ABSTRACT

Poly- and perfluoroalkyl substances (PFASs) are of growing concern worldwide, due to their ubiquitous presence and adverse health effects in humans and the environment. Surface waters in the northeastern United States in particular have displayed elevated concentrations of PFASs. Passive sampling devices are excellent monitoring tools, that accumulate contaminant loadings through passive diffusion and adsorption to the sampler, and provide a long-term, time-weighted average of the contaminant over large temporal and spatial scales. Here we utilize a novel integrative passive sampler—a microporous polyethylene (PE) tube filled with Hydrophilic-Lipophilic-Balanced sorbent—to gain a better understanding of its function, utility, and uptake rates in field environments. Three sampling campaigns were conducted in the fall of 2017 and summer 2018, deploying a total of seventy-two PE tube passive samplers across nine sites in a well-mixed estuary and in two wastewater treatment plant effluents for one month’s duration. Twenty-four PFASs (including carboxylic acids, sulfonates, and precursors) were measured across all sites in the passive samplers, as well as complementary water samples, using Ultra Performance Liquid Chromatography/Mass Spectrometry. In the estuary, the PE tube samplers accumulated a sum PFASs of 2 to 15 ng sampler\(^{-1}\), and in the waste water treatment plant effluent 60 to 70 ng sampler\(^{-1}\). \textit{In situ} sampling rates, which are essential when needed to calculate the contaminant concentrations in water, were characterized using a first order kinetic model, yielding sampling rates of 10-50 mL day\(^{-1}\). Results from this study imply that these passive samplers can be successfully used to determine dissolved concentrations
of PFASs in surface waters, though the sampling rate seems to vary with external water flow velocity.
ACKNOWLEDGMENTS

I would like to thank my advisor, Dr. Rainer Lohmann, for his support, expertise, and guidance throughout this project and in writing of my thesis. I have grown a lot as a scientist and person, and I am grateful for the opportunity to be mentored by him. I would like to thank all my collaborators at the Narragansett Bay Commission (Rebecca Songolo, John Motta, and Jim Kelly) and US EPA (Mark Cantwell and Dave Katz), who greatly helped me in field work and laboratory analysis. I would like to thank my lab mates (Anna Robuck and Jitka Becanova) and the STEEP team for their scientific expertise, collaboration, and comradery for the past two years—I couldn’t have done it without you! I would also like to thank all my friends and family, for the emotional support and encouragement thorough out my masters. Especially my parents, who didn’t know they would be raising a future oceanographer, but have been incredible role models my whole life. I love you guys so much.

INTRODUCTION

This thesis is presented in manuscript format, and is currently in preparation for submission to the journal *Environmental Science and Technology*. 
BACKGROUND

Poly- and perfluoroalkyl substances (PFASs) are a class of man-made chemicals, composed of over 4,000 individual compounds, which are of growing global concern (Wang et al. 2017). Production of PFASs began in the 1940s and 50s; they are used for various industrial purposes in non-stick and water-resistant coatings used in consumer products, as well as a major component of aqueous film forming foams (AFFF) (Lindstrom et al. 2011). In the last couple of decades, these contaminants have been found globally distributed in the air, environment and drinking water sources, and due to their fluorinated chemical structure—polar, hydrophilic, high thermal, chemical, and biological inertness—PFASs are highly persistent in the environment (Wang et al. 2017). They are known to bioaccumulate in wildlife (Kannan et al. 2005), are found prevalently in human blood samples (Karrman et al. 2006), and are considered immunosuppressants by decreasing the antibody count from vaccines in children (Grandjean et al. 2012).

PFASs are also linked to several negative health effects (immune, developmental, neurobehavioral, endocrine, and metabolic) in laboratory rodent experiments (Benskin et al. 2009). Due to their negative health impacts, production of a few compounds (namely perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA) and other legacy compounds) has been voluntarily phased out in the United States, with the support of the U.S. Environmental Protection Agency (U.S. EPA 2016), and they are being evaluated for listing, under the Stockholm Convention on Persistent Organic Chemicals (UN Environment Programme).
PFASs enter the environment primarily through waste water treatment plant (WWTP) effluent, septic system leaking and discharge, and aqueous film forming foams (AFFF) used by airports, military bases and fire training areas (Möller et al. 2010, Moody & Field 2000, Schaider et al. 2016). One of the biggest environmental sources of these compounds are through manufacturing discharge. An estimated 2,610-21,400 tons of perfluoroalkyl carboxylic acids were produced globally from 1951-2015, and 65%-98% of this was discharged into surface waters (Wang et al. 2014). These compounds then leach into the ground water, aquifers and enter drinking water supplies. The northeastern United States, in particular, has shown to have elevated levels of PFAS in its surface and groundwaters (Zhang et al. 2016; Weber et al. 2017).

Passive sampling tools have been successfully used for decades to easily and time-effectively monitor different groups of contaminants in the environment. These sampling tools work through the passive diffusion of analyte molecules from the sampled medium to a collecting medium due to a difference in chemical potentials (Górecki & Namieśnik 2002). Passive samplers are inexpensive, small, easy to use, and can be deployed over large spatial and temporal scales, without the need of daily environmental sampling. Passive samplers accumulate compounds over the deployment period and generate a reliable time weighted average of those compounds in water/air (Vrana et al. 2005), which is more representative of the environmental variation of contaminant concentration over time, as compared to an active grab sample which only represents a single moment in time. Due to the accumulation and concentration of the compounds onto the sampler overtime, contaminant concentrations can often be detected in the sampler that would otherwise be undetectable in a grab sample at lower concentrations.
Another benefit of passive samplers is that they can mimic the portion of contaminants bioavailable to organisms and help predict biomonitoring results (Vrana et al. 2005). These sampling devices are especially useful when studying remote areas, large spatial scales or long-term monitoring projects, because they vastly decrease the amount of field and lab work needed to determine environmental contaminant concentrations.

