There is some anecdotal evidence that oxygen-ozone therapy may be beneficial in some human diseases. However, so far only a few biochemical and pharmacodynamic mechanisms have been elucidated. On the basis of preliminary data we postulated that controlled ozone administration would promote an oxidative preconditioning preventing the hepatocellular damage mediated by free radicals. Six groups of rats were classified as follows: (1) negative control, using intraperitoneal sunflower oil; (2) positive control using carbon tetrachloride (CCl₄) as an oxidative challenge; (3) ozone-ozone, pretreatment via rectal insufflation (15 sessions) and after it, CCl₄; (4) oxygen, as group 3 but using oxygen only; (5) control oxygen-ozone, as group 3, but without CCl₄; group (6) control oxygen, as group 5, but using oxygen only. We have evaluated critical biochemical parameters such as levels of transaminase, cholinesterase, superoxide dismutase, catalase, phospholipase A, calcium dependent ATPase, reduced glutathione, glucose 6 phosphate dehydrogenase and lipid peroxidation. Interestingly, in spite of CCl₄ administration, group 3 did not differ from group 1, while groups 2 and 4 showed significant differences from groups 1 and 3 and displayed hepatic damage. To our knowledge these are the first experimental results showing that repeated administration of ozone in toxic doses is able to induce an adaptation to oxidative stress thus enabling the animals to maintain hepatocellular integrity after CCl₄ poisoning.

Key words: Ozone, Oxidative stress, Preconditioning, Free radicals, Antioxidant defence system

Introduction

Ozone (O₃) has been used as a therapeutic agent for the treatment of different, apparently nonrelated diseases and beneficial effects have been observed in cerebrovascular ischaemia, chronic ulcers, arteriosclerosis obliterans, retinitis pigmentosa, humoral immunity deficiency, hepatic steatosis, and heart ischaemia. In spite of these encouraging results obtained with ozonotherapy, its clinical use remains controversial due to the scarce knowledge of the biochemical and pharmacodynamic mechanisms which underlie its therapeutic action and the efficacy in such heterogeneous pathologies. Last but not least, O₃ has been associated with environmental pollutions and to different pathologies. These factors have contributed to scepticism and prejudice of official medical authorities, delaying the acceptance of ozonotherapy. In order to provide scientific support to the aforementioned clinical data, some experimental strategies have been developed in order to increase our knowledge concerning its probable mechanisms of action. On the basis of the oxidant properties of O₃ and on the possibility that specific cell sensors activated by lipid oxidation products (LOP) may upregulate the antioxidant system, we postulate that O₃ may induce an adaptation to oxidative stress. Moreover, not only O₃ could induce tolerance to itself but it could prepare the host to face physiopathological conditions mediated by reactive oxygen species (ROS). With the aim to demonstrate the capability of O₃ to promote an oxidative preconditioning process, we induced hepatocellular damage with a single dose of carbon tetrachloride (CCl₄), which is a recognized organic agent able to produce a cellular injury through generation of free radicals.

Materials and Methods

Animals and sample preparation

Adult female Sprague-Dawley rats (220–250 g) were used for these studies. Rats were maintained in an air filtered and temperature conditioned (20–22°C) room with a relative humidity of 50–52%. Rats were fed with standard commercial pellets and water ad
libitum. O$_3$ was generated by an OZOMED equipment manufactured by the Ozone Research Center (Cuba) and was administered by rectal insufflation. O$_3$ obtained from medical grade oxygen was used immediately and it represented only about 3% of the gas (O$_2$ + O$_3$) mixture. The O$_3$ concentration is measured by using an UV spectrophotometer at 254 nm and is very precise. The ozone dose is the product of the O$_3$ concentration (expressed as mg/l) by the gas (O$_2$ + O$_3$) volume (l). By knowing the body weight of the rat the O$_3$ dose is calculated as 1 mg/kg. Rats received 15 ozone treatments, one per day, 4.4–5.0 ml with O$_3$ concentration of 50 mg/ml before challenge with CCl$_4$. After the last ozone treatment, rats received CCl$_4$ (1 ml/kg) by intraperitoneal administration of a solution of 10% CCl$_4$ in sunflower oil. The animals were euthanized by ether anesthesia, 24 h after receiving CCl$_4$. Immediately after, blood samples were obtained from the abdominal aorta and mixed with 3.8% sodium citrate, used as an anticoagulant, for biochemical determinations. Afterwards, some representative samples of different liver portions were taken for histopathological studies and tissue homogenates. Liver homogenates were obtained using a tissue homogenator Edmund Bulher LBMA at 4°C. The homogenates were prepared by using a 50 mM KCl/histidine buffer pH 7.4, 1:10 (w/v) and were spun down with a Sigma Centrifuge 2K15, at 4°C and 8500 $\times$ g for 20 min. The supernatants were taken for biochemical determinations.

