Abstract. In this paper we address the synthesis problem for specifications given in linear temporal single-agent epistemic logic, KLTL (or KL₁), over single-agent systems having imperfect information of the environment state. [18] have shown that this problem is 2Exptime complete. However, their procedure relies on complex automata constructions that are notoriously resistant to efficient implementations as they use Safra-like determinization.

We propose a “Safraless” synthesis procedure for a large fragment of KLTL. The construction transforms first the synthesis problem into the problem of checking emptiness for universal co-Büchi tree automata using an information-set construction. Then we build a safety game that can be solved using an antichain-based symbolic technique exploiting the structure of the underlying automata. The technique is implemented and applied to a couple of case studies.

1 Introduction

The goal of system verification is to check that a system satisfies a given property. One of the major achievements in system verification is the theory of model checking, that uses automata-based techniques to check properties expressed in temporal logics, for systems modelled as transitions systems. The synthesis problem is more ambitious: given a specification of the system, the aim is to automatically synthesise a system that fulfils the constraints defined by the specification. Therefore, the constraints do not need to be checked a posteriori, and this allows the designer to focus on defining high-level specifications, rather than designing complex computational models of the systems.

Reactive systems are non-terminating systems that interact with some environment, e.g., hardware or software that control transportations systems, or medical devices. One of the main challenge of synthesis of reactive systems is to cope with the uncontrollable behaviour of the environment, which usually leads to computationally harder decision problems, compared to system verification. For instance, model-checking properties expressed in linear time temporal logic (LTL) is PSpace-c while LTL synthesis is 2Exptime-c [15]. Synthesis of reactive systems from temporal specifications has gain a lot of interest recently as several works have shown its practical feasibility [14, 4, 3, 12, 9]. These progresses were supported by Kupferman and Vardi’s breakthrough in automata-based synthesis techniques [14]. More precisely, they have shown that the complex Safra’s determinization operation, used in the classical LTL synthesis algorithm [15], could be avoided by working directly with universal co-Büchi automata. Since then,
several other “Safraless” procedures have been defined [14,17,10,9]. In [17,9], it is shown that LTL synthesis reduces to testing the emptiness of a universal co-Büchi tree automaton, that in turn can be reduced to solving a safety game. The structure of the safety games can be exploited to define a symbolic game solving algorithm based on compact antichain representations [9].

In these works, the system is assumed to have perfect information about the state of the environment. However in many practical scenarios, this assumption is not realistic since some environment information may be hidden to the system (e.g. private variables). Towards the (more realistic) synthesis of partially informed systems, imperfect information two-player games on graphs have been studied [16,6,2,7]. However, they consider explicit state transition systems rather than synthesis from temporal specifications. Moreover, the winning objectives that they consider cannot express fine properties about imperfect information, i.e., cannot speak about knowledge.

Epistemic Temporal Logics [11] are logics formatted for reasoning about multi-agent situations. They are extensions of temporal logics with knowledge operators $K_i$ for each agent. They have been successfully used for verification of various distributed systems in which the knowledge of the agents is essential for the correctness of the system specification.

Synthesis problem with temporal epistemic objectives Vardi and van der Meyden [18] have considered epistemic temporal logics to define specifications that can, in addition to temporal properties, also express properties that refer to the imperfect information, and they studied the synthesis problem. They define the synthesis problem in a multi-agent setting, for specifications written in LTL extended with knowledge operators $K_i$ for each agent (KLTL). In such models, transitions between states of the environment model depend on actions of the environment and the system. The system does not see which actions are played by the environment but get some observation on the states in which the environment can be (observations are subsets of states). An execution of the environment model, from the point of view of the system, is therefore an infinite sequence alternating between its own actions and observations.

The goal of the KLTL synthesis problem is to automatically generate a strategy for the system (if it exists) that tells it which action should be played, depending on finite histories, so that whatever the environment does, all the (concrete) infinite executions resulting from this strategy satisfy the KLTL formula. In [18], this problem was shown to be undecidable even for two agents against the environment. On the other hand, for single agent against environment situations, they show that the problem is 2ExpTime-hard, by reduction to the emptiness of alternating Büchi automata. This theoretically elegant construction is however difficult to implement and optimize, as it relies on complex Safra-like automata operations (Muller-Schupp construction).

Contributions In this paper, we follow the formalisation of [18] and, as our main contribution, define and implement a Safraless synthesis procedure for the positive fragment of KLTL (KLTL$^+$), i.e., KLTL formulas where the operator $K$ does not occur under an odd number of negations. Our procedure relies on universal co-Büchi tree automata (UCT). More precisely, given a KLTL$^+$ formula $\varphi$ and some environment model $M_E$, we show how to construct a UCT $T_\varphi$ whose language is exactly the set of strategies that realize $\varphi$ in $M_E$.
Despite the fact that our procedure has 2-ExpTime worst-case complexity, we have implemented it and shown its practical feasibility through a set of examples. In particular, based on ideas of [9], we reduce the problem of checking the emptiness of $T_\varphi$ to solving a safety game whose state space can be ordered and compactly represented by antichains. Moreover, rather than using the reduction of [9] as a blackbox, we further optimize the antichain representations to improve their compactness. Our implementation is based on the tool Acacia [5] and, to the best of our knowledge, it is the first implementation of a synthesis procedure for epistemic temporal specifications. As an application, this implementation can be used to solve two-player games of imperfect information whose objectives are given as LTL formulas, or universal co-Büchi automata.

**Organization of the paper** In Section 2, we define the KLTL synthesis problem. In Section 3, we define universal co-Büchi automata for infinite words and trees. In Section 4, we consider the particular case of LTL synthesis in an environment model with imperfect information. The construction explained in that section will be used in the generalization to KLTL and moreover, it can be used to solve two-player imperfect information games with LTL (and more generally $\omega$-regular) objectives. In Section 5, we define our Safraless procedure for KLTL, and show in Section 6 how to implement it with antichain-based symbolic techniques. Finally, we describe our implementation in Section 7. Full proofs can be found in Appendix in which, for self-containment, we also explain the reduction to safety games.