Traditional passive samplers, such as polyethylene sheets or polyurethane foam, are excellent monitoring tools for nonpolar contaminants, such as dioxins, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs) (Lohmann et al. 2012).

For these traditional samplers, Performance Reference Compounds (PRCs) are added prior to sampler deployment, to determine uptake rates (the rate at which the target analytes are taken up by the sampler), which are greatly dependent on environmental conditions, such as flow rate, temperature and biofouling. PRCs are non-interfering, mass-labeled compounds which slowly diffuse out of the sampler, while the compounds of interest sorb to the sampler. The known PRC loss is related to the uptake of the target compound, and thus an uptake rate can be derived (Huckins et al. 2002).

Due to their polar nature, and high affinity for water, PFASs do not sorb strongly to traditional passive samplers, which typically target non-polar analytes. A Polar Organic Chemical Integrative Sampler (POCIS) has been developed for polar compounds, including PFASs. This device incorporates a metal ring sandwiching a charged powered adsorbent which binds the polar compound, between a thin polyethersulfone membrane (Alvarez et al. 2004). The main drawback of the POCIS sampler is that the thin membrane is very permeable to water, thus causing the sampling uptake rate to be strongly dependent on the flow rate of the medium the sampler is
deployed in (Gobelius et al. 2019; Kaserzon et al. 2012; Kaserson et al. 2013).

Additionally, PRCs cannot be used for these polar samplers, because the PRC affinity to
the adsorbent powder is much too great, and the compounds would not diffuse out of the
 sampler.

Another, much newer and less widely used passive sampler has been developed
for polar compounds (see Figure 1). This sampler consists of a hollow microporous
polyethylene (PE) tube filled with charged powdered adsorbent and sealed at both ends
(Kaserzon et al. 2019). The PE tubes have thick porous walls (2 mm) to reduce the effects
of the flow rate of the medium. Instead, uptake is presumably limited by the passive
diffusion of the compounds (i.e. their chemical properties) through the polyethene walls.
These passive samplers have been previously used for the detection of polar herbicides
(Fauvelle et al. 2017a) and PFASs in ground water (Kaserzon et al. 2019), but more work
still needs to be performed to better characterize these samplers.

The research performed for this MS thesis consists of initial field studies to
determine if these samplers are a promising tool for detection of dissolved PFASs in
surface water. If these tube samplers prove useful, further studies should be conducted
assessing these specific variables to better understand the applicability of these samplers
for PFASs uptake. For example, to be able to predict the uptake rate of individual
PFASs, we would need to understand the permeability of the tube and mass transfer of
the compounds by studying the porosity of the tube, the particle size of the analyte, the
membrane resistance and therefore resistance to flow rate of the medium as discussed by
Fauvelle et al. (2017b).
This study will evaluate and field validate the PE tube passive sampler as a sampling tool for PFASs in aquatic environments. While drinking water is a main human exposure source, studying PFASs concentrations in surface waters is critical. Surface water can often be predictive of contaminant levels in ground water (Heberer et al. 1998; Thurman et al. 1991) as the aquifers recharge with human use and rainfall. Additionally, marine and fresh water organisms bioaccumulate PFASs from the environment, which humans are later exposed to through consumption of seafood and shellfish (Berger et al. 2009). A regular monitoring tool, such as this passive sampler, could be used to provide baseline concentrations of PFASs, and predict levels of contaminant bioaccumulation and set advisory limits for human consumption.

A suite of twenty-five PFASs compounds were analyzed in all samples and are comprised of legacy compounds (including PFOA and PFOS) produced in high volumes and emerging compounds (short and long chain compounds, fluorotelomer sulfonates and Gen-X) which replaced the legacy compounds after they were phased out. Specifically, this suite of compounds was selected due to their known prevalence in the environment, and occurrence in waste water treatment plants, airports and military bases. This study was conducted in two parts, with initial deployments in two waste water treatment plants in Providence followed by a field deployment in Narragansett Bay. WWTPs are ideal study sites, due to their high concentrations of PFASs, controlled and consistent conditions (flow rate, temperature, salinity, dissolved oxygen) and availability of daily composite water samples from the regular maintenance and monitoring by the WWTP staff. PE tube samplers were initially deployed in the final effluent of the two WWTPs, to observe preliminary uptake rates, PFASs concentrations, and method validation. A follow
up time series study was also conducted at each WWTP to determine the linear uptake phase, optimal deployment time and any preferential compound uptake over time. A secondary study was performed in Narragansett Bay (NB), to test the application of the PE tube sampler in the field, and determine how the samplers work in a natural environment.

