Abstract
Despite efforts to treat obstructive sleep apnea syndrome (OSA), the condition remains an important risk factor in the development of cardiovascular disease. Early detection of RV dysfunction with novel echocardiographic techniques (speckle tracking echocardiography) may be useful in preventing progression to pulmonary hypertension, with subsequent heart failure and cardiovascular death. Echocardiography is the method of choice for the evaluation of OSA consequences on the heart. Although standard echocardiographic parameters are routinely used in these patients, there are several limitations in the early detection of RV dysfunction. The main concerns are the complex geometry of RV and the impact of pre- and afterload on RV myocardium, which cannot be assessed through standard measurements. The aim of this review is to highlight the utility of advanced echocardiographic parameters in the identification of OSA patients with subclinical myocardial dysfunction, which are at risk of developing heart failure and later adverse events. Speckle tracking echocardiography might provide higher sensitivity in unmasking alterations in RV function when conventional echocardiographic methods cannot detect them. Therefore, this method has a major role in the detection of early stages of RV dysfunction, along with better risk stratification and better timing in the initiation of therapy.

Keywords: obstructive sleep apnea; speckle tracking; echocardiography

Introduction
Obstructive sleep apnea (OSA) is a potentially dangerous sleep disorder, with an incidence of about 4-7% in the general adult population [1]. It is characterized by the presence of intermittent episodes of partial or complete obstruction of the upper airways during sleep, leading to intermittent hypoxemia, fragmentation of sleep, snoring and daytime sleepiness. Obesity is an important risk factor, alongside smoking, alcohol consumption and male sex. The hallmark of OSA is the craniofacial morphology, with its contribution to upper airway collapsibility [2]. Some of these risk factors for OSA are also established risk factors for cardiovascular diseases, making it difficult to demonstrate a causal relationship between OSA cardiac damage independent of these potentially confounding factors [3].

In order to diagnose OSA, sleep studies (polysomnography) are required; these can quantify the apnea-hypopnea index (AHI), which places OSA in a severity class (mild, moderate and severe, respectively 5-14, 15-30 and >30 events/hour) [4]. A large number of epidemiological evidences describes a link between OSA syndrome and cardiovascular morbidity and mortality [1,4,5], evidence that has prompted the American Heart Association (AHA) to issue a scientific statement describing the need for a standardized approach to treatment in sleep apnea syndrome.
to recognize this pathology as an important target for cardiovascular disease risk reduction therapy [5]. Front-line treatment of OSA implies stabilizing the upper airway mechanically, by introducing a column of air via continuous positive airway pressure (CPAP). Although CPAP is considered the “gold standard” treatment, its results are narrowed by poor patient adherence to, due to various side effects [6]. Several forms of cardiovascular diseases (CVD) including stroke, heart failure, hypertension, coronary artery disease, arrhythmias (atrial fibrillation), have been associated with OSA [7]. However, the exact effect of OSA on cardiac structure and function is not fully understood [8]. Previous reports have shown that pulmonary hypertension (PH) occurs in up to 40% of patients with OSA along with heart or pulmonary disease, but it may also develop in OSA patients in the absence of known cardiopulmonary disorders. Although PH is mild to moderate in OSA, it can lead to RV hypertrophy and dysfunction. [9]. Podszus et al [10] found that OSA is a predisposing factor for the development of pulmonary hypertension, but there are still few and discrepant data concerning the repercussions of OSA on the structural and functional changes of the right heart [11].

A comprehensive echocardiography screening for subclinical heart failure in OSA patients is needed. It is well known that assessment of the right ventricle (RV) by echocardiography in day-to-day practice is often based on qualitative evaluation, thus being recognized as the “forgotten chamber” [12]. It is important to obtain a complete assessment of the RV, quantitative as well as qualitative, using combined techniques. Three-dimensional echocardiography (3DE) and speckle tracking echocardiography (STE) allow the evaluator to overcome the limitations of conventional echocardiography.