**Treatment schedule**

The protocol consisted of six experimental groups ($n$ = 60). (1) negative control group treated only with sunflower oil by intraperitoneal route; (2) positive control group using 1 ml/kg of 10% CCl$_4$ solution; (3) ozone (O$_3$) group receiving 15 O$_3$ treatments (1 mg/kg) + CCl$_4$; (4) oxygen (O$_2$) group with 15 O$_2$ treatments (26 mg/kg) + CCl$_4$; (5) O$_3$ control group with 15 O$_3$ treatments (1 mg/kg); (6) O$_2$ control group with 15 O$_2$ treatments (26 mg/kg).

**Biochemical determinations**

The biochemical parameters were determined by spectrophotometric methods using an Ultraspect Plus Spectrophotometer from Pharmacia LKB. Aspartic alanine transaminase (ASAT) and cholinesterase (CHEase) levels were measured in plasma using standard commercial kits produced by Boehringer Mannheim. In liver, homogenates were assayed for total superoxide dismutases (Cu/Zn and Mn SODs) activity determining the capacity of the enzyme in inhibiting the autoxidation of pyrogallol by 50%. The catalase concentration was measured through the catalytic activity which promotes the reduction of hydrogen peroxide (H$_2$O$_2$) to oxygen and water. The phospholipase A activity was determined according to a standard procedure. Lipid peroxidation was assessed by reading thiobarbituric acid-reactive substances (TBARM). The determination of the activity of calcium-dependent ATPase (Ca-ATPase) and glucose-6-phosphate dehydrogenase (G6PD) were carried out as described. After precipitation of thiol proteins using 10% TCA the reduced glutathione levels (GSH) were determined in supernatants of 10% w/v homogenates. The proteins were measured by a standard Coomassie Blue method.

**Histological study**

Samples of rat liver were taken and fixed in neutral 10% formalin, processed and embedded in paraffin. The histological sections were stained with haematoxylin and eosin. In addition, neutral lipids were demonstrated with oil red staining in frozen sections. From the sections embedded in paraffin and after a previous study of the microscopic alterations, the cells with balloon degeneration were counted at the zone III of the Rappaport acini. Ten fields were taken, at random, per animal with a magnification of 250 × and the count made in a blind way by two pathologists. From the frozen sections stained with oil red, the damage area by lipidosis was calculated in other 10 fields per animal, using a morphometric software system.

**Statistical analysis**

The statistical analysis was started by using the OUTFIERS preliminary tests for detection of error values. Afterward, the Anova method (Single Way) was used followed by homogeneity variance test (Bartlett-Box). In addition, a multiple comparison test was used (Duncan test); values are expressed by the mean ± standard error of mean ($n$ = 10 per group). Different letters indicate a statistical significance of at least $P < 0.05$.

**Results**

Figure 1 shows the mean values ± SEM of the biochemical parameters measured for the first four groups of treatments. Groups treated with either CCl$_4$ or O$_2$ + CCl$_4$, showed a significant increase of ASAT activity in comparison with both the control and O$_3$ + CCl$_4$ groups. In contrast CHEase activity for the CCl$_4$ and O$_2$ + CCl$_4$ treatment groups was reduced significantly in comparison with both the O$_3$ + CCl$_4$ and control groups. A similar trend has been observed for SODs activity although the O$_2$ + CCl$_4$ group has an enzymatic activity significantly lower than the CCl$_4$ group. Catalase levels increased in CCl$_4$ and O$_2$ + CCl$_4$ treatment groups, while no modifications were observed under O$_3$ + CCl$_4$ treatment group with
respect to the control group. Ca-ATPase activity markedly decreased with CCl₄ and the O₂ + CCl₄ treatments in comparison with both the control and O₃ + CCl₄ treatment groups. The phospholipase A concentration in the O₃ + CCl₄ group did not differ from the control group and it was significantly lower in comparison with the CCl₄ and the O₂ + CCl₄ treatment groups. The latter group was markedly increased in comparison with the control group. G6PD was significantly reduced in both the CCl₄ and O₂ + CCl₄ groups, while O₃ treatment prior to CCl₄ maintained the enzyme at a control level. Interestingly, the O₃ treatment was also able to preserve a normal GSH level while the O₂ treatment + CCl₄ markedly reduce it. In line with these results, the TBARM, as an index of lipid peroxidation, was kept under control by the O₃ treatment.