## 2 KLTL Realizability and Synthesis

In this section, we define the realizability and synthesis problems for KLTL specifications, for one partially informed agent, called the system, against an environment.

**Environment Model** We assume to have, as input of the problem, a model of the behaviour of the environment as a transition system. This transition system is defined over two disjoint sets of actions $\Sigma_1$ and $\Sigma_2$, for the system and the environment respectively. The transition relation from states to states is defined with respect to pairs of actions in $\Sigma_1 \times \Sigma_2$. Additionally, each state $s$ of the environment model carries an interpretation $\tau_e(s)$ over a (finite) set of propositions $\mathcal{P}$. However, the system is not perfectly informed about the value of some propositions, i.e., some propositions are visible to the system, and some are not. Therefore, we partition the set $\mathcal{P}$ into two sets $\mathcal{P}_v$ (the visible propositions) and $\mathcal{P}_i$ (the invisible ones).

An environment model is a tuple $\mathcal{M}_E = (\mathcal{P}, \Sigma_1, \Sigma_2, S_e, S_0, \Delta_e, \tau_e)$ where

- $\mathcal{P}$ is a finite set of propositions, $\Sigma_1$ and $\Sigma_2$ are finite set of actions for the system and the environment resp.,
- $S_e$ is a set of states, $S_0 \subseteq S_e$ a set of initial states,
- $\tau_e : S_e \rightarrow 2^\mathcal{P}$ is a labelling function,
- $\Delta_e \subseteq S_e \times \Sigma_1 \times \Sigma_2 \times S_e$ is a transition relation.

The model is assumed to be deadlock-free, i.e. from any state, there exists at least one outgoing transition. Moreover, the model is assumed to be complete for all actions of the system, i.e. for all states and all actions of the system, there exists an outgoing transition. The set of executions of $\mathcal{M}_E$, denoted by $\text{exec}(\mathcal{M}_E)$, is the set of infinite sequences of states $\rho = s_0 s_1 \cdots \in S_e^\omega$ such that $s_0 \in S_0$ and for all
i > 0, \( (s_i, a_1, a_2, s_{i+1}) \) ∈ \( \Delta_e \) for some \( (a_1, a_2) \) ∈ \( \Sigma_1 \times \Sigma_2 \). Given a sequence of states \( \rho = s_0 s_1 \ldots \) and a set \( P \subseteq P \), we denote by \( \text{trace}_P(\rho) \) its projection over \( P \), i.e. \( \text{trace}_P(\rho) = (\tau_e(s_0) \cap P)(\tau_e(s_1) \cap P) \ldots \). The visible trace of \( \rho \) is defined by \( \text{trace}_e(\rho) = \text{trace}_P(\rho) \). The language of \( \mathcal{M}_E \) with respect to \( P \) is defined as \( \mathcal{L}_P(\mathcal{M}_E) = \{ \text{trace}_P(\rho) \mid \rho \in \text{exec}(\mathcal{M}_E) \} \). The language of \( \mathcal{M}_E \) is defined as \( \mathcal{L}_P(\mathcal{M}_E) \). Finally, given an infinite sequence of actions \( a = a_0 a_1 \ldots \in (\Sigma_1, \Sigma_2)^\omega \) and an execution \( \rho = s_0 s_1 \ldots \) of \( \mathcal{M}_E \), we say that \( a \) is compatible with \( \rho \) if for all \( i \geq 0 \), \( (s_i, a_1, a_2, s_{i+1}) \) ∈ \( \Delta_e \).

This formalization is very close to that of [18]. However in [18], partial observation is modeled as a partition of the state space. The two models are equivalent. In particular, we will see that partitioning the propositions into visible and invisible ones also induces a partition of the state space into observations.

**Example 1.** We illustrate the notion of environment model on the example of [18], that describes the behaviour of an environment against a system acting on a timed toggle switch with two positions (on, off) and a light. It is depicted in Fig. 1. The set \( P = \{ t, l \} \) contains two propositions \( t \) (true iff the toggle is on) and \( l \) (true iff the light is on). Actions of the system are \( \Sigma_1 = \{ T, S \} \) for “toggle” and “skip” respectively. The system can change the position of the toggle only if it plays \( T \), and \( S \) has no effect. Actions of the environment are \( \Sigma_2 = \{ (t_{out}, l_{on}) \mid t_{out}, l_{on} \in \{ 0, 1 \} \} \). The boolean variables \( (t_{out} \text{ and } l_{on}) \) indicate that the environment times out the toggle and that it switches on the light. The transition function is depicted on the figure as well as the labelling function \( \tau_e : S_e \rightarrow 2^P \). The star \( * \) means “any action”. The light can be on only if the toggle is on (state \( s_1 \)), but it can be off even if the toggle is on (state \( s_2 \)), in case it is broken. This parameter is uncontrollable by the system, and therefore it is controlled by the environment (action \( l_{on} \)). The timer is assumed to be unreliable and therefore the environment can timeout at any time (action \( t_{out} \)). The system sees only the light, i.e. \( P_v = \{ l \} \) and \( P_l = \{ t \} \). The goal of the system is to have a strategy such that he always knows the position of the toggle.

**Observations.** The partition of the set of propositions \( P \) into a set of visible propositions \( P_v \) and a set of invisible propositions \( P_i \) induces an indistinguishability relation over the states \( S_e \). Two states are indistinguishable, denoted \( s_1 \sim s_2 \), if they have the

![Fig. 1: Environment model \( \mathcal{M}_E \) of Example 1](image-url)
same visible propositions, i.e. \( \tau_e(s_1) \cap \mathcal{P}_v = \tau_e(s_2) \cap \mathcal{P}_v \). It is easy to see that \( \sim \) is an equivalence relation over \( S_e \). Each equivalence class of \( S_e \) induced by \( \sim \) is called an *observation*. The equivalence class of a state \( s \in S_e \) is denoted by \( o(s) \) and the set of observations is denoted by \( \mathcal{O} \). The relation \( \sim \) is naturally extended to (finite or infinite) executions: \( \rho_1 \sim \rho_2 \) if \( \text{trace}_v(\rho_1) = \text{trace}_v(\rho_2) \). Similarly, two executions \( \rho = s_0 s_1 \ldots \) and \( \rho' = s'_0 s'_1 \ldots \) are said to be indistinguishable *up to some position* \( i \) if \( \text{trace}_v(s_0 \ldots s_i) = \text{trace}_v(s'_0 \ldots s'_i) \). This indistinguishability notion also is an equivalence relation over executions that we denote by \( \sim_i \).

