The In-Plane Anisotropy of WTe$_2$
Investigated by Angle-Dependent and Polarized Raman Spectroscopy

Tungsten ditelluride (WTe$_2$) is a semi-metallic layered transition metal dichalcogenide with a stable distorted 1T phase. The reduced symmetry of this system leads to in-plane anisotropy in various materials properties. We have systemically studied the in-plane anisotropy of Raman modes in few-layer and bulk WTe$_2$ by angle-dependent and polarized Raman spectroscopy (ADPRS). Ten Raman modes are clearly resolved. Their intensities show periodic variation with sample rotating. We identify the symmetries of the detected modes by quantitatively analyzing the ADPRS results based on the symmetry selection rules. Material absorption effect on the phonon modes with high vibration frequencies is investigated by considering complex Raman tensor elements. We also provide a rapid and nondestructive method to identify the crystallographic orientation of WTe$_2$. The crystallographic orientation is further confirmed by the quantitative atomic-resolution force image. Finally, we find that the atomic vibrational tendency and complexity of detected modes are also reflected in the shrinkage degree defined based on ADPRS, which is confirmed by corresponding density functional calculation. Our work provides a deep understanding of the interaction between WTe$_2$ and light, which will benefit in future studies about the anisotropic physical properties of WTe$_2$ and other in-plane anisotropic materials.

Transition metal dichalcogenides (TMDs) have attracted a lot of attention because of their emerging and remarkable electrical, optical and mechanical properties$^{1,2}$. In contrast to the widely studied TMDs like MoS$_2$, WS$_2$, MoSe$_2$, WSe$_2$ and MoTe$_2$$^{3,5}$, which are in-plane isotropous, WTe$_2$ crystallizes in a distorted structure with an octahedral coordination around the metal, referred to as Td-polytype$^6$. The recent discovery of non-saturating giant positive magnetoresistance and excellent thermoelectric behaviors in WTe$_2$ arouses great interest in this material$^{7,8}$. In addition, WTe$_2$ is predicted to be a novel type of topological semimetal for further quantum transport studies$^{9}$. The Td-WTe$_2$ is constituted with triple-layer covalently bonded Te-W-Te atomic planes stacking along the c-axis through van der Waals interactions, as shown in Fig. 1a,b. The Td-WTe$_2$ is strongly distorted from the ideal hexagonal net, because the off-centering W atoms form the slightly buckled W-W zigzag chains along the a-axis of the orthorhombic unit cell, as shown in Fig. 1c. The reduced crystal symmetry of WTe$_2$ leads to the strong in-plane anisotropy.

Raman spectroscopy of both few-layer and bulk WTe$_2$ was reported recently, which was crucial first step for WTe$_2$ crystal structure characterization$^{6,11-14}$. However, in order to further study the particular property of WTe$_2$ and exploit related novel electronic and optoelectronic devices, more detailed study about few-layer and bulk WTe$_2$ Raman spectra is still needed. In this work, we investigate the detailed Raman responses of both few-layer and bulk WTe$_2$ flakes using the high-resolution angle-dependent and polarized Raman spectroscopy (ADPRS). The detected Raman modes are much more compared with the previous literatures$^{6,11-13}$. By combining the
symmetry analysis of the ADPRS results and the first principle calculation, we can accurately identify the symmetries of the detected modes and obtain the relation between their symmetries and lattice vibrations. We also identify the crystalline orientation of the WTe2 flakes based on the “in-plane anisotropy”, which is a precise and non-destructive all-optical method. Our work provides a deep understanding of the interaction between WTe2 and light, which will benefit in future studies about the anisotropic optical, electrical, and mechanical properties of WTe2 and other in-plane anisotropic materials15–35.

Results and Discussion

The Td-WTe2 bulk crystal used in this work was grown by the chemical vapor transport (CVT) method (more details in Method). The mono- and few-layer WTe2 were mechanically exfoliated on 300 nm SiO2/Si and quartz substrates (Supplementary Fig. S1) from the crystal. Figure 2a shows the optical microscope image of an as-exfoliated few-layer WTe2. Usually a well-defined edge (indicated by the white double-headed arrow) is naturally formed after exfoliation, due to the small cleave energy along the a-axis (i.e., the direction along the W-W chains). This is further confirmed by the quantitative atomic resolution force image probed by high-resolution atomic force microscopy (HR-AFM)36. Here, we define the a-axis as x-axis, the in plane direction perpendicular to it as y-axis, and the direction perpendicular to the 2D plane (c-axis) as z-axis. Figure 2b is an AFM image of the few-layer WTe2 (the red box area) in Fig. 2a. The corresponding HR-AFM image (the green box area) is shown in Fig. 2c. The smoothed HR-AFM image after the fast Fourier transform (FFT) is depicted in Fig. 2d. We can observe clearly one dimensional atomic chains parallel to the well-defined edge shown in Fig. 2a. The inset in Fig. 2d is the FFT image, where the distorted hexagon shape origins from the two different tungsten-tellurium bond lengths (2.7 Å and 2.8 Å). The height variation induced by the protruding tellurium atoms (highlighted in yellow in the inset) perpendicular to the one dimensional chains is shown in Fig. 2e. The average peak distance is about 6.65 Å, close to the lattice constant b.