Data from group 5 (O₃) and group 6 (O₂), without the final challenge with CCl₄ are not shown because they remained in the range of the control group, except phospholipase A levels were significantly (P < 0.05) higher (80.3 ± 14.2) in the O₂ group than control (60.0 ± 12.0).

Table 1 shows the qualitative results of the general hepatic damage (hepatocellular necrosis, balloonic degeneration, lipidosis and mesenchymal reaction) and the total amount of cells that have undergone balloonic degeneration (BD). In spite of a minimal degree of general hepatic damage and a marked reduction in the amount of cells with BD, values from

**FIG. 1.** The effect of ozone oxidative preconditioning in preventing CCl₄ damage in rats. The white and black bars represent either the negative or the positive controls, respectively. The hatched bars represent the situation either after O₂ exposure (diagonal lines) or after O₂ exposure (horizontal lines), respectively, prior to CCl₄. Values represent mean ± SEM.
rats treated with O\textsubscript{3} + CCl\textsubscript{4} were not significantly different from those, highly variable, of the CCl\textsubscript{4} treatment group. On the other hand, the morphometric evaluation of the hepatic damage by lipidosis (Table 2) demonstrated a significant reduction (P < 0.05) of the damage area in the group treated with O\textsubscript{3} in comparison with the CCl\textsubscript{4} treatment group. No differences were observed between the CCl\textsubscript{4} treatment group and the group treated with O\textsubscript{2} + CCl\textsubscript{4}.

### Discussion

In order to test our hypothesis that prolonged administration of judicious doses of O\textsubscript{3} may promote the phenomenon of oxidative preconditioning, we had to demonstrate that hepatocytes can become resistant to the damage induced by free radicals after CCl\textsubscript{4} poisoning. The results obtained in the present work fully support this postulation. It is worth remembering that Murry et al.\textsuperscript{22} in 1986 proposed the concept of ‘ischaemic preconditioning’ obtained by several cycles of brief coronary occlusion eventually able to minimize myocardial damage after a severe heart ischaemia.

Our experimental results have shown that repeated administration of a gas mixture composed of O\textsubscript{2}–O\textsubscript{3} via the colorectal route can induce a sort of cross-tolerance to free radicals released after one single dose of CCl\textsubscript{4}. On the contrary, experimental groups (2 and 4) treated with either CCl\textsubscript{4} or O\textsubscript{2} + CCl\textsubscript{4}, respectively, displayed a significant cellular damage. These results were well correlated with the histopathological findings in regard to the degree of ballonic degeneration and lipidosis. It must be pointed out that administration of O\textsubscript{3} in rats could be carried out neither by inhalation, due to its toxicity\textsuperscript{23,24} nor by ozonated autohaemotherapy for technical reasons. Nonetheless the colorectal route, although somewhat empirical, is easy, practical, atoxic and has the rationale that ozonated products reach the liver via portal circulation.\textsuperscript{25} Taking into account an interspecies factor based on the murine metabolic rate, a correct dose of ozone is 1 mg/kg in the rat and 0.25 mg/kg in humans, respectively. SODs and catalase are recognized scavengers of reactive oxygen species\textsuperscript{26} and they have been tested as therapeutic agents against cellular damage induced by ischaemia\textsuperscript{27,28} in spite of their low bioavailability and antibody formation. The significant stimulation of endogenous SODs in O\textsubscript{3} + CCl\textsubscript{4} group in comparison with CCl\textsubscript{4} and O\textsubscript{2} + CCl\textsubscript{4} groups, suggests cellular protection most likely through the reduction in the availability of superoxide anion (\textbullet \textsubscript{O}\textsubscript{2}). This result was somewhat expected on the basis of several findings\textsuperscript{29–31} reporting increased activities of SOD, catalase and peroxidases after chronic O\textsubscript{3} exposure. It is noteworthy that plants can also express a protective response to O\textsubscript{3}\textsuperscript{32–34} suggesting that living organisms chronically exposed to O\textsubscript{3} have the option of either programming their death or to react and survive by upregulating the antioxidant defence system capable to readjust the redox balance. Moreover in patients, we and others have found\textsuperscript{3,25,35} that calculated, transient oxidative stresses such as those obtained during a cycle of ozonated autohaemotherapy can also induce a state of tolerance characterized by a simultaneous overexpression of SOD, G6PD and possibly a reduction of TBARM levels in plasma. The rectal insufflation of O\textsubscript{3} (group 3) is apparently able to enhance the antioxidant system in a coordinate fashion because the increased activity of catalase on its own (groups 2 and 4) is unable to quench CCl\textsubscript{4} toxicity.