Coming back to Example 1, since the set of visible propositions is \( \mathcal{P}_v = \{ l \} \) and the set of invisible ones is \( \mathcal{P}_i = \{ t \} \), the states \( s_2 \) and \( s_3 \) are indistinguishable (in both \( s_2, s_3 \) the light is off) and therefore \( \mathcal{O} = \{ o_0, o_1 \} \) with \( o_0 = \{ s_2, s_3 \} \) and \( o_1 = \{ s_1 \} \).

Given an infinite sequence \( u = a_1 a_2 a_2 o_2 \ldots \in (\Sigma_1, \mathcal{O})^\omega \) of actions of Player 1, and observations, we associate with \( u \) the set of possible executions of \( \mathcal{M}_E \) that are compatible with \( u \). Formally, we define \( \text{exec}(\mathcal{M}_E, u) \) the set of executions \( \rho = s_0 s_1 \ldots \in \text{exec}(\mathcal{M}_E) \) such that for all \( i \geq 1 \), \( o(s_i) = o_i \) and there exists an action \( b_i \) of the environment such that \( (s_{i-1}, a_i, b_i, s_i) \in \Delta_e \). We also define the traces of \( u \) as the set of traces of all executions of \( \mathcal{M}_E \) compatible with \( u \), i.e. \( \text{traces}(u) = \{ \text{traces}(\rho) \mid \rho \in \text{exec}(\mathcal{M}_E, u) \} \).

### Epistemic Linear Time Temporal Logic (KLTL)

We now define the logic KLTL for one-agent (the system). The logic KLTL extends the logic LTL with an epistemic operator \( K \phi \), modelling the property that the system knows that the formula \( \phi \) holds. *KLTL formulae* are defined over the set of atomic propositions \( \mathcal{P} \) by:

\[
\phi ::= p \mid \neg \phi \mid \phi \lor \phi \mid \phi U \phi \mid K \phi
\]

in which \( p \in \mathcal{P} \) and \( \lor \) and \( U \) are the "next" and "until" operators from linear temporal logic. Formulas of the type \( K \phi \) are read as "the system knows that \( \phi \) holds". We define the macros \( \Diamond \) (eventually) and \( \Box \) (always) as usual. LTL is the fragment of KLTL without the \( K \) operator.

The semantics of a KLTL formula \( \phi \) is defined for an environment model \( \mathcal{M}_E = (\mathcal{P}, \Sigma_1, \Sigma_2, \mathcal{S}_e, S_0, \Delta_e, \tau_e) \), a set of executions \( R \subseteq \text{exec}(\mathcal{M}_E) \), an execution \( \rho = s_0 s_1 \ldots \in R \) and a position \( i \geq 0 \) in \( \rho \). It is defined inductively:

- \( R, \rho, i \models p \) if \( p \in \tau_e(s_i) \),
- \( R, \rho, i \models \neg \phi \) if \( R, \rho, i \not\models \phi \),
- \( R, \rho, i \models \phi \lor \phi_2 \) if \( R, \rho, i \models \phi_1 \) or \( R, \rho, i \models \phi_2 \),
- \( R, \rho, i \models \phi U \phi_2 \) if \( \exists j \geq i \text{ s.t. } R, \rho, j \models \phi_2 \) and \( \forall i \leq k < j, R, \rho, k \models \phi_1 \),
- \( R, \rho, i \models K \phi \) if for all \( \rho' \in R \text{ s.t. } \rho_i \sim_i \rho' \), we have \( R, \rho', i \models \phi \).

In particular, the system knows \( \phi \) at position \( i \) in the execution \( \rho \), if all other executions in \( R \) whose prefix up to position \( i \) are indistinguishable from that of \( \rho \), also satisfy \( \phi \). We write \( R, \rho, 0 \models \phi \) if \( R, \rho, 0 \models \phi \), and \( R \models \phi \) if \( R, \rho \models \phi \) for all executions \( \rho \in R \).

We also write \( \mathcal{M}_E \models \phi \) to mean \( \text{exec}(\mathcal{M}_E) \models \phi \). Note that \( \mathcal{M}_E \models \phi \) iff \( \mathcal{M}_E \models K \phi \).

Consider Example 1 and the set \( R \) of executions that eventually loops is \( s_1 \). Pick any \( \rho \in R \). Then \( R, \rho, 0 \models \Box K \Diamond (l) \). Indeed, take any position \( i \) in \( \rho \) and any other executions \( \rho' \in R \) such that \( \rho_i \sim_i \rho' \). Then since \( \rho' \) will eventually loop in \( s_1 \), it will satisfy \( \Diamond (l) \). Therefore \( R, \rho, i \models K \Diamond (l) \), for all \( i \geq 0 \).
**KLTL Realizability and Synthesis** As presented in [9] for the perfect information setting, the realizability problem, given the environment model $M_E$ and the KLTL formula $\varphi$, is best seen as a turn-based game between the system (Player 1) and the environment (Player 2). In the first round of the play, Player 1 picks some action $a_1^0 \in \Sigma_1$ and then Player 2 picks some action in $a_2^0 \in \Sigma_2$ and solves the nondeterminism in $\Delta_e$, and a new round starts. The two players play for an infinite duration and the outcome is an infinite sequence $w = a_1^0 a_2^0 a_1^1 a_2^1 \ldots$. The winning objective is given by some KLTL formula $\varphi$. Player 1 wins the play if for all executions $\rho$ of $M_E$ that are compatible with $w$, we have $M_E, \rho \models \varphi$.