The aim of this review was to highlight the utility of advanced echocardiography parameters in identifying OSA patients with subclinical myocardial dysfunction, along with better risk stratification and well-timed initiation of therapy.

Is 3D echocardiography a reality of daily clinical practice when assessing the RV?

Most conventional methods of echocardiographic evaluation of the RV function and dimensions are based on approximate volumetric measurements. Such approaches are limited by the complex geometry of the RV and by their angle or load dependency. As a rule, the problem of the complex geometry of the RV could be solved through real time 3DE and that of the angle/load dependence through STE (fig 1). Compared to bidimensional echocardiography (2DE), the real time 3DE allows a better anatomical definition of the RV, with good highlighting of the base, apex and outflow tract [11,13].

Novel techniques using software based on RV 3DE acquisitions have proven the utility to accurately and reproducibly assess the RV dimensions and function [14]. A first study to assess 3DE derived global and regional RV shape parameters in normal subjects and in patients with PH was developed by Addetia et al [15]. The authors showed that in PH, RV expresses modifications in regional curvature evident in apical and septal free-wall regions and in the outflow tract, when compared to normal RV. In this study, the outflow tract was found to be rounder, with more convex apical and body portions of the septum, bulging into the left ventricle (LV) at end-diastole and end-systole, while the apical free wall was found to be more flattened. These findings demonstrate that curvature analysis using 3DE allows a better quantitative assessment of RV remodeling, due to the tracking of changes in the regional RV shape [15]. The feasibility, accuracy, and reproducibility of RV volumes and ejection fraction (EF) assessment using real-time 3D echocardiographic imaging were pointed out in several studies. For example, the value of 3DE in the evaluation of RV structure and function in patients with congenital heart disease (CHD) was assessed by van der Zwaan et al [16] who used cardiac magnetic resonance imaging (CMR) as a reference. They have compared 3DE derived RV volumes and EF with 2DE derived measurements for RV assessment and demonstrated that 3DE showed a higher specificity to exclude RV myocardial dysfunction. These findings are in agreement with other published studies. Moreover, Nagata et al showed that in 446 patients, 3DE RV-EF was independently correlated with cardiac outcomes.
in subjects with diverse backgrounds. Furthermore, 3DE RV-EF offered additional values over clinical risk factors and other echocardiographic parameters, in prediction of future cardiovascular adverse outcomes [17].

Other advantages of 3DE are the relatively short time required for off-line analysis of acquisitions and the good quality of 3D images used for reconstructions, which were demonstrated by the study of Tamborini et al [18]. Several previous studies have proven the reproducibility and fidelity of 3DE in the evaluation of RV systolic function and global volume [19-20]. For example, Zhou et al [3] concluded that using real time 3DE in the assessment of RV systolic function is an important key in the noninvasive evaluation of severity in OSA; furthermore, they have demonstrated patients with OSA, RV global EF assessed by 3DE was lower than in controls with an inverse relationship to the severity of OSA as assessed by AHI. Similar results were obtained by Vitarelli et al [21], who demonstrated that RVEF assessed by 3DE was lower in subjects with moderate-sever OSA compared with controls, irrespective of the presence of PH. Moreover, the authors have concluded that changes in parameters were independently associated with AHI. Interestingly, after using CPAP for 4 months, the subgroup with severe OSA showed a significantly lower pulmonary artery pressure than that of patients at baseline and an improvement in RV dysfunction with an increase of RV EF.

It is well known that CMR represents the gold standard in terms of quantitative assessment of the RV; however, its common use in daily practice is limited because it is expensive, time-consuming and sometimes contraindicated. In a number of studies, the accuracy of 3DE was compared with CMR, and they were in good concordance [22]. Jenkins et al confirmed that 3DE has less variation and higher correlation to CMR than all 2DE techniques, when being compared in patients after acute myocardial infarction [23]. Also, when comparing 3DE and 2DE with CMR, 3DE EF was the most reliable echocardiographic variable for recognizing CMR-derived RV EF <50% [24]. On the other hand, Kjaergaard et al [25], found at best modest correlations between 3DE and CMR, concluding that tricuspid annular plane systolic excursion (TAPSE) is the best option for RV function assessment for daily clinical purposes. However, it is important to keep in mind that TAPSE assesses only longitudinal RV shortening, which does not represent the RV global function, especially if extensive regional abnormalities are present [26].