Main questions of the project:

1. Do these novel PE tube samplers take up PFASs? Which ones? What is the reproducibility of the sampler?
2. How long is the linear uptake phase? What is the optimal deployment time?
3. What is the sampling rate of the sampler? A sampling range for the different compounds?
METHODS

Polyethylene tube integrative passive samplers

Passive samplers were made from microporous polyethylene Filtroplast tubing, model FL10, 2.5 μm filtration grade (manufactured by Pall Corp., Germany), 7 cm in length and membrane thickness of 2 mm. These tubes were filled with 0.6 g of Oasis Hydrophilic-Lipophilic-Balanced (HLB) sorbent (Waters Corp., Milford, MA, USA), allowing room for 1 cm of head space. The tubes were then capped with push-in polyethylene plugs (McMaster-Carr Supply Company, Elmhurst, IL), creating an exposed surface area of 18.8 cm$^2$ and a surface area to mass sorbent ratio of 31 cm$^2$ g$^{-1}$. To condition the sorbent for compound uptake in the field, the samplers were placed on a shaker table in methanol for 24 hours, followed by basic methanol (1.0% ammonium hydroxide in methanol) for 24 hours, followed by LC/MS Optima grade water for 24 hours.

Standards and materials

For all extractions, conditioning, and standard preparation LC/MS grade methanol (Honeywell Burdick & Jackson, Muskegon, MI, USA), LC/MS Optima grade water and ammonium hydroxide (28-30 w/w%) (Thermo Fisher Scientific, Waltham, MA, USA) were used. All laboratory equipment (test tubes, pipettes, graduated cylinders, sampling bottles) were high density polyethylene and rinsed three times each with basic methanol.
(3% ammonium hydroxide in water), regular methanol, and Optima-grade water before handling the samples. All analytical standards were purchased from Wellington Laboratories (Guelph, Canada). A native standard mix of PFAC-24PAR (a mixture of 24 native PFASs compounds) along with hexafluoropropylene oxide dimer acid (Gen-X) were used to prepare calibration standards in 25:75 methanol:water with 4mM ammonium acetate, ranging from 0.25 to 50.0 ng mL\(^{-1}\). A 10.0 ng mL\(^{-1}\) native standard was also prepared in the same way for matrix effect determination and recovery standards. A mass-labeled surrogate standard was prepared from MPFAC-24ES (a mixture of 19 mass-labeled (13C or 2H) PFASs compounds) and M-Gen-X (M3HFPO-DA) at 50 ng mL\(^{-1}\). See Table A and B in the Appendix for further standard information.

**Waste water treatment plant deployment**

Two waste water treatment plants (Field’s Point and Bucklin Point, see Figure 3) servicing Providence, RI, were used as the study site for an *in situ* calibration deployment for these novel passive samplers. A pilot study was conducted for a one-month duration in the fall of 2017, Field’s Point and Bucklin Point, Providence, RI. At each WWTP, 3 samplers were deployed sequentially for consecutive 10-day periods (for a total of 6 passive samplers between the two sites). Water samples were also collected in pre-cleaned polyethylene bottles, during deployment and recovery of the passive samplers (for a total of 8 water samples between the two sites). Field blanks were collected for quality assurance—optima-grade water was brought along and transferred at the site of water collection into another pre-cleaned polyethylene bottle, to mimic the water collection process and account for any potential environmental contamination.
In the late spring of 2018, a second deployment was conducted in the final WWTP effluents. At each WWTP, passive samplers were deployed in triplicate for 2, 4, 8, 16, and 29 day periods, to gain an understanding of the kinetic PFASs uptake by the passive samplers (5 time periods x 3 samplers = 15 samplers per site) daily composite water sample (sub samples collected every hour for the twenty-four-hour period and combined) was collected every day. Field blanks were also collected for quality assurance as described above.

**Estuary field trial deployment**

Narragansett Bay (NB) is a well-mixed, tidally influenced estuary in Rhode Island, USA (Pilson 1985). Many of the Bay’s sources of PFASs are freshwater inputs, including WWTP effluents, industrial point sources, septic leaching and AFFF run off from airports and military bases in the northern part of NB (i.e. higher impacted sites). The less impacted sites, e.g., areas with little or no known sources of PFASs, are located towards the (southern) mouth of the Bay. PFASs sources are linked with human activity, and this relationship can be observed in Figure 2. Nine deployment sites (see Figure 3) were chosen in NB to cover this North-South gradient of high to low PFASs concentrations, and five sites were chosen next to long-term monitoring buoy locations (run by the Rhode Island Department of Environmental Management), to compare PFASs concentration to water quality parameters from buoy data (temperature, salinity, dissolved oxygen, and pH).

Duplicate passive samplers were anchored to sediment traps to sample the mid water column, roughly 3 meters from the bottom. The samplers were deployed for a one-month
duration, from September to October of 2017, and grab water samples were collected during deployment and recovery. A follow up study was conducted in July of 2019 to test the reproducibility of the passive samplers. Six ‘caged’ and six ‘naked’ passive samplers were deployed at the Pawtuxet River site for three weeks duration, and water samples were collected upon deployment and recovery. The naked samplers consist of the bare PE tube being zip-tied to the anchored line (the style of samplers deployed at both waste water treatment plants), and the caged samplers had a polyethylene mesh cage wrapped around them, to minimize biofouling (the style of samplers deployed throughout Narragansett Bay).