Player 1 plays according to strategies (called protocols in [18]). Since Player 1 has only partial information about the state of the environment, his strategies are based on the histories of his own actions and the observations he got from the environment. Formally, a strategy for Player 1 is a mapping $\lambda : (\Sigma_1 \mathcal{O})^* \rightarrow \Sigma_1$, where as defined before, $\mathcal{O}$ denotes the set of observations of Player 1 over the states of $M_E$. Fixing a strategy $\lambda$ of Player 1 restricts the set of executions of the environment model $M_E$. An execution $\rho = s_0 s_1 \cdots \in \text{exec}(M_E)$ is said to be compatible with $\lambda$ if there exists an infinite sequence of actions $a = a_1^0 a_2^0 \ldots \in (\Sigma_1, \Sigma_2)^\omega$, compatible with $\rho$ such that for all $i \geq 0$, $a_i^0 = \lambda(a_i^0 o(s_0) a_i^1 o(s_1) \ldots a_{i-1}^1 o(s_{i-1}))$. We denote by $\text{exec}(M_E, \lambda)$ the set of executions of $M_E$ compatible with $\lambda$.

**Definition 1.** A KLTL formula $\varphi$ is realizable in $M_E$ if there exists a strategy $\lambda$ for the system such that $\text{exec}(M_E, \lambda) \models \varphi$.

**Theorem 1 ([18]).** The KLTL realizability problem (for one agent) is $2\text{ExpTime}$-complete.

If a formula is realizable, the synthesis problem asks to generate a finite-memory strategy that realizes the formula. Such a strategy always exists if the specification is realizable [18]. Finite memory strategies can be represented by Moore machines that read observations and output actions of Player 1. We refer the reader to [9] for a formal definition of finite-memory strategies.

Considering again Example 1, the formula $\varphi = \Box(K(t) \lor K(\neg t))$ expresses the fact that the system knows at each step the position of the toggle. As argued in [18], this formula is realizable if the initial set of the environment is $\{s_1, s_2\}$ since both states are labelled with $t$. Then, one strategy of the system is to play first time $T$, action that will lead to $s_3$, and then always play $S$ in order to stay in that state. Following this strategy, in the first step the formula $K(t)$ is satisfied and then $K(\neg t)$ becomes true. However, the formula is not realizable if the set of initial states of the environment is $\{s_2, s_3\}$ since from the beginning the system doesn’t know the value of the toggle.

### 3 Automata for Infinite Words and Trees

**Automata on infinite Words** An infinite word automaton over some (finite) alphabet $\Sigma$ is a tuple $A = (\Sigma, Q, Q_0, \Delta, \alpha)$ where $\Sigma$ is the finite input alphabet, $Q$ is the finite set of states, $Q_0 \subseteq Q$ is the set of initial states, $\alpha \subseteq Q$ is the set of final states (accepting states) and $\Delta \subseteq Q \times \Sigma \times Q$ is the transition relation.

For all $q \in Q$ and all $\sigma \in \Sigma$, we let $\Delta(q, \sigma) = \{ q' | (q, \sigma, q') \in \Delta \}$. We let $|A| = |Q| + |\Delta|$. We say that $A$ is deterministic if $|Q_0| = 1$ and $\forall q \in Q, \forall \sigma \in$
\(\Sigma, |\Delta(q, \sigma)| \leq 1\). It is complete if \(\forall q \in Q, \forall \sigma \in \Sigma, \Delta(q, \sigma) \neq \emptyset\). In this paper we assume, w.l.o.g., that the word automata are always complete.

A run on the automaton \(A\) over an infinite input word \(w = w_0w_1w_2,\ldots\), is a sequence \(r = q_0q_1q_2,\ldots \in Q^\omega\) such that \((q_i, w_i, q_{i+1}) \in \Delta\) for all \(i \geq 0\) and \(q_0 \in Q_0\). We denote by \(\text{Runs}_A(w)\) the set of runs of \(A\) on \(w\) and by \(\text{Visit}(r, q)\) the number of times the state \(q\) is visited along the run \(r\) (or \(\infty\) if the path visit the state \(q\) infinitely often). Here, we consider two accepting conditions for infinite word automata and name the infinite word automata according to the used accepting condition. Let \(B \in \mathbb{N}\). A word \(w \in \Sigma^\omega\) is accepted by \(A\) if (according to the accepting condition):

- **Universal Co-Büchi**: \(\forall r \in \text{Runs}_A(w), \forall q \in \alpha, \text{Visit}(r, q) < \infty\)
- **Universal B-Co-Büchi**: \(\forall r \in \text{Runs}_A(w), \forall q \in \alpha, \text{Visit}(r, q) \leq B\)

The set of words accepted by \(A\) with the universal co-Büchi (resp. B-co-Büchi) accepting condition is denoted by \(\mathcal{L}_{uc}(A)\) (resp. \(\mathcal{L}_{uc,B}(A)\)). We say that \(A\) is a universal co-Büchi word automaton (UCW) if the first acceptance condition is used and that \((A, B)\) is an universal B-co-Büchi word automaton (UBCW) if the second one is used.

Given an LTL formula \(\varphi\), we can translate it into an equivalent universal co-Büchi word automaton \(A_{\varphi}\). This can be done with a single exponential blow-up by first negat-