In order to use 3DE for RV assessment it is important to remember that the RV cavity borders can be difficult to define, given the numerous trabeculations of RV free wall. This may be the explanation for the differences between 3DE and CMR in the evaluation of RV function and volumes and also the reason why there are cases when RV chamber is underestimated using 3DE [27].

Speckle tracking echocardiography in the evaluation of the RV: the future is here, what’s next?

Conventional and Tissue-Doppler Echocardiography allow the evaluation of RV function through fractional area change (FAC), myocardial performance index (MPI), TAPSE and lateral S’ wave by tissue-Doppler. STE is a relatively new technique used in the evaluation of myocardial function and is less angle independent. As a principle of this method, random noise is filtered out, while preserving unique stable myocardial features, mentioned as speckles. These blocks of speckles can be unmasked within the myocardium based on frame-by-frame tracking, simultaneously in several regions of a plan; therefore, the parameters of myocardial function (velocity, strain, strain rate), being evaluated in the longitudinal, radial and circumferential ventricular axis. Basically, information on both global and segmental myocardial deformation is provided by this method [28]. However, these parameters are limited by load and angle dependency and do not assess all the axis of RV myocardial contractility. Several studies that have used these conventional echocardiographic parameters reported changes in RV function and structure in patients with OSA [29,30]. Moreover, some studies revealed no abnormalities of RV structure and function in OSA patients [31-32]. Thus, it remains a question when the other techniques are necessary, in order to detect more subtle changes in RV deformation, which might be present in patients with OSA. Novel echocardiographic techniques including 2DE and 3DE speckle tracking methods might therefore provide higher sensitivity in unmasking alterations in RV function and structure, in the early stages of RV dysfunction, when conventional echocardiographic methods cannot detect them [9,33,34]. These methods proved their utility in the assessment of RV function in acute conditions. For example, Trivedi et al in a retrospective study conducted on patients with pulmonary embolism (PE), demonstrated that RV function assessed by 2D RV free wall strain (FWS) was reduced in PE patients compared with controls. Adding RV FWS to the existing parameters of RV size and function significantly improved the sensitivity and specificity of the diagnosis of PE and might play a role in guiding treatment. [35] More recently Li et al evaluated in 120 patients suffering from COVID-19, the relationship between echocardiography variables (including 2D RV LS) and clinical variables to predict patient prognosis including mortality. RV LS predicted mortality, with a sensitivity and specificity
of 94.4 % and 64.7% respectively. The prognostic value of RV LS was better than other indicators of RV function used alone or in combination, and it was maintained in univariate and multivariate Cox regression analysis [36].