**Extraction of water grab samples**

Samples were stored in 1 L pre-rinsed polyethylene bottles at −20°C and thawed to room temperature for extraction. 300 to 500 mL of the sample were spiked with 10 ng (100 uL at 0.05 ng mL⁻¹) 25 mix mass-labeled PFAS mixture, as surrogate standards for quantification. The water samples were then filtered using glass fiber filters, and extracted using Oasis Weak Anion EXchange (WAX) solid phase extraction cartridges (6 mL, 150 mg of sorbent), collecting the final methanol elution as the sample extract. The water extraction procedure follows EPA method LOP-AED/PEB/DK17-01-00.

**Extraction of polyethylene tube samplers**

Passive samplers were cleaned with deionized water to remove algal growth. Whole passive samplers were centrifuged three times for three minutes at 4,000 rpms, to remove remaining water trapped inside the tube. Passive samplers were then transferred to
precleaned 15 mL Falcon centrifuge tubes, filled with 6mL methanol, spiked with 10 ng internal PFAS standard and let sit for 24 hours. The methanol was then transferred to another precleaned Falcon tube, and the PE Tube were fill with another 6 mL methanol and the process repeated three more times, for a total of four extraction steps per passive sampler. All individual sampler extracts were combined as the sample extract.

**Instrument analysis and QA/QC**

All final sample extracts (water and passive samplers) were volume reduced using a nitrogen evaporator (Microvap) to 250 μL, and reconstituted with 750 μL 4 mM ammonium acetate water, yielding a final sample of 1000 μL 25:75 methanol:water. Extracts were centrifuged to remove any remaining particulates, and the supernatant were transferred to auto sampler vials for analysis. Samples were analyzed at the Environmental Protection Agency’s ORD Narragansett Bay location through liquid chromatography mass spectrometry on a Waters Acquity H-Class Ultra Performance Liquid Chromatography System (UPLC) paired with a Waters Xevo Triple Quadrupole MS/MS System (Waters, Milford, MA) run in negative electrospray ionization (-ESI) mode. A 40 μL sample injection is run in duplicate, followed by an injection blank to insure no carry-over between samples. Analytes of interest are separated using a BEH C18 column and a mobile phase gradient of 75% aqueous to 10% aqueous. Compound identification is carried out through ion fragmentation and referenced to calibration standards and quantified through isotope dilution mass spectrometry.

All equipment used to handle samples (collection bottles, spatulas, aluminum foil, test tubes, extraction manifold, etc.) were washed three times with basic methanol (3%
ammonium hydroxide), follow by three washes with LC/MS grade methanol, to insure no previous PFASs contamination on the equipment. Gloves and protective equipment were used when handling samples (to protect the samples and myself). No PFASs containing products (i.e. Teflon) or glass (to prevent compound sorption to the container) were used to handle/store the samples, only high-density polyethylene and polypropylene were used (as they have much less reactive surfaces to prevent compound sorption). Mass-labeled internal standard were always added to the sample prior to any manipulation, to account for any losses in the method.

Field blanks, process blanks and instrument blanks were performed at every step of collection, extraction and analysis to account for any outside commination or sample loss. Matrix samples were also performed to determine how the water matrix effects the PFASs behavior and recovery.

**Data analysis**

A five-point calibration curve was made and analyzed on the instrument to determine linearity of the MS detector and derive sample concentrations. All integrations and chromatogram analysis were done using Mass/Target Lynx software. Sample concentrations were then volume/mass, blank and recovery corrected.

Histograms of water and passive sampler concentrations were computed, and a heat map of Narragansett Bay PFASs concentrations was created by extrapolating the known concentrations from the 9 sampling sites on Ocean Data View computing software. Sampler concentrations of PFASs were compared to water parameters.
(temperature, salinity, dissolved oxygen, etc.) through a generalized linear model on R to determine if environmental conditions effect uptake rate of the samplers.

The sampler concentration of the WWTP time series experiment were plotted against the samplers’ deployment time, to observe the PFASs uptake kinetics, and to determine whether the uptake remains linear. Regressions were ran to calculate the linearity of the uptake rate, and determine an optimal deployment time, by calculating the time needed to reach equilibrium. The optimal deployment time was based on how long the uptake is linear (before it reaches equilibrium with the environment), and if the samplers have accumulated a high enough concentration of PFASs to pass the detection limits of the instrument.

Compound specific uptake rates were analyzed to discern if there is differential uptake between chain lengths and functional groups (carboxylic acids vs sulfonates). Shorter chain compounds are expected to have higher uptake rates, due to their higher diffusivity when compared to long chain compounds.
RESULTS AND DISCUSSION

Waste water treatment plant

The initial pilot study demonstrated that the passive samplers, the extraction and analytical method could be successfully used for the detection for 24 target analytes in both WWTPs (with the exception of HFPODA-Gen- due to instrument interference). The detection of these compounds in both the effluent (Figure 4) and in the passive samplers (Figure 5) validates the extraction and instrument procedure, thus providing a good protocol for the other sampling campaigns. In the time series study, both effluents were dominated by carboxylic acids, primarily PFBA, PFPeA, PFHxA, PFHpA, and PFOA. Those five compounds combined were present at 86 ng L\(^{-1}\) (67\%) of the PFASs load in Fields Point and 86 ng L\(^{-1}\) (64\%) in Bucklin Point (Figures 6 and 7, Table 1 and 2). Sulfonates (PFBS, PFHxS, PFHpS, and PFOS) combined reached 24 ng L\(^{-1}\) (25\%) at Fields Point and 28 ng L\(^{-1}\) (21\%) at Bucklin’s WWTP. Precursors and longer chain PFASs (greater than nine carbons) were observed at much lower concentrations, ranging from 3.0 to 0.01 ng L\(^{-1}\). Across the month-long sampling period, both locations maintained fairly steady PFASs concentrations, with sum 24 PFASs of 110 ± 20 ng L\(^{-1}\) at Fields Point and 130 ± 20 ng L\(^{-1}\) at Bucklin Point. These stable conditions will allow for an accurate analysis and calibration the passive sampler uptake in this environment.