### Automata on Infinite Trees

Given a finite set \(D\) of directions, a \(D\)-tree is a prefix-closed set \(T \subseteq D^*\), i.e., if \(x \cdot d \in T\), where \(d \in D\), then \(x \in T\). The elements of \(T\) are called nodes and the empty word \(\epsilon\) is the root of \(T\). For every \(x \in T\), the nodes \(x \cdot d\), for \(d \in D\), are the successors of \(x\). A node \(x\) is a leaf if it has no successor in \(T\), formally, \(\forall d \in D, x \cdot d \notin T\). The tree \(T\) is complete if for all nodes, there are successors in all directions, formally, \(\forall x \in T, \forall d \in D, x \cdot d \in T\). Finite and infinite branches \(\pi\) in a tree \(T\) are naturally defined, respectively, as finite and infinite paths in \(T\) starting from the root node. Given an alphabet \(\Sigma\), a \(\Sigma\)-labelled \(D\)-tree is a pair \((T, \tau)\) where \(T\) is a tree and \(\tau : T \rightarrow \Sigma\) maps each node of \(T\) to a letter in \(\Sigma\). We omit \(\tau\) when it is clear from the context. Then, in a tree \(T\), an infinite (resp. finite) branch \(\pi\) induces an infinite (resp. finite) sequence of labels and directions in \((\Sigma, D)^\omega\) (resp. \((\Sigma, D)^*\)). We denote this sequence by \(\tau(\pi)\). For instance, for a set of system’s actions \(\Sigma_1\) and a set of observations \(O\), a strategy \(\lambda : (\Sigma_1 \cdot O)^* \rightarrow \Sigma_1\) of the system can be seen has a \(\Sigma_1\)-labelled \(O\)-tree whose nodes are finite outcomes\(^3\).

A universal co-Büchi tree automaton (UCT) is a tuple \(\mathcal{T} = (\Sigma, Q, Q_0, D, \Delta, \alpha)\) where \(\Sigma\) is the finite alphabet, \(Q\) is a finite set of states, \(Q_0 \subseteq Q\) is the set of initial states, \(D\) is the set of directions, \(\Delta : Q \times \Sigma \times D \rightarrow 2^Q\) is the transition relation (assumed to be total) and \(\alpha\) is the set of final states. If the tree automaton is in some state \(q\) at some node \(x\) labelled by some \(\sigma \in \Sigma\), it will evaluate, for all \(d \in D\), the subtree rooted at \(x \cdot d\) in parallel from all the states of \(\Delta(q, \sigma, d)\). Let us define the notion of run formally.

---

\(^3\)Technically, a strategy \(\lambda\) is defined also for histories that are not accessible by \(\lambda\) itself from the initial (empty) history \(\epsilon\). The tree represents only accessible histories but we can, in the rest of the paper, assume that strategies are only defined for their accessible histories. Formally, we assume that a strategy is a partial function whose domain \(H\) satisfies \(\epsilon \in H\) and for all \(h \in H\) and all \(o \in O, h.\lambda(h).o \in H\), and \(H\) is minimal (for inclusion) w.r.t. this property.
For all $q \in Q$ and $\sigma \in \Sigma$, we denote by $\Delta(q, \sigma) = \{(q_1, d_1), \ldots, (q_n, d_n)\}$ the disjoint union of all sets $\Delta(q, \sigma, d)$ for all $d \in D$. A run of $T$ on an infinite $\Sigma$-labelled $\Delta$-tree $\langle T, \tau \rangle$ is a $(Q \times D^*)$-labelled $\mathbb{N}$-tree $\langle T_r, \tau_r \rangle$ such that $\tau_r(\epsilon) \in Q_0 \times \{\epsilon\}$ and, for all $x \in T_r$, such that $\tau_r(x) = (q, v)$, if $\Delta(q, \tau(v)) = \{(q_1, d_1), \ldots, (q_n, d_n)\}$, we have $x \cdot i \in T_r$ and $\tau_r(x \cdot i) = (q_i, v \cdot d_i)$ for all $0 < i \leq n$. Note that there is at most one run per input tree (up to tree isomorphism). A run $\langle T_r, \tau_r \rangle$ is accepting if for all infinite branches $\pi$ of $T_r$, $\tau_r(\pi)$ visits a finite number of accepting states. The language of $T$, denoted by $L_{uc}(T)$, is the set of $\Sigma$-labelled $\Delta$-trees such that there exists an accepting run on them. Similarly, we define universal $B$-co-B"uchi tree automata by strengthening the acceptance conditions on all branches to the $B$-co-B"uchi condition.

As noted in [9,17], testing the emptiness of a UCT automaton reduces to testing the emptiness of a universal $B$-co-B"uchi accepting condition for a sufficiently large bound $B$, which in turn reduces to solving a safety game. Symbolic techniques that are also exploited in this paper have been used to solve the safety games.

4 LTL synthesis under imperfect information

In this section, we first explain an automata-based procedure to decide realizability under imperfect information of LTL formulas against an environment model. This procedure will be extended in the next section to handle the $K$ operator.

Take an environment model $M_E = (P, \Sigma_1, \Sigma_2, S_e, S_0, \Delta_e, \tau_e)$. Then, a complete $\Sigma_1$-labelled $O$-tree $\langle T, \tau \rangle$ defines a strategy of the system. Any infinite branch $\pi$ of $\langle T, \tau \rangle$ defines an infinite sequence of actions and observations of $M_E$, which in turn corresponds to a set of possible traces in $M_E$. We denote by $\text{traces}(\pi)$ this set of traces, and it is formally defined by $\text{traces}(\pi) = \text{traces}(\tau(\pi))$ (recall that the set of traces of a sequence of actions and observations has been defined in Section 2).

Given an LTL formula $\psi$, we construct a universal co-B"uchi tree automaton $T = (\Sigma_1, Q, Q_0, O, \Delta, \alpha)$ that accepts all the strategies of Player 1 (the system) that realize $\psi$ under the environment model $M_E$. First, one converts $\psi$ into an equivalent $\text{UCW}$ $A = (2^P, Q^A, Q_0^A, A^A, \alpha^A)$. Then, as a direct consequence of the definition of KLTL realizability:

**Proposition 1.** Given a complete $\Sigma_1$-labelled $O$-trees $\langle T, \tau \rangle$, $\langle T, \tau \rangle$ defines a strategy that realizes $\psi$ under $M_E$ iff for all infinite branches $\pi$ of $\langle T, \tau \rangle$ and all traces $\rho \in \text{traces}(\pi)$, $\rho \in L(A)$.