**2DE speckle tracking of the RV in patients with OSA**

RV function plays an important role in the morbidity and mortality of patients with OSA. Early detection of RV dysfunction before the onset of pulmonary hypertension is crucial in preventing progression to heart failure and cardiac death [37]. This became possible using 2D speckle tracking echocardiography. Studies showed that RV longitudinal strain had a predicted value in several cardiovascular diseases (CHD, heart failure, valvular heart disease, PH and OSA). RV strain in OSA patients has not been yet rigorously and exhaustively explored, but there are investigations on this subject with encouraging results [38]. Recent studies have shown that patients with OSA have shown impairment of global longitudinal strain (GLS-RV) and lateral wall strain (LS-RV) in the presence of preserved RV-EF. As Buonauro et al [39], concluded in their study, OSA patients showed significant reduction in RV GLS (18.2±2.4%, p<0.001) and LS-RV (17.8±4.8%, p<0.001), but not in septal longitudinal strain (SLS-RV) (18.8±3.6 %, p=0.229) compared with healthy controls. RV-GLS correlated with OSA severity, in the absence of important alteration of other echocardiographic parameters of RV systolic function, such as 3D-EF or TAPSE. Li et al [40] showed significantly reduced RV LS and strain rates of RV apical segments in patients with mild OSA compared to controls, results confirmed by the study of Kepez et al [11]. D’Andrea et al [41], revealed a reduction in both LV and RV GLS (-14.5 ± 8.2 %, p<0.001) and LS-RV (17.8±4.8 %, p<0.01), as well as RV LS in OSA patients compared with controls. In concordance with these findings, Hammerstingl et al [42], found that RV 2DE GLS (-14.5 ± 8.2 %, p<0.001) was significantly lower in subjects with higher AHI, compared with controls; and was positively associated with the severity of OSA. Moreover, conventional echocardiography parameters, such as TAPSE, RV MPI, were not significantly impaired in these patients, supposing that they are not sufficiently sensitive in detecting subclinical changes of RV function in OSA.

RV dysfunction might be the expression of pulmonary hypertension. This hypothesis is supported by several studies, which demonstrate that patients with OSA and right ventricular systolic pressure (RVSP) ≥30 mmHg, show substantially lower GLS-RV (18.2±2.4%, p<0.001), LLS-RV (17.8± 4.8%, p<0.001), compared with patients with RVSP<30 mmHg (GLS-RV=22.7±4.8%, LLS-RV=25.1±7.0%) [28]. However, these data are in opposition with the results obtained by Altekin et al [37], who did not find any differences in strain or strain rate at patients with OSA and pulmonary hypertension. Concerning RV strain in OSA patients during CPAP therapy, free wall RV strains and global strain improved after CPAP treatment, even in the presence of unchanged conventional parameters [39]. Kim et al showed that CPAP therapy, unlike sham therapy significantly improved RV GLS and also reduced RV dimension [43]. Other data report strain improvement under CPAP therapy in apical segments, but not in the medial or basal ones, explaining why RV global longitudinal strain (average of apical, medial and basal segments) remained unchanged after 6 months of CPAP therapy [42].

**3D speckle tracking in the evaluation of the RV: a new era**

The RV has a complex pattern of contraction, which occurs along three anatomically relevant axes: longitudinal shortening with tricuspid annulus traction towards the apex, anteroposterior shortening by stretching the free wall over the interventricular septum and radial movement of the free wall, also known as the “bellows effect”. Although it is well known that the subepicardial layer of the myocardium is rich in circumferential myofibers, in the daily echocardiographic evaluation of the right ventricle, non-longitudinal motion directions are often omitted [44]. Therefore, the mix of deformation marks provides insight into the pathophysiologic mechanics of RV dysfunction. In comparison to 2D STE, the advantage of using 3D STE consists of the possibility of simultaneous assessment of various wall motion indices, in particular: radial strain (RS), longitudinal strain (LS) and circumferential strain (CS) in the entire RV myocardium. Another unique parameter assessed by 3D STE is the area change ratio (ACR) or area strain in a regional or entire tracking area [45]. The clinical utility and feasibility of the 3D STE of RV technique were evaluated by Atsumi et al [46], in both an experimental and clinical study, by using sonomicrometry crystals implanted in the RV endocardium, in order to validate 3D STE data. The authors obtained significant correlation between the two techniques. The PH group had significantly lower RV global deformation parameters than the control group. These findings confirm the results of previous studies that used 3D STE modified for RV software, showing that PH patients have reduced RV strain values, poorer outcomes, lowered ACR, LS and CS and increased mortality risk compared with controls [47]. On the other hand, Liu et al evaluated and compared the value of RV LS detected by both 2DE and 3D STE in the risk stratification of patients with pre-capillary PH. Authors demonstrated that 2D RV LS is better than 3D RV LS for the detections of patients with pre-capillary hypertension intermediate-high risk [48].
3D speckle tracking echocardiography for the RV: are regional deformation parameters also necessary?