In the ADPRS measurement, a WTe2 flake on SiO2/Si substrate was initially placed with an arbitrary angle θ0 between the x-axis and horizontal direction. Herein, θ0 can be used to denote the crystalline orientation. We define θ0 to be positive (negative) value, when the x-axis is clockwise (anti-clockwise) compared to the horizontal direction (more details in Method and Supplementary Fig. S2). Figure 3a shows the Raman spectra of WTe2 in the un-, parallel- and cross-polarized configurations measured at an angle with the maximum number of Raman active modes. Altogether, ten Raman modes can be resolved. All of them can be well fitted by Lorentzian lineshape. Figure 3b–d show the angular dependences of the normalized Raman intensity spectra in the un-, parallel- and cross-polarized configurations, respectively. The sample rotation angle is in a range of 0–360°. The highest peak in each spectrum is used for normalization. We can see that, in the parallel-polarized configuration, the modes at ~80, 133, 135, 137 and 212 cm−1 yield 2-lobed shape with two maximum intensity angles at about 65° and 245°; the modes at ~117 and 164 cm−1 yield 2-lobed shape with two maximum intensity angles at about 155° and 335°; and the modes at ~91, 112 and 161 cm−1 yield 4-lobed shape with maximum intensity angles at about 20°, 110°, 200° and 290°. In the cross-polarized configuration, all modes yield 4-lobed shape. The four maximum intensity angles for the modes at ~91, 112 and 161 cm−1 are θ = 65°, 155°, 245° and 335°, and those for the rest ones are 20°, 110°, 200° and 290°. In addition, we can see that the intensities of the three neighbored modes at 133, 135 and 137 cm−1 have similar angular dependent relations; while those of the two neighbored modes at 161 and 164 cm−1 have different angular dependent relations. The related angular dependent evolutions of these detected modes in the rotation angle range of 0–90° under the three polarized configurations are shown in Supplementary Figs S4–7, respectively. The ADPRS results for WTe2 with four representative different thicknesses (~3 nm, 10 nm, 25 nm and 40 nm) are shown in Supplementary Fig. S3. The results show that the anisotropic Raman spectra of WTe2 flakes have no clear thickness (≥3 nm) dependence.

We can quantitatively analyze these observed anisotropic phenomena, based on the group theory, Raman tensors and density functional theory (DFT) calculations. According to symmetry analysis, the bulk Td-WTe2 belongs to the space group Pmm2, and point group C2v13,37. The unit cell of bulk Td-WTe2 contains two tungsten atoms and four tellurium atoms. There are 33 normal optical phonon modes at the Brillouin zone center Γ point, with irreducible representation as ℏωbulk = 11A1 + 6A2 + 5B1 + 11B2, where all the vibration modes are Raman...

Figure 4. Raman tensor forms for all Raman active modes in bulk WTe₂.

active. The 11A₁, 5B₁, and 11B₂ modes are also infrared active. There exists a correlation between the Raman tensors of bulk and few-layer WTe₂ (more details in Supplementary Information). For simplicity, we use the Raman tensors of bulk WTe₂ (Fig. 4) to do the analysis.

According to the classical Placzek approximation, the Raman intensity of a phonon mode can be written as:

$$I \propto |\mathbf{e}_i \cdot \mathbf{R} \cdot \mathbf{e}_s|^2$$

where $\mathbf{e}_i$ and $\mathbf{e}_s$ are the electric polarization unitary vectors of the incident and scattered lights, respectively, and $\mathbf{R}$ is the Raman tensor. The Raman tensors for all Raman active modes in bulk WTe₂ are given in Fig. 4. Based on the Cartesian coordinates denoted above, the $\mathbf{e}_i$ and $\mathbf{e}_s$ are fixed in $xy$ plane. For a sample with rotation angle of $\theta$ (clockwise rotation, as shown in Fig. S2), $e_i = (\cos(\theta + \theta_0) \sin(\theta + \theta_0) 0)$ for the incident light, and $e_s = (\cos(\theta + \theta_0) \sin(\theta + \theta_0) 0)$ for the scattered light in the parallel- and cross-polarized configurations, respectively. A phonon mode can only be detected when $|\mathbf{e}_i \cdot \mathbf{R} \cdot \mathbf{e}_s|^2$ has non-zero value. Therefore, in the backscattering geometry, only $A_1$ and $A_2$ Raman modes can be observed. Using the above defined unitary vectors $e_i$ and $e_s$, as well as the Raman tensors of $A_1$ and $A_2$ modes, we can obtain the angular dependent intensity expressions for the $A_1$ and $A_2$ modes to be:

$$I_{A1} \propto a^2 \left( \frac{b}{a} - 1 \right) \sin^2(\theta + \theta_0)$$

(2)

$$I_{A1} \propto \frac{1}{4} a^2 \left( \frac{b}{a} - 1 \right) \sin^2 2(\theta + \theta_0)$$

(3)

$$I_{A2} \propto a^2 \sin^2(\theta + \theta_0)$$

(4)

$$I_{A2} \propto a^2 \cos^2(\theta + \theta_0).$$

(5)

As the initial angle $\theta_0$ is fixed, the intensity of $A_1$ or $A_2$ mode is a function of the corresponding elements of Raman tensor ($a$ and $b$) and the rotation angle $\theta$. In the parallel-polarized configuration, the angular dependence for the intensity of $A_1$ mode has two cases, both of which have a variation period of $180^\circ$. For $A_1$ mode with $a < b$, the maximum intensity appears at $\theta = 180^\circ - \theta_0$ and $360^\circ - \theta_0$, corresponding to the incident light polarization parallel to the W-W chains. On the contrary, the minimum intensity appears at $\theta = 0^\circ - \theta_0$ and $360^\circ - \theta_0$, corresponding to the incident light polarization perpendicular to the W-W chains. For the $A_1$ mode with $a > b$, the maximum intensity angles are $\theta = 90^\circ - \theta_0$ and $270^\circ - \theta_0$, and the minimum intensity angles are $\theta = 180^\circ - \theta_0$ and $360^\circ - \theta_0$, corresponding to the incident light polarization perpendicular and parallel to the W-W chains, respectively. In the parallel-polarized configuration, the angular dependence for the intensity of $A_2$ mode has a variation period of $90^\circ$ with the maximum intensity at $\theta = 45^\circ - \theta_0$, $135^\circ - \theta_0$, $225^\circ - \theta_0$ and $315^\circ - \theta_0$ and the minimum intensity at $\theta = 90^\circ - \theta_0$, $180^\circ - \theta_0$, $270^\circ - \theta_0$ and $360^\circ - \theta_0$. In the cross-polarized configuration, both of $A_1$ and $A_2$ modes have a variation period of $90^\circ$. The intensity of $A_1$ mode ($A_2$ mode) reaches its maximum (minimum) at $\theta = 45^\circ - \theta_0$, $135^\circ - \theta_0$, $225^\circ - \theta_0$ and $315^\circ - \theta_0$, and reaches its minimum (maximum) at $\theta = 45^\circ + \theta_0$, $135^\circ + \theta_0$, $225^\circ + \theta_0$ and $315^\circ + \theta_0$. In addition, the normalized Raman intensities of the ten detected modes (except for $A_2$ modes) in un-polarized configuration exhibit similar angular dependences to those in parallel-polarized configuration, as shown in Supplementary Fig. S8. It is worth noting that, as sample rotates, the full width at half maximum (FWHM) of each detected mode keeps almost constant, as shown in Supplementary Fig. S9.