We now show how to construct a universal tree automaton that checks the property mentioned in the previous proposition, for all branches of the trees. We use universal transitions to check, on every branch of the tree, that all the possible traces (possibly uncountably many) compatible with the sequence of actions in $\Sigma_1$ and observations in $O$ defined by the branch satisfy $\psi$. Based on finite sequences of observations that the system has received, it can define its knowledge $I$ of the possible states in which the environment can be a subset of states of $S_e$. Given an action $a_1 \in \Sigma_1$ of the system and some observation $o \in O$, we denote by $\text{post}_A(I, o)$ the new knowledge that the system can infer from the observation $o$, the action $a$ and its previous information $I$. Formally, $\text{post}_A(I, o) = \{s \in S_e \cap o \mid \exists a_2 \in \Sigma_2, \exists s' \in I \text{ s.t. } (s', a, a_2, s) \in \Delta_e\}$.

The states of the universal tree automaton $T$ are pairs of states of $A$ and knowledges plus some extra state $(q_w, \emptyset)$, i.e. $Q = Q^A \times 2^{S_e} \cup \{(q_w, \emptyset)\}$ where $(q_w, \emptyset)$ is added
interpretations of propositions that do not correspond to any trace of

Note that, since \( (q, s, a) \) to associate the new knowledge post

\( s \) cause the traces up to state \( s \) that

accepted by \( A \)

all the traces of

\( I \)

one should only consider states of

\( S \), \( \Delta = \{(q, \tau(s), q') \in \Delta^A : q' \in I \} \) and the automaton is universal,

the system does not have better knowledge by restricting the knowledge sets.

Now suppose that post\(_a(I, o)\) is non-empty. Since the automaton must check that

all the traces of \( M_E \) that are compatible with actions of \( \Sigma_1 \) and observations are accepted by \( A \), intuitively, one would define \( \Delta((q, I), a, o) \) as the set of states of

the form \( (q', \text{post}_a(I, o)) \) for all states \( q' \) such that there exists \( s \in I \) such that

\( (q, \tau_e(s), q') \in \Delta^A \). However, it is not correct for several reasons. First, it could be

that \( s \) has no successor in \( o \) for action \( a \), and therefore one should not consider it

because the traces up to state \( s \) die at the next step after getting observation \( o \). Therefore,

one should only consider states of \( I \) that have a successor in \( o \). Second, it is not correct

to associate the new knowledge \( \text{post}_a(I, o) \) with \( q' \), because it could be that there exists

a state \( s' \in \text{post}_a(I, o) \) such that for all its predecessors \( s'' \) in \( I \), there is not transition

\( (q, \tau_e(s''), q') \in \Delta^A \), and therefore, one would also take into account sequences of

interpretations of propositions that do not correspond to any trace of \( M_E \).

Taking into account these two remarks, we define, for all states \( q' \), the set \( \text{I}_{q,q'} = 

\{ s \in I \mid \{(q, \tau(s), q') \in \Delta^A\} \}. \) Then, \( \Delta((q, I), a, o) \) is defined as the set

\[ \Delta((q, I), a, o) = \{ \text{I}_{q,q'}(a, \text{I}_{q,q'}) \} \mid \exists s \in I, (q, \tau(s), q') \in \Delta^A \} \]

Note that, since \( \bigcup_{q' \in Q} \text{I}_{q,q'}(a, \text{I}_{q,q'}) = \text{I}_{q,q'}(a, \text{I}_{q,q'}) \) and the automaton is universal,

the system does not have better knowledge by restricting the knowledge sets.

**Lemma 1.** The LTL formula \( \psi \) is realizable in \( M_E \) iff \( \mathcal{L}(T) \neq \emptyset \).

Moreover, it is known that if a UCT has a non-empty language, then it accepts a
tree that is the unfolding of a finite graph, or equivalently, that can be represented by a
Moore machine. Therefore if \( \psi \) is realizable, it is realizable by a finite-memory strategy.

## 5 Safraless procedure for positive KLTL synthesis

In this section, we extend the construction of Section 4 to the positive fragment of
KLTL. Positive formulas are defined by the following grammar:

\[ \varphi ::= p \mid \neg \varphi \mid \varphi \land \varphi \mid \varphi \lor \varphi \mid \Diamond \varphi \mid \Box \varphi \mid K \varphi \mid \varphi U \varphi \]

Note that this fragment is equivalent to the fragment of KLTL in which formulas with
the knowledge operator \( K \) occurring under an even number of negations. This is
obtained by straightforwardly pushing the negations down towards the atoms. We denoted
this fragment of KLTL by KLTL\( ^+ \).

**Sketch of the construction** Given a KLTL\( ^+ \) formula \( \varphi \) and an environment model
\( M_E = (P, \Sigma_1, \Sigma_2, S_e, S_0, \Delta_e, \tau_e) \), we show how to construct a UCT \( T \) such that
\( \mathcal{L}(T) \neq \emptyset \) iff \( \varphi \) is realizable in \( M_E \). The construction is compositional and follows,
for the basic blocks, the construction of Section 4 for LTL formulas. The main idea
is to replace subformulas of the form \( K \gamma \) by fresh atomic propositions \( k, \gamma \) so that we
get an LTL formula for which the realizability problem can be transformed into the emptiness of a UCT. The realizability of the subformulas $K\gamma$ that have been replaced by $k_i$ is checked by branching universally to a UCT for $\gamma$, constructed as in Section 4. Since transitions are universal, this will ensure that all the infinite branches of the tree from the current node where a new UCT has been triggered also satisfy $\gamma$. The UCTs we construct are defined over an extended alphabet that contains the new atomic propositions, but we show that we can safely project the final UCT on the alphabet $\Sigma$. The assumption on positivity of KTLT formulas implies that there is no subformulas of the form $\neg K\gamma$. The rewriting of subformulas by fresh atomic propositions cannot be done in any order. We now describe it formally.