The accumulation of PFASs in the PE-tube samplers deployed in the Fields Point WWTP exhibited a linear uptake for the compounds observed (Figure 8, Table 3),
accumulating a sum 24 PFASs of 74 ng sampler\(^{-1}\) after 29 days. PFHxA had the highest concentration of 17 ng sampler\(^{-1}\), and 4:2-FTS the lowest with 0.01 ng sampler\(^{-1}\). The carboxylic acids made up a predominant portion of the sum PFASs, similar to the concurrently collected effluent grab samples.

Bucklin Point WWTP displayed a different uptake pattern (Figure 9, Table 3), with the greatest PFASs concentration accumulating on day 16 (69 ng sampler\(^{-1}\)), and tapering off slightly on day 29 (60 ng sampler\(^{-1}\)). At both time periods, PFHxA had the highest concentration and 4:2-FTS the least, with carboxylic acids making up the bulk of the PFASs loading, which is also consistent with the concurrently taken effluent grab samples. There are several factors that could be contributing to this leveling off the sampler’s PFAS uptake—flow rate, biofouling, saturation of the sorbent, other conflicts with in the WWTP—and these will be discussed in greater depth later.

**Estuary field deployment**

The Narragansett Bay PFASs surface water concentrations (mean of the two grab samples collected on deployment and recovery of the passive samplers) were mapped and extrapolated to cover the Bay as a whole (Figure 10). The PFASs distribution is in line with what was predicted, with the highest concentrations being north near a large human population and industry, and lower concentrations towards the mouth of the Bay. Throughout the Bay, total PFASs were also dominated by carboxylic acids, with sulfonates comprising the next biggest fraction (Figure 11, Table 4). Some of the spatial distribution can be explained: Site 1 (Phillipsdale Landing) is located just south of the Bucklin Point WWTP outfall, and while it is lower than the WWTP effluent itself (42
ng L\(^{-1}\) compared to 130 ng L\(^{-1}\)) it is the second highest concentration we observed in the Bay. Site 2 (Field’s Point Bay) is located near the Fields Point WWTP outfall, and also displayed elevated PFASs levels of 22 ng L\(^{-1}\). Site 3 (Pawtuxet River) is located at the mouth of a tributary meeting Narragansett Bay, and displays the highest PFASs levels (62 ng L\(^{-1}\)) we observed in the Bay. There is a big industry presence up stream of the Pawtuxet River, most notably electrical and metal plating, which use some PFASs containing surfactants in their production, and it is likely that industry discharge is leading to these elevated concentrations (Clara et al. (2008); Lin et al. (2009)). Site 7 (Quonset Point) is located off an air force base, and it displays a very unique PFASs signature, where 6:2-FTS and EtFOSAA are the dominant compounds (34% and 20% respectively, compared to the average of the other sites 1.3% and 2.6% respectively). These two precursors are known additives to aqueous film forming foams (AFFF), which are pervasively used across the military for fire training, and a recent fire training activity could lead to this unique PFAS signature observed at site 7 (Barzen-Hanson et al. (2017); Houtz et al. (2013). The remaining five sites are located in the wider part of the Bay with more mixing with the Atlantic Ocean water and lower human population density leading to lower PFASs levels than observed at the previous four sites. This broad range of PFASs concentrations and field conditions creates a good opportunity to test how well samplers work across a range of environmental settings.

In the Narragansett Bay field deployments, the passive samplers accumulated a sum 24 PFASs of 2.5 to 15 ng sampler\(^{-1}\) (Figure 12, Table 5). In general, the trend is that higher PFASs water concentration lead to a higher passive sampler concentration. The accumulation of PFASs by the passive samplers seemed to conserve their general
contribution in the water, with carboxylic acids being the dominant fraction. A notable exception, is that the passive samplers at site 7 were not dominated by 6:2-FTS and EtFOSAA like the water grab, which will be further explored in a later section.

**Reproducibility and sampler type**

The twelve passive samplers deployed to test the reproducibility of the PE tubes, accumulated an average of $7.1 \pm 0.3$ ng sampler$^{-1}$, and had consistent concentrations across all replicates (Figure 13, Table 6). For fourteen out of the twenty-four compounds observed, the relative percent difference between replicates was between 20% and 30%, and as low as 5% for PFDS and 4:2-FTS, indicating very good reproducibility for the more abundant compounds. For the longer chain compounds (chain length greater than ten) and precursors, greater variability is observed. This variability is likely due to the compounds being present at such low concentrations (two or three orders of magnitude lower than the dominate compounds), that any fluctuation has a much greater relative impact. This variability is likely exacerbated by instrumental detection limits and poor optimization for these larger compounds with much longer retention times. Generally, the PE tube samplers appear to be reproducible, with reproducibility being mainly limited by instrumental detection limits and acquisition.

