantly broadened at low frequencies and (iii) the pulse period is near 20 ms where there is significant power line generated Radio Frequency Interference (RFI). Since the second of these seems a priori the most likely, a follow-up higher frequency GMRT pulsar search was made at 1170 MHz.

4.1 Observing and analysis details

G76.9+1.0 was observed at 1170 MHz with the GMRT on 2010 June 16. Data were recorded simultaneously in the interferometric and phased array modes. All the available antennas were used to obtain visibilities in the interferometric mode, whereas only the central square and the first arm antennas were added in phase to obtain the pulsar search data. The visibilities as well as the pulsar search data were recorded separately as 256-channel, 33-MHz baseband data with the GMRT Software Backend (GSB; Roy et al. 2010). 3C147 and 3C286 were used as primary calibrators for interferometric observations. 2052+365 was observed every 45 minutes for interferometric observations to enable phase calibration and interpolation, which simultaneously also served as phasing scans for the pulsar search observation. The data reduction and analysis were very similar to that of the earlier 610-MHz observations. Regrettably, the upper half of the 33-MHz bandwidth was not usable due to the presence of intermittent RFI. Therefore, the centre frequency of this putative pulsar is beamed towards us. Possible causes for this include the following: (i) the rotation and magnetic axes of the pulsar are aligned; (ii) the pulse is significantly broadened at low

4.2 Results

G76.9+1.0 is ~9 × 12 arcmin² in size, and much of its flux is expected to be resolved out at the GMRT at 1160 MHz. Hence, no attempt was made to measure its total flux at 1160 MHz. The full-resolution image (Fig. 4) however shows a clear detection of the point source seen earlier at 618 MHz. The position measured from the 1160-MHz data (α = 20°22′21′′67, δ = 38°42′14″5, J2000) is in excellent agreement with that measured at 618 MHz. Here again, the positional uncertainty is ~1.7 arcsec. The measured flux density at 1160 MHz is 171 ± 22 µJy, giving a spectral index of α = −2.1+0.45+0.36. To cross-check the calibration, we reprocessed archival 1465-MHz VLA data for this field. A comparison of the flux densities measured by the VLA and the GMRT for the four brightest sources is shown in Table 1. As can be seen, they are in good agreement.

The pulsar search attained a detectability limit of 100 µJy, similar to the 610-MHz figure. Given that the time-averaged flux density of the source at this same epoch is ~170 µJy, one would have expected the pulsar emission to have been easily detected. However, no pulsed emission was detected despite searching through a DM range of 1–500 pc cc⁻¹ (using the same procedure as used earlier at 610 MHz). We discuss this further in Section 6.1.

Given the lack of detection of pulsed emission, it is difficult to assert with certainty that the point source that we see is indeed the central pulsar in this SNR. X-ray observations could however provide support to this interpretation. A search of the Chandra archival data revealed that this source had indeed been observed...
The central point source in G76.9+1.0

Figure 4. The point source seen at the same position at 1160 MHz with the GMRT. The beam in this full-resolution map is 3.4 × 2.2 arcsec$^2$ and the map rms noise is 22 µJy. The peak flux density of the unresolved source is 171 µJy.

Table 1. A comparison between GMRT 1160-MHz and VLA 1465-MHz flux densities is shown in this table for the four brightest sources around G76.9+1.0, excluding 4C39.61. The VLA 1465 MHz C/D array data were taken on 1988 May 17. The leftmost column gives the right ascension and declination in J2000 coordinates.

and that data were available in the public domain. We discuss next archival Chandra X-ray data for this source.

5 Chandra X-RAY DATA AND ANALYSIS

ACIS-S detector data from the 2005 August 1 Chandra observation of G79.6+1.0 (exposure time 54.4 ks) was downloaded from the archive. The unprocessed Chandra X-ray image in the 0.3–7 keV band is shown in Fig. 5. An unresolved source is detected at $\alpha = 20^h22^m21^s.7$, $\delta = 38^\circ42^\prime14^\prime$.8, J2000, establishing unambiguously that the radio counterparts at 618 and 1160 MHz are the same objects. The overall 90 per cent uncertainty circle of Chandra X-ray absolute position has a radius of 0.6 arcsec. We reprocessed the Level 1 event files from the observation using the latest version of the Chandra Interactive Analysis of Observations software (CIAO 4.2) and calibration data base (CALDB 4.2), and filtered them using the good time interval files to obtain the Level 2 event files. We extracted the ACIS-S image in the 0.3–7 keV band and smoothed it by convolving with a Gaussian of full width at half-maximum (FWHM) of 2 pixel. The smoothed image is shown in Fig. 6.