The myofibers in the myocardium are a complex 3D network, arranged as a multiple helical display with important functional effect. The orientation of these myofibers is important because it helps to understand the pattern of RV contraction in 3D space [42]. Knowing that 3D STE allows a better perception of RV wall dynamic/motion, the question is which of the 3D strain parameters is more dependable.

Atsumi et al [46] showed in their experimental study (10 sheep), that RV ACR and RV LS were significantly lower in moderate pulmonary artery banding (peak RV pressure>40 mmHg) and in severe pulmonary artery banding (peak RV pressure >60 mmHg) compared to baseline values; however, RV CS differed significantly only between baseline and sever PAB, revealing that longitudinal contraction may be more reactive to pressure overload. The difference between LS and CS was explained by the RV myofibers arrangement: the endocardial layer contains longitudinal myofibers, the epicardial layer comprises circumferential myofibers, whereas the epicardial fiber is continuous with the left ventricular myocardium. Therefore, circumferential contraction might be less affected by pressure overload solely in the RV due to its preservation by LV contraction.

On the other hand, in a study comparing 97 patients suffering from PHT with 60 controls, Smith et al [47] demonstrated that all PHT patients had reduced RV strain indices compared with controls; RV AS and CS were strongly correlated to RV EF (p<0.001). LS and RS were also correlated to RV EF, but lesser. Moreover, the authors evaluated mortality at 24 months, showing that RV AS, CS and LS predicted it most accurately. Furthermore, only AS, and in a lesser level, age, were predictors of death, underling the superiority of 3D STE RV – AS over other parameters. A possible explication for why RV CS may be more affected in the group of patients with PHT, is that important structural changes happen during the development of PHT, including a change in fiber orientation and increased wall stress, leading to reduced circumferential contraction (fig 2).

3D speckle tracking of RV in patients with OSA: future directions

The impact of OSA on the right ventricular structure and function has been demonstrated, since PAH, impairment of RV systolic function and RV dysynchrony have an important influence on cardiovascular morbidity and mortality. 3DE speckle tracking allows a better and more comprehensive assessment of the RV wall motion. Moreover, this novel technique is able to detect alterations in subclinical stages of RV dysfunction. Furthermore, it might be useful in evaluating the efficacy of continuous positive air pressure therapy in improving cardiac function. Thus, an earlier initiation of OSA therapy can reduce cardiovascular risk.

Although these data provide motivation for using the more recent echocardiographic techniques for the assessment of cardiac function in patients with OSA and their response to therapy, several issues need further investigation in order to be accepted as mainstream methods for the quantitative assessment of RV function. Speckle tracking imaging is a more sensitive technique for detecting subclinical alterations in ventricular functions that contrarily may be missed by conventional echocardiography. The favourite deformation parameter is the global longitudinal strain due to its reproducibility and feasibility. 3DE is useful in the determination of ejection fraction, RV volumes and intracardiac anatomy. It is strongly recommended to develop and validate a dedicated echocardiography program for each specific OSA lesion and to combine deformation imaging with 3DE [49].

Conclusion

Deterioration of RV mechanics occurs before functional and structural heart damage. Therefore, recent echocardiographic techniques seem to be the cornerstone of detecting subtle cardiac changes in the RV. Since RV demonstrated an important predictive value in several pathologies, it should be more widely used in the evalu-
Echocardiography in patients with obstructive sleep apnea and RV subclinical myocardial dysfunction.

section of patients with OSA, which might present early changes in RV contraction, even in the presence of an apparently preserved systolic function. Risk stratification in these patients using modern echocardiography techniques might bring future information regarding the impact on the cardiac function of the disease and might also offer guidance for early therapy in order to prevent further damage on the systolic RV function.