The uptake of the two different sampler types was also compared. For the Bay study, ‘caged’ samplers (PE tubes wrapped in polyethylene mesh) were deployed throughout the Bay, in hopes of preventing biofouling. While ‘naked’ samplers (bare PE tubes) were used in both WWTPs, in anticipation of less biofouling due to the sterilization of the treatment process. For all twenty-four compounds, there was found to
be no significant difference (p > 0.05) in mean uptake between the two sampler types (Table 6). By visual observation, the cage did not reduce biofouling, so the simpler naked design should be used in future studies for ease of use. Additionally, in most cases the reproducibility of the naked samplers was better (lower standard error) than of the caged passive samplers (Table 6). Lastly, this lack of difference between the two samplers, enables the comparison of the Bay and WWTP sampler uptake without needing to correct for the different sampler design.

**Sampling rate**

The sampling rate is needed to back-calculate the water concentration of the environment the passive sampler was deployed in. The sampling rates (R<sub>s</sub>) for individual compounds were calculated using a first-order kinetic model:

(1) \[ R_s = \frac{-\ln\left(1 - \frac{C_s}{K_{sw}C_w}\right) m_s K_{sw}}{t} = \frac{L}{\text{day}} \]

Where \( C_s \) is the passive sampler concentration, \( C_w \) is the water concentration, \( m_s \) is the mass of the sorbent used, \( K_{sw} \) is the sorbent-water sorption coefficient, \( t \) is time in days. \( K_{sw} \) values were taken from Urik & Vrana (2019) (see values in Table C), where they only calculated values for eleven PFASs compounds, so of those, I focused on the nine dominate compounds.

Across all three study locations, sampling rates displayed similar values, ranging from 10 to 50 mL day<sup>-1</sup> (Figure 15) for the nine compounds examined (PFBS, PFHxS, PFOS, PFPeA, PFHxA, PFHpA, PFOA, PFNA, and PFDA). However, Bucklin Point
displays significantly greater sampling rates (40 ± 5.1 mL day\(^{-1}\)) than both Fields Point (29 ± 2.9 mL day\(^{-1}\)) and Narragansett Bay (23 ± 4.2 mL day\(^{-1}\)), and Fields point displayed significantly greater Rs than the Bay as well (Table 7). Sampling rates at all study locations also seem to be linked to the chain length of the compound (Figure 16), where compounds with longer chain lengths, exhibit higher sampling rates. Similar results were also noted by Kaserzon et al. (2019). An increase of Rs with increasing chain length is contrary to expectations, as molecular diffusivity decreases with increasing chain length. It might indicate the importance of PFASs adsorbing to the sampler surface, as partitioning constants will increase with increasing chain length (Urik and Vrana (2019)).

The sampling rate was further explored using a more simplified linear uptake model:

\[
R_s = \frac{c_s}{c_{w,t}} = \frac{L}{\text{day}}
\]

The sampling rates calculated from both equations were compared (Figure 17, Table 8), and at all three study sites, were not found to be significantly different (p-value > 0.32), with Fields Pt WWTP linear calculation being 29 ± 2.2 mL day\(^{-1}\) and 29 ± 2.9 mL day\(^{-1}\) for the kinetic model, 40 ± 4.1 mL day\(^{-1}\) for Bucklin’s linear and 40 ± 5.1 mL day\(^{-1}\) for the kinetic, and 22 ± 3.0 mL day\(^{-1}\) for the Bay’s linear and 23 ± 4.2 mL day\(^{-1}\) for the kinetic. This is useful when wanting to calculate the sampling rate for compounds whose partitioning constants (K\(_{sw}\)) are not known, we can estimate the sampling rates by using this more simplified linear calculation.
Linear uptake

The duration of linear uptake is an important consideration for integrative passive samplers, such as this PE tube, and helps determine the optimal deployment period. The Fields Point time series study displayed linear uptake ($R^2>0.96$) for the nine compounds examined (PFBS, PFHxS, PFOS, PFPeA, PFHxA, PFHpA, PFOA, PFNA, and PFDA) (Figure 18, Table 9). Calculating the time the sampler takes to reach equilibrium ($t_{eq}$) is a useful metric to determine the maximum deployment period:

\[
(t_{eq}) = \frac{K_{sw} m_s}{R_s} \quad \text{(equ. 3)}
\]

Using the mean $K_{sw}$, 201368 L kg$^{-1}$, of the nine compounds analyzed, sorbent mass ($m_s$) of 6x10$^{-4}$ kg, and mean $R_s$ of 0.02921 L day$^{-1}$, we get a $t_{eq}$ value of 4166 days. Indicating that our thirty-day deployment was well within the linear uptake phase. The optimal deployment period is typically constrained by temporal resolution, over-coming instrumental detection limits, and biofouling, so finding a compromise between these factors (likely one to several months) would be a useful deployment period for the future.

Environmental factors

Five of the Narragansett Bay fields deployment sites were located next to long term monitoring buoys that record temperature, salinity, density, dissolved oxygen, pH and chlorophyll a. When these environmental factors were plotted against the mean sampling rates at each site (Figure 19), regressions suggest there are probable links between sampling rate and environmental factors, most notable pH ($R^2=0.62$) and density.
To explore these relationships further, a generalized linear model and Akaike Information Criterion (AIC) likelihood of fit indices were analyzed (Table D). Chlorophyll (which can be used as a proxy for organic carbon) and pH generated the strongest relationship with the sampling rate. However, this data interpretation is likely skewed by one low outlier, so this sample set is too small to derive useful conclusions on these variables.