We inductively define a sequence of formulas associated with $\varphi$ as: $\varphi^0 = \varphi$ and, for all $i > 0$, $\varphi^i$ is the formula $\varphi^{i-1}$ in which the innermost subformulas $K\gamma$ are replaced by fresh atomic propositions $k_i$. Let $d$ be the smallest index such that $\varphi^d$ is an LTL formula (in other words, $d$ is the maximal nesting level of $K$ operators). Let $\mathbb{K}$ denote the set of new atomic propositions, i.e., $\mathbb{K} = \bigcup_{i=0}^d \{k_i \mid K\gamma \in \varphi^i\}$, and let $\mathcal{P}' = \mathcal{P} \cup \mathbb{K}$. Note that by definition of the formulas $\varphi^i$, for all atomic proposition $k_i$ occurring in $\varphi^i$, $\gamma$ is an LTL formula over $\mathcal{P}'$. E.g. if $\varphi = p = K(q \rightarrow Kr \lor Kz)$ and $\mathcal{P} = \{p, q, r, z\}$, then the sequence of formulas is: $\varphi^0 = \varphi$, $\varphi^1 = p = K(q \rightarrow kr \lor k_z)$ $\varphi^2 = p = k_i$ where $\gamma = q \rightarrow kr \lor k_z$.

Then, we construct incrementally a chain of universal co-Büchi tree automata $\mathcal{T}^d, \ldots, \mathcal{T}^0$ such that $\mathcal{L}(\mathcal{T}^d) \supseteq \mathcal{L}(\mathcal{T}^{d-1}) \supseteq \ldots \supseteq \mathcal{L}(\mathcal{T}^0)$ and, the following invariant is satisfied: for all $i \in \{0, \ldots, d\}$, $\mathcal{T}^i$ accepts exactly the set of strategies that realize $\varphi^i$ in $\mathcal{M}_E$. Intuitively, the automaton $\mathcal{T}^i$ is defined by adding new transitions in $\mathcal{T}^{i+1}$, such that for all atomic propositions $k_i$ occurring in $\varphi^{i+1}$, $\mathcal{T}^i$ will ensure that $K\gamma$ is indeed satisfied, by branching to a UCT checking $\gamma$ whenever the atomic proposition $k_i$ is met. Since formulas $\varphi^i$ are defined over the extended alphabet $\mathcal{P}' = \mathcal{P} \cup \mathbb{K}$ and $\mathcal{M}_E$ is defined over $\mathcal{P}$, we now make clear what we mean by realizability of a formula $\varphi^i$ in $\mathcal{M}_E$. It uses the notion of extended model executions and extended strategies.

Extended actions, model executions and strategies We extend the actions of the system to $\Sigma_1^* = \Sigma_1 \times 2^\mathbb{K}$ (call $e$-actions). Informally, the system plays an $e$-action $(a, K)$ if it considers formulas $K\gamma$ for all $k_i \in K$ to be true. An extended execution (e-execution) of $\mathcal{M}_E$ is a infinite sequence $\rho = (s_0, K_0) \ldots \in (S_e \times 2^\mathbb{K})^\omega$ such that $s_0s_1 \ldots \in \text{exec}(\mathcal{M}_E)$. We denote $s_0s_1 \ldots$ by $\text{proj}_1(\rho)$ and $K_0K_1 \ldots$ by $\text{proj}_2(\rho)$.

The extended labelling function $\tau^e_\rho$ is a function from $S_e \times 2^\mathbb{K}$ to $\mathcal{P}'$ defined by $\tau^e_\rho(s, K) = \tau_\rho(s) \cup K$. The indistinguishability relation between extended executions is defined, for any two extended executions $\rho_1, \rho_2$, by $\rho_1 \sim \rho_2$ iff $\text{proj}_1(\rho_1) \sim \text{proj}_1(\rho_2)$ and $\text{proj}_2(\rho_1) = \text{proj}_2(\rho_2)$, i.e., the propositions in $\mathbb{K}$ are visible to the system. We define $\sim_\rho$ over extended executions similarly. Given the extended labelling functions and indistinguishability relation, the KTLT satisifiability notion $R, \rho, i \models \psi$ can be naturally defined for a set of e-execution $R, \rho \in \mathcal{P}'$ and $\psi$ a KTLT formula over $\mathcal{P}' = \mathcal{P} \cup \mathbb{K}$.

An extended strategy is a strategy defined over $e$-actions, i.e. a function from $(\Sigma_1^1)^* \rightarrow \Sigma_1'$. For an infinite sequence $u = (a_0, K_0)a_0(a_1, K_1)a_1 \cdots \in (\Sigma_1^1)^*$, we define $\text{proj}_1(u)$ as $a_0a_0 \ldots$. The sequence $u$ defines a set of compatible e-executions $\text{exec}(\mathcal{M}_E, u)$ as follows: it is the set of e-executions $\rho = (s_0, K_0)(s_1, K_1) \ldots \in (S_e \times 2^\mathbb{K})^\omega$ such that $\text{proj}_1(\rho) \in \text{exec}(\mathcal{M}_E, \text{proj}_1(u))$. Similarly, we define for e-strategies $\lambda'$ the set $\text{exec}(\mathcal{M}_E, \lambda')$ of e-executions compatible with $\lambda'$. A KTLT for-
mula ψ over P' is realizable in ME if there exists an e-strategy λ' such that for all runs ρ ∈ exec(ME, λ'), we have exec(ME, λ'), ρ, 0 ⊨ ψ.

**Proposition 2.** There exists an e-strategy λ' : (Σ_1(Ω))^* → Σ_1 realizing ϕ^0 in ME iff there exists a strategy λ : (Σ_1(Ω))^* → Σ_1 realizing ϕ^0 in ME.

**Proof.** Let see e-strategies and strategies as Σ_1—labelled (resp. Σ_1-labelled) O-trees. Given a tree representing λ', we project its labels on Σ_1 to get a tree representing λ. The strategy λ defined in this way realises ϕ^0, as ϕ^0 does not contain any occurrence of propositions in Ω. Conversely, given a tree representing λ, we extend its labels with ∅ to get a tree representing λ'. It can be shown for the same reasons that λ' realizes ϕ^0. □

**Incremental tree automata construction** The invariant mentioned before can now be stated more precisely: for all i, T^i accepts the e-strategies λ' : (Σ_1(Ω)) → Σ_1 that realise ϕ^i in ME. Therefore, the UCT T^i are labelled with e-actions Σ. We now explain how they are constructed.