According to the above analysis, we can use the ADPRS to identify the symmetries of the detected modes. The intensity variation periods for $A_1$ modes are $180^\circ$ and $90^\circ$ in parallel- and cross-polarized configurations, respectively, while those for $A_2$ phonon modes are $90^\circ$ in both configurations. Therefore, seven phonon modes located at $\approx 80, 117, 133, 135, 137, 164$ and $212$ cm$^{-1}$ belong to $A_1$ modes, and three modes located at $\approx 91, 112$ and $161$ cm$^{-1}$ belong to $A_2$ modes. In addition, we find that when the incident polarization is parallel to the well-defined edge (i.e. parallel to the W-W chains) of the sample, the Raman modes at $117$ and $164$ cm$^{-1}$ reach their maximum intensities. Therefore, we assign them to $A_1$ modes with $a > b$. The rest $A_1$ modes are with $a < b$. The lattice vibrations of
all phonon modes are calculated by the density functional theory (DFT, more details in Method, Supplementary Fig. S11 and Table S1), and atomic displacements of detected ones are shown in Fig. 5. Because monolayer WTe$_2$ (with space group $P2_1/m$ and point group $C_{2h}^2$) has different crystal symmetry with the bulk one, the 2-lobed modes in monolayer WTe$_2$ can be labelled as $A_g$, and the 4-lobed ones can be labelled as $B_g$. Notably, there is no odd and even layer number dependence of crystal symmetry for WTe$_2$. Therefore, for $N$-layer WTe$_2$ ($N \geq 2$, with space group $Pm$ and point group $C_{1s}$), the 2-lobed and 4-lobed modes can be labelled as $A'_g$ and $A''_g$, respectively.

Notably, according to above results, we can use the maximum intensity of the mode at $\sim 164$ cm$^{-1}$ in un- and parallel-polarized configurations to identify the crystallographic orientation (i.e. the direction of W-W chains) rapidly and nondestructively. This is important in case that the well-defined edge of a few-layer WTe$_2$ cannot be easily identified by the optical microscopy. In our case, it is represented by $\theta_0 \sim 25^\circ$. The angular dependence of the normalized Raman intensities for the ten detected modes in the parallel- and cross-polarized configurations are shown in the polar plots in Fig. 6a–j. Notably, since the opposite angular dependent relations for $A_1$ modes with $a < b$ and $a > b$, their intensity ratio shows a clearer 2-lobed characteristic with sample rotating, as shown in Fig. 6k. By curving fitting Fig. 6k, we can obtain a more accurate $\theta_0$ to be $27.5^\circ$. The angular dependences of the Raman intensity ratios between other $A_1$ and $A_2$ modes, which are also helpful for identifying the crystallographic orientation, are shown in Supplementary Fig. S10.

It is worth noting that, the polar plots of $A_1$ modes with higher frequencies (164 and 212 cm$^{-1}$) in Fig. 6i,j cannot be well fitted by equation (2) (the blue and purple lines are the corresponding fitting results). In order to explain this, we consider the light absorption effect on the Raman tensor elements. In an absorptive material, the elements of the Raman tensor should be complex numbers, with real and imaginary parts. In this case, the tensor elements of $A_1$ and $A_2$ can be written as:

\[ a = |a|e^{i\phi_a}, \quad b = |b|e^{i\phi_b}, \quad d = |d|e^{i\phi_d} \]

where $\phi_a$, $\phi_b$ and $\phi_d$ are the corresponding phases. Substituting in equation (1) with the unitary vectors $e_i$ and $e_j$ and the above Raman tensor elements, we can modify the angular dependent intensity expressions of the $A_1$ and $A_2$ modes as:

\[ I_{A1} \propto |a|^2 \left[ 1 + \frac{|b|}{|a|} - 1 \right] \sin^2(\theta + \theta_0) \frac{1}{2} \left[ \frac{|b|}{|a|} \sin^2 2(\theta + \theta_0) (\cos \phi_{ba} - 1) \right] \]

Figure 5. The calculated atomic displacements for the lattice vibrations of the ten detected modes in WTe$_2$, together with their corresponding irreducible representations. The theoretical frequency is given below its experimental counterpart in each plot. The motions of W (Te) atoms are presented by red (blue) arrows.
where $\phi_{ha} = \phi_h - \phi_a$ is the phase difference between the Raman tensor elements $b$ and $a$. The expressions for $A_2$ modes (equations 9 and 10) are identical to their counterparts (equations 4 and 5) obtained considering only real part of the Raman tensor elements. However, the expressions for $A_1$ modes are different. We can see that the absorption effect on the ADPRS reflects in phase difference. The angular dependent intensities of $A_1$ modes at 164 and 212 cm$^{-1}$ can be well fitted by equations (7) and (8), as shown in Fig. 6i,j.