**Potential effect of water flow velocity**

Kaserzon et al. (2019) presented a similar study conducted with these polyethylene tube samplers in ground water, and the Rs values derived in their study were compared to the sampling rates calculated for Narragansett Bay and the two waste water treatment plants. Water flow velocities were estimated based on average expected conditions for the three environments and compared to the calculated Rs values (Figure 20). Their sampling rate for ground water (3.2 mL day\(^{-1}\)) was an order of magnitude lower than the sampling rates for the Bay (23 mL day\(^{-1}\)) and WWTP (37 mL day\(^{-1}\)). These results indicate that environmental flow rate is likely more impactful on the sampling rate than initially expected. Where higher flow environments facilitate a higher sampling rate, by reducing the water boundary layer between the sampler and medium (Fauvelle et al. 2017b).

**Back-calculating surface water concentrations using the sampling rate**

Knowing that the one month’s deployment is well within the linear uptake phase, and that the sampler design (caged vs naked) does not affect the uptake, we can use the
sampling rates derived from Field’s Point validation study to back calculate the surface water concentrations of Narragansett Bay. In order to do so, the linear model to determine the sampling rate was used, due to the fact that not all $K_{sw}$ values are known for all twenty-four compounds needed for the kinetic model. The passive sampler concentration and time deployed is also needed to make the calculation such that: 

$$C_w = \frac{C_s}{t_R s} = \frac{ng}{L}$$

(Table 10).

Water grab concentrations of PFASs at deployment and recovery of the passive sampler in the Bay were plotted independently, along with the calculated surface water values (Figure 21). Quite a bit of variability is observed between the two water grabs, particularly for site 7 (Quonsett Point), which displayed extremely high levels of 6:2-FTS and EtFOSAA only during the first grab sampling event. This was possibly due to release from AFFF application event, due to the proximity of the air force base, and that these concentrations dissipated quickly, thus not being represented in the passive samplers or in second grab sample. Sites 1 and 3 also display some variability in the two different water grab concentrations, while sites 6, 8, and 9 have more consistent PFASs levels, perhaps due to being located further from direct point sources and therefore are only exposed to consistent background levels. These observations further the notion that estuaries fluctuate quite a bit, and that a long-term passive sampler could be incredibly beneficial for more representative data.

The calculated surface water concentrations appear to underestimate the observed PFASs concentrations, particularly for the sites in the north of the Bay (1, 2, and 3) (Figure 21 and 22). Suspecting that the flow rate of the system does indeed factor in to the sampling rate of the PE tube, the $R_s$ values from Field’s Point are likely not
representative of what is observed in the specific nine sites throughout Narragansett Bay, especially with tidal and freshwater influence. Moving forward, measuring the flow rate of a deployment site is recommended in order to derive a flow rate specific sampling rate and derive more accurate PFAS concentrations.

**POCIS versus Polyethylene Tube Sampler**

Two previous studies have been conducted using POCIS to monitor PFASs in aquatic environments. A Swedish study used a traditional POCIS in a drinking water treatment plant, and found an average sampling rate of 45 mL day\(^{-1}\) (Gobelius et al. 2019), and correcting for the surface area (46 cm\(^2\)), its uptake rate is 0.98 mL day\(^{-1}\) cm\(^{-2}\). Another Australian study used a modified POCIS (smaller surface area and greater sorbent amount than a traditional POCIS) and found an uptake rate of 16.8 mL day\(^{-1}\) cm\(^{-2}\) (270 mL day\(^{-1}\) over 16 cm\(^2\)) (Kaserzon et al. 2012). Comparatively, the uptake rate produced by the PE tube sampler in Narragansett Bay was 1.28 mL day\(^{-1}\) cm\(^{-2}\) (23 mL day\(^{-1}\) over 19 cm\(^2\)). While each study has its own limitations for comparison—the Gobelius study taking place in a drinking water treatment plant, thus without the environmental and tidal fluctuations of an estuary, and the Kaserzon study, while in an estuary, however did use a modified POCIS—the PE tube sampler seems comparable to the POCIS, and has a much lower sampling rate than the modified POCIS, stipulating that the PE tubes have a reduced effect of flow rate in comparison. These PE tube samplers with a lower \(R_s\) and reduced flow rate dependence are more desirable in field deployments in order to control for environmental impacts as much as possible. However, to gain a better
understanding of how these two passive samplers compare, a side by side deployment would be helpful to determine how the sampling rates correlate.