Figure 5. The point source seen at the same position in the raw 0.3–7 keV Chandra image, establishing unambiguously that the radio counterparts at 618 and 1160 MHz are the same objects. The GMRT 618-MHz contours are overlaid to highlight the location of the compact X-ray source with respect to the diffuse radio bridge of emission.

Figure 6. The observed ACIS-S image (top left panel), the model image (top right panel) in the 0.3–7 keV band. The residual image (observed model) is shown in the bottom panel.

Monthly Notices of the Royal Astronomical Society © 2011 RAS
The observed ACIS-S spectral data, the best-fitting model consisting of an absorbed power-law component, and the deviations of the observed data from the model.

from the model are shown in Fig. 8. The observed 0.5–8 keV flux is $4.6 \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$ and the corresponding unabsorbed flux is $5.9 \times 10^{-13}$. Addition of a blackbody component does not improve the fit ($\Delta \chi^2 = -0.7$ for two additional parameters). Similarly, an additional power-law component is not required by the data.

6 THE NATURE OF THE CENTRAL POINT SOURCE

One can compute the approximate age of the remnant and therefore of the neutron star. We invoke equipartition between the magnetic field and the particles to obtain the equipartition pressure. An unbroken power law with $\alpha = -0.61$ in the range 10 MHz–10 G Hz gives a radio synchrotron luminosity of $L_r \sim 8 \times 10^{36}$ erg s$^{-1}$. The pressure obtained from the equipartition magnetic field – $P_{eq} \sim 0.6$ mG – is $P \sim 1.5 \times 10^{-8}$ erg cm$^{-3}$. The mean expansion velocity, $\sim 1000$ km s$^{-1}$, gives an estimate of the age of the neutron star as $\sim 5 \times 10^5$ kyr, where $n_p$ is the particle number density. For a mean particle density of 1 cc$^{-1}$, the approximate age of the remnant is 5 kyr.

6.1 Non-detectability of the radio pulsar

The location, steep radio spectrum and the X-ray counterpart of the point source make a strong case for assuming that it arises from the central pulsar associated with this SNR. The lack of detection of pulsed emission is however puzzling. Lorimer, Lyne & Camilo (1998) had also failed to detect pulsed emission from G76.9+1.0; however, their limits are substantially weaker than those presented here. In Section 4 we had advanced three possibilities for the lack of pulsed emission. Out of the three, the most likely cause for the lack of pulsed emission appears to be temporal broadening. The expected temporal broadening using equation (7) from Bhat et al. (2004) is

$$\log(\tau_d) \approx a + b \ log(DM) + c \ (\log(DM))^2 - \alpha \ \log(\nu),$$

where $a = -6.46, b = 0.154, c = 1.07$ and $\alpha = 3.86$. Here, the temporal broadening $\tau_d$ is in ms and observing frequency $\nu$ is in GHz. For the DM range of 250–500 pc cc$^{-1}$, the expected pulse broadening at 618 and 1170 MHz are 8–380 and 0.6–30 ms, respectively. Clearly, if the DM lies in the upper end of the likely...
range and the pulsar has a period in the 10–30 ms range, the pulse broadening will be comparable to the pulse period, making it very difficult to detect the pulsar. We note in this context that during the pulsar search candidates were identified by summing up to 16 harmonics, and hence even if only the fundamental alone was statistically significant the pulsar should have been detected. The period of the pulsar (J2022+3842) is \( \sim 24 \) ms, and the DM is \( 430 \) pc cc\(^{-1}\) (Arzoumanian & Ransom, private communication), consistent with our non-detections at lower frequencies. Their 2-GHz flux of \( \sim 75 \) \( \mu \)Jy agrees well with the spectral index measured with the GMRT. This establishes beyond any ambiguity that the pulsar non-detections at the GMRT were not sensitivity limited, but because of the large DM and the lower observing frequencies, the pulsed signal would be appreciably broadened. It seems a reasonable conclusion, therefore, that the radio emission seen in the GMRT images as the unresolved source comes from the pulsar, but that only because of temporal broadening we do not detect any pulsed emission. We turn now to the discussion of the diffuse emission seen in the X-ray image.