To further characterize the vibration direction of atoms for these detected modes, we choose defined $x, y$ and $z$ axes as the reference directions. Compared with the typical atomic displacements in 2H-type TMDs, such as MoS$_2$, WS$_2$, MoSe$_2$, and WSe$_2$, etc., the atomic displacements in WTe$_2$ is relative complicated and disordered due to the lower symmetry. The related Raman tensor element ratios $(b/a)$, phase differences, and shrinkage degrees for the ten detected modes are summarized in Table 1. Here, we define the shrinkage degree as the ratio of the maximum intensity and its orthogonal direction intensity in a polar plot. Considering the absorption effect, we can obtain the
shrinkage degrees for \( A_1 \) modes to be: 
\[
\frac{\cos \phi_{ba}}{|b|} = \left( 1 + \frac{1}{4} \cos \phi_{ba} - 1 \right) \left( 1 + \frac{1}{4} \cos \phi_{ba} - 1 \right) \frac{|a|}{|b|} < \frac{|b|}{|a|} \text{ and } \frac{\cos \phi_{ba}}{|b|} = \left( 1 + \frac{1}{4} \cos \phi_{ba} - 1 \right) \left( 1 + \frac{1}{4} \cos \phi_{ba} - 1 \right) \frac{|a|}{|b|} > \frac{|b|}{|a|}.
\]

For the \( A_2 \) modes, whose shrinkage degrees are close to one (minimum value), both W and Te atoms vibrate along the W-W chains (x-axis). In the case of \( A_1 \) modes with relative small shrinkage degrees, for the \( A_1 \) mode, all the W and Te atoms vibrate along the z axis. For the \( A_1 \) mode, all the W (Te) atoms have the tendency to vibrate along the \( y \) axis. For the \( A_1 \) mode at \( \sim 164 \text{ cm}^{-1} \), all the W atoms have the tendency to vibrate along the \( z \) axis, and half of the Te atoms have the tendency to vibrate along the \( y \) axis. For the \( A_1 \) mode at \( \sim 164 \text{ cm}^{-1} \), all the W (Te) atoms have the tendency to vibrate along the \( y \) axis. For the \( A_1 \) mode at \( \sim 212 \text{ cm}^{-1} \), all the W (Te) atoms have the tendency to vibrate along the \( z \) axis. For the rest four \( A_1 \) modes with larger shrinkage degrees, their vibrations are more complicated. This finding may be applied for studying the complicated atomic vibrations in other anisotropic materials.

### Conclusion

In this work, we study the ADPRS of WTe\(_2\). Ten Raman modes are clearly resolved. Their intensities show periodic variation with sample rotating. We identify the symmetries of these detected modes by quantitatively analyzing the ADPRS results using the symmetry selection rules based on the Raman tensors, and do the curve fitting to the angular dependent intensities of them using the complex Raman tensor elements induced by absorption effect. We also provide a rapid and nondestructive method to identify the crystallographic orientation of WTe\(_2\). We find that the defined shrinkage degree based on ADPRS also reflects the vibrational tendency and complexity of detected modes, which is confirmed by their atomic vibrations calculated by density functional theory. Our work provides a deep understanding of the interaction between WTe\(_2\) and light, which will benefit in future studies about the anisotropic optical, electrical, and mechanical properties of WTe\(_2\) as well as other in-plane anisotropic materials.

### Methods

#### Growth of bulk WTe\(_2\)

WTe\(_2\) single crystals were grown by the CVT method\(^4\). Stoichiometric W and Te powders were ground together and loaded into a quartz tube with a small amount of TeBr\(_4\) (transport agent). All weighing and mixing were carried out in a glove box. The tube was sealed under vacuum and placed in a two-zone furnace. The hot and cold zones were maintained at 800 °C and 700 °C, respectively, for 10 days. The crystal product appeared in cold zone.

#### Measurements.

The quantitative atomic resolution force image of WTe\(_2\) was measured by HR-AFM (Bruker Dimension Icon-PT). The angle- and polarization-resolved Raman spectra of exfoliated MoTe\(_2\) on 300 nm SiO\(_2\)/Si substrate were measured by a commercial micro-Raman system (Horiba Jobin Yvon HR800) under the backscattering geometry. In order to obtain high-resolution spectra, we used a 100× objective lens, and the grating with 1800 or 2400 grooves/mm. The exposure time is 100 seconds. The excitation wavelength was 633 nm, and the light power was below 400 μW. The incident light was polarized along the horizontal direction. The parallel- and cross-polarized configurations were constructed by placing an analyzer before the spectrometer.

### Density Functional Calculations.

The calculations of phonon spectra were performed within local-density approximation (LDA) using projector-augmented wave potentials. A 3 × 2 × 1 supercell was created and the interatomic forces were computed using the Vienna ab initio simulation package code with the small displacements method\(^40\). From these, force constant matrices and phonon frequencies were extracted using the PHONOPY Code\(^41\). The kinetic energy cutoff of the plane-wave basis was set to be 350 eV and 3 × 2 × 2 Monkhorst Pack grid was used in the phonon calculation.