It is known that an increase of intracellular Ca\textsuperscript{2+} concentration plays an important role in the damage and cellular death, representing a critical and early event in the development of toxicity of hepatocytes submitted to oxidative stress.\textsuperscript{36} The suggestion that free radicals may affect the activity of the Ca-ATPase, thus contributing to the hepatocellular injury,\textsuperscript{37} is well supported by our data because the Ca-ATPase activity was severely inhibited in groups 2 and 4 while the O\textsubscript{3} treated group equalized the control. Indeed it has been previously shown that Ca\textsuperscript{2+}-ATPase enzymes have critical thiol groups rapidly inactivated by ROS.\textsuperscript{38,39} Calcium-dependent phospholipase A activity was decreased in the O\textsubscript{3} + CCl\textsubscript{4} treatment group indicating that ozone exerted indirectly a protection against the cellular disruption, mediated by the activation of an enzyme which generates lysophospholipids and other metabolites responsible for cellular lysis. The increased phospholipase A activity in the fourth (O\textsubscript{2} + CCl\textsubscript{4}) group suggests the participation of this enzyme in the hepatocellular damage noted in the histopathologic

### Table 1. Evaluation of the general hepatic damage in the three groups challenged with CCl\textsubscript{4}

| Groups       | Degree | BD       |
|--------------|--------|----------|
| CCl\textsubscript{4} | 1.4    | 51.0 ± 22.2\textsuperscript{29} |
| O\textsubscript{3} + CCl\textsubscript{4} | 0.2    | 6.2 ± 6.2\textsuperscript{29} |
| O\textsubscript{2} + CCl\textsubscript{4} | 2      | 88.0 ± 33.0\textsuperscript{29} |

Degree of hepatic damage: 1, slight, 2, moderate, 3, severe. Values are expressed by the mean ± SEM.

### Table 2. Morphometric evaluation of the hepatic damage by lipidosis

| Groups       | Damage areas (mm\textsuperscript{2}) |
|--------------|--------------------------------------|
| CCl\textsubscript{4} | 0.0580 ± 0.0248\textsuperscript{a} |
| O\textsubscript{3} + CCl\textsubscript{4} | 0.0287 ± 0.0237\textsuperscript{b} |
| O\textsubscript{2} + CCl\textsubscript{4} | 0.0512 ± 0.0240\textsuperscript{a} |

Values are expressed by the mean ± SEM.
studies. CCl₄ poisoning on its own caused only a modest increase of phospholipase A activity with respect to the control, probably due to the moderate character of the oxidative challenge after one single dose of CCl₄. The greater cellular damage observed after oxygen administration plus the hepatotoxic treatment indicates the deleterious effect of hyper-oxygenation.

Sustained levels of GSH and G6PD can be taken as reliable markers of antioxidant defenses in the face of an oxidative challenge. Finally the decrease in hepatic lipid peroxidation obtained in the O₃ + CCl₄ group was in good agreement with the reduction of the lipidosis observed in the histopathologic studies, while under CCl₄ and O₂ + CCl₄ treatments lipid peroxidation levels were raised significantly. Why the O₃ treatment, without the final challenge with CCl₄ (Group 5), did not show a significant increase of antioxidant enzymes may be explained by either the fairly short treatment or, more likely, by the fact that O₃ acts best when there is an ongoing oxidative insult.

In conclusion, the present study contributes to clarify an important pharmacodynamic effect after prolonged ozonetherapy in rats. The phenomenon can be described as an induction of tolerance to O₃, and ROS generated by toxic agents and has been denominated as either ‘oxidative preconditioning’, or ‘oxidative stress adaptation’. Ozonetherapy has been able to preserve liver integrity by inducing either enzymes or activating metabolic pathways that maintain an equilibrated redox balance. High SODs and GSH levels, low peroxidation and a normal Ca²⁺ homeostasis are clear examples of the efficacy of ozonetherapy. We believe that the possibility shown by appropriate ozonetherapy to upregulate the antioxidant system represents a fundamental property of this complementary medical approach and that O₃ comes to typify a unique drug. In fact exogenous administration of antioxidant substances such as ascorbic acid, GSH, n-acetyl cysteine, SOD and the like are useful but hardly able to dramatically reverse a chronic oxidative stress. In this sense the improvement of the antioxidant defences is bound to be crucial in cancer, chronic viral infections and neurodegenerative diseases, where the control of endogenous oxidation has gone awry with progressive cell damage. Therefore we should most actively pursue this lead for improving the therapy of these diseases.