### 6.2 The geometry of the wind nebula

The X-ray image in Fig. 6 shows diffuse emission, whose major axis is approximately aligned to the bipolar structure seen in the radio images. No radio counterpart to this diffuse X-ray emission is obvious in our data: this may partly be due to the difficulties in disentangling it from the more extended emission in the SNR.

The pulsar is located at the centre of the diffuse X-ray emission, but offset from the central depression in the radio image. In the case of the PWNe DA495, there is a similar offset between the location of the pulsar and the central depression in the bipolar emission, although the alignment with the diffuse X-ray emission is not clear (Arzoumanian et al. 2008; Kothes et al. 2008). Kothes et al. (2008) interpret the maxima in the radio bipolar structure as lying along the rotation axis. They also suggest that the minima in the radio image correspond to dense gas emitted earlier by an equatorial wind of the parent star. Since synchrotron particles cannot penetrate this dense material this leads to a minimum in the radio emission. Guided by the ellipticity of the diffuse component of the X-ray emission in G76.9+1.0, we suggest a different interpretation for this PWN. We assume that the diffuse elliptical component of the X-ray emission traces the equatorially flowing wind from the pulsar, and this wind continues to produce a radio synchrotron torus at large radii, which we see as a ‘limb-brightened’ bipolar structure (see Fig. 9). The minimum in the radio emission would then be perpendicular to the equatorial wind, i.e. along the rotation axis of the pulsar as projected on the sky. In this context, it is interesting to note that in the radio image there is a smaller secondary minimum diametrically opposite the central one (i.e. at \( \alpha \sim 20^h 22^m 35^s, \delta \sim 38^\circ 42' \)), similar to the situation in DA495. In our model, this would arise because in the equatorial wind one would expect a minimum in the emission along the rotation axis (or its projection on the sky). Interestingly, in the X-ray image (Fig. 6) there is a jet-like feature perpendicular to the diffuse emission, i.e. aligned with the minima which we posit to lie along the rotation axis. Narrow, jet-like features in PWNe are generally posited to lie along the rotation axis of the pulsar (Lai, Chernoff & Cordes 2001). It has also been suggested that the feature lies along the projection of the magnetic axis on to the rotation axis (Radhakrishnan & Deshpande 2001), in which case particle beams emanating from the magnetic poles, offset from the rotation axis, trace out a pair of arcs, as seen in the Vela, and the wind eventually settles down on the equatorial plane at large radii. In either case, one would expect the observed perpendicularity of the jet and the equatorial plane. In our picture, the polarization seen in G76.9+1.0 by Landecker et al. (1993) would be caused by the magnetic field becoming approximately radial at large distances from the pulsar.

### 7 CONCLUSIONS

We report the serendipitous discovery of an unresolved, steep spectrum radio source in the SNR G76.9+1.0. The mean measured radio position of this point source is \( \alpha = 20^h 22^m 21.69^s \pm 0.11, \delta = 38^\circ 42'14''8^s \pm 1.7'' \), J2000. Analysis of archival Chandra X-ray data shows this to be coincident with an unresolved X-ray source. Despite a deep search, no pulsed emission was detected at 610 and 1160 MHz with the GMRT. However, the pulsar has been seen with the GBT at 2 GHz. This has been understood as the consequence of the temporal broadening of the pulse due to the large dispersion measure along the line of sight to the pulsar and the low radio frequencies with which it was observed at the GMRT. The X-ray emission also shows a diffuse elliptical structure aligned along the bipolar structure seen in the radio. We suggest that these structures arise because of an equatorial wind from the pulsar. We underline the usefulness of a high-resolution radio imaging study in locating and prospecting for pulsar candidates in SNRs, which could otherwise be missed in a time series pulsar search observation.

### ACKNOWLEDGMENTS

We thank the GMRT staff for having made possible the observations used for the research reported in this paper. The GMRT is run by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. We are grateful to Z. Arzoumanian and