**Limitations**

An uncertainty of this study is the uptake pattern of the Bucklin Point time series, which could be affected by a number of factors. With a $t_{eq}$ of 4000 days, the sampler is unlikely to be at sorptive capacity for PFASs after 28 days. After the month’s deployment and an approximate $R_s$ of 40 mL day$^{-1}$, the sampler would have sampled 1.2 liters of water, and with 6 grams of sorbent in the sampler, it can sample 40 liters of water. A more likely reason for the leveling off of the uptake is the biofouling of the sampler and the pores getting clogged. Water samples from Fields Point and Buckling Point were filtered with glass fiber filters. The particulates accumulated from Fields Point weighed twice as much as Bucklin Point, but Bucklin Point took twice as long to filter, indicating that the particles in Bucklin Point WWTP are smaller than in Fields Point WWTP, and more likely to clog the pores in the samplers. The two waste water treatment plants are set up differently—Fields Point uses chlorine whereas Bucklin Point uses UV to sterilize the effluent—and these differences in treatment could lead to differences in particle size and effluent composition which could lead to differences in the sampler uptake. Visually, the effluent flow at Bucklin Point appeared to be faster than at Fields Point, which could explain why Bucklin exhibited higher sampling rates than Fields, but without measuring the effluent with a flow meter, no definite conclusions can be drawn. Within the effluent, there are likely hundreds of other compounds, beyond PFASs, that could interfere with the sampler uptake. In order to rule out the potential effect of interference, whole effluent
samples should be analyzed and screened for other compounds, in particularly pharmaceuticals, which are polar and would accumulate in the PE tubes samplers as well.

Another limitation of this study is the lack of flow rate measurements, especially in light of the data presented here that the flow of the water is a driver of the sampling rate. The WWTP flow is likely fairly stable, but the Bay is tidally influenced, and knowing the flow rate at the specific sites would be helpful to calibrate the sampling rate. Additionally, PFASs concentration is inherently correlated with other environmental factors in the Bay (salinity, temperature, etc.) due to the physical set up of the estuary. The generalized linear model accounted for some of the variability of the PFAS water concentration, but a study with the same PFASs concentration and a wider range of environmental factors would be better to discern specific environmental effects.

Conclusions

Twenty-four PFASs were detected *in situ* in the polyethylene tube sampler, across both waste water treatment plants and Bay deployments, with the samplers being optimized for carboxylic acid and sulfonate groups. Sampling rates vary from 10 to 50 mL day$^{-1}$ across all sites, with mean rates of $40 \pm 5.1$ mL day$^{-1}$ for Bucklin Point WWTP, $29 \pm 2.9$ mL day$^{-1}$ for Fields Point WWTP, and $23 \pm 4.2$ mL day$^{-1}$ for Narragansett Bay. Unexpectedly, sampling rates tended to increase with increasing chain length of the compounds, possibly due to adsorption of the longer-chain compounds. The samplers show good agreement with the PFASs water concentrations, with the most abundant compounds (PFBA, PFPeA, PFHxA, PFHpA, and PFOA) in the active grab samples, also being the most abundant in the passive samplers. The one-month deployment was well
within the linear uptake phase (which could last for years). The optimal deployment will hence be a compromise between the desired temporal resolution, limitations from biofouling and amassing sufficient PFAS to overcome detection limits easily. The samplers appear to be reproducible across all sites, with PFASs uptake being 2 to 15 ng per sampler in the Bay and 60 to 70 ng per sampler in the waste water treatment plants. For the most prominent compounds, the samplers display 5% to 30% variability between replicates, suggesting that reproducibility is mainly limited by instrumental detection limits and analytical uncertainty. The water flow velocity is likely an important driver for the sampling rate, which leads to the difference in PFASs uptake between the samplers in the Bay and WWTP. Overall, these polyethylene tube samplers exhibit the successful accumulation of PFASs in surface waters, and provide a suitable solution for long-term monitoring of these compounds. Moving forward, more detailed experimentation needs to be conducted in order to understand how the flow rate and other water properties, including particles, effect the uptake rate of the passive samplers. A controlled laboratory experiment, with consistent PFASs concentrations and varying environmental conditions, would be beneficial to calibrate the sampling rates of the samplers across a wide range of environmental conditions.

Figure 13. Passive sampler reproducibility, six naked (N) and six caged (C) samplers were deployed at the same location.
**Figure 14.** Passive sampler reproducibility relative percent difference. Calculated for all twelve replicates by taking the standard deviation and dividing by the mean of each compound, then multiplying by one hundred.
Table 6. Comparison of naked versus caged passive sampler types (N=naked, C=caged). The mean is the average of the six replicates of each type of sampler ± the standard error (ng sampler$^{-1}$). P-value was computed using a two-way t-test assuming equal variance.

Figure 19. Plot of sampling rates ($R_s$) versus various environmental measurements for five sites in Narragansett Bay, with deployments located next to the DEM MERL monitoring buoys.
Figure 20. Plot of the log sampling rates ($R_s$) versus the log flow rates of aquatic environments. Bay is the average of the Narragansett Bay sampling rates, WWTP is the average of Bucking and Fields Point waste water treatment plants, and GW is ground water data taken from Kaserzon et al. (2019) where they deploy similar PE tube samplers in ground water. Note: all of these flow rates are estimated calculations based on average expected conditions at each of these sites, none of these are measured rates.
Figure 21. Calculated Narragansett Bay surface water. At each site, surface water concentrations are displayed for the water grabs collected on deployment (dep) and recovery (rec), as well as the calculated values using the sampling rate (calc). Deployment surface water concentrations are not available for stations 4 and 5.
Figure 22. Plot of the calculated versus measured Narragansett Bay surface water values.

The measured values displayed here are the mean from both water grabs upon passive sampler deployment and recovery. The dashed line represents the one to one ratio between the two parameters.
Table 10. Narragansett Bay surface water concentrations (ng L\(^{-1}\)) back-calculated (\(C_w=C_s/t*R_s\)) from Field’s Point (FP) sampling rate (\(R_s\)) from the linear model (equation 2).