Since ϕ^d is an LTL formula, we follow the construction of Section 4 to build the UCT T^d. Then, we construct T^i from T^{i+1}, for 0 ≤ i < d. The invariant tells us that T^{i+1} defines all the e-strategies that realize ϕ^{i+1} in ME. It is only an over-approximation of the set of e-strategies that realize ϕ^i in ME (and a fortiori ϕ^0), since the subformulas of ϕ^i of the form Kγ correspond to atomic propositions k_γ in ϕ^{i+1}, and therefore T^{i+1} does not check that they are satisfied. Therefore to maintain the invariant, T^i is obtained from T^{i+1} such that whenever an action that contains some formula k_γ ∈ sub(ϕ^{i+1}) occurs on a transition of T^{i+1}, we trigger (universally) a new transition to a UCT Tγ,j, for the current information set I in T^{i+1}, that will check that Kγ indeed holds. The assumption on positivity of KLTL formulas is necessary here as we do not have to check for formulas of the form ¬Kγ, which could not be done without an involved “non Safraless” complementation step. Since γ is necessarily an LTL formula over P' by definition of the formula ϕ^{i+1}, we can apply the construction of Section 4 to build Tγ,j.

Formally, from the incremental way of constructing the automata T^j for j ≥ i, we know that T^{i+1} has a set of states Q_{i+1} where all states are of the form (q, I) where I ⊆ S_e is some knowledge. In particular, it can be verified to be true for the state space of T^d by definition of the construction of Section 4. Let also Δ_{i+1} be the transition relation of T^{i+1}. For all formulas γ such that k_γ occurs in ϕ^{i+1}, we let Q_γ be the set of states of Tγ,j and Δ_γ its set of transitions. Again from the construction of Section 4, we know that Q_γ = Q × 2^{S_e} where Q is the set of states of a UCW associated with γ (assumed to be disjoint from that of T^{i+1}) and Q^0_γ = Q × I.

We define the set of states Q_i of T^i by Q_{i+1} ∪ ⋃_{k_γ ∈ sub(ϕ^{i+1})} Q_γ. Its set of transitions Δ_i is defined as follows. Assume w.l.o.g. that there is a unique initial state q_0 ∈ Q in the UCW A_. If (q', I') ∈ Δ_{i+1}((q, I), (a, K), o) where I, I' ⊆ S_e, a ∈ Σ_1, K ⊆ K, o ∈ O and k_γ ∈ K is such that k_γ occurs in ϕ^{i+1}, then we let (q', I') ∈ Δ_γ((q, I), (a, K), o) and Δ_γ,((q_0, I), (a, K), o) ⊆ Δ_i((q, I), (a, K), o). The whole construction is given in Appendix, as well as the proof of its correctness. The invariant is satisfied:

**Lemma 2.** For all i ≥ 0, L(T^i) accepts the set of e-strategies that realize ϕ^i in ME.
From Lemma 2, we know that $\mathcal{L}(\mathcal{T}^0)$ accepts the set of $e$-strategies that realize $\varphi^0 = \varphi$ in $\mathcal{M}_E$. Then by Proposition 2 we get:

**Corollary 1.** The KLTL$^+$ formula $\varphi$ is realizable in $\mathcal{M}_E$ iff $\mathcal{L}(\mathcal{T}^0) \neq \emptyset$.

We now let $\mathcal{T}_\varphi$ be the UCT obtained by projecting $\mathcal{T}^0$ on $\Sigma_1$. We have:

**Theorem 2.** For any KLTL$^+$ formula $\varphi$, one can construct a UCT $\mathcal{T}_\varphi$ such that $\mathcal{L}(\mathcal{T}_\varphi)$ is the set of strategies that realize $\varphi$ in $\mathcal{M}_E$.

The number of states of $\mathcal{T}_\varphi$ is (in the worst-case) $2^{|S_e|}, (2^{|\varphi^d|} + \sum_{\gamma \in K} 2^{|\gamma|})$, and since $|\varphi^d| + \sum_{\gamma \in K} |\gamma|$ is bounded by $|\varphi|$, the number of states of $\mathcal{T}_\varphi$ is $O(2^{|S_e|} + |\varphi|)$.

### 6 Antichain Algorithm

In the previous sections, we have shown how to reduce the problem of checking the realizability of some KLTL$^+$ formula $\varphi$ to the emptiness of a UCT $\mathcal{T}_\varphi$ (Theorem 2). In this section, we describe an antichain symbolic algorithm to test the emptiness of $\mathcal{T}_\varphi$.

It is already known from [9] that checking emptiness of the language defined by a UCT $\mathcal{T}$ can be reduced to checking the emptiness of $\mathcal{L}_{uc,B}(\mathcal{T})$ for a sufficiently large bound $B$, which in turn can be reduced to solving a safety game. Clearly, for all $B \geq 0$, if $\mathcal{L}_{uc,B}(\mathcal{T}) \neq \emptyset$, then $\mathcal{L}_{uc}(\mathcal{T}) \neq \emptyset$. This has led to an incremental algorithm by starting with some small bound $b$ and the experiments have shown that in general, a small bound $b$ is necessary to conclude for realizability of an LTL formula (transformed into the emptiness of a UCT). We also exploit this idea in our implementation and show that for KLTL$^+$ specifications that we considered, this observation still holds: small bounds are enough.

In [9], it is shown that the safety games can be solved on-the-fly without constructing them explicitly, and that the fixpoint algorithm used to solve these safety games could be optimized by using some antichain representation of the sets constructed during the fixpoint computation. Rather than using the algorithm of [9] as a black box, we study the state space of the safety games constructed from the UCT $\mathcal{T}_\varphi$ and show that they are also equipped with a partial order that allows one to get more compact antichain representations. We briefly recall the reduction of [9], the full construction of the safety games is given in Appendix.

Given a bound $b \geq 0$ and a UCT $\mathcal{T}$, the idea is to construct a safety game $G(\mathcal{T}, b)$ such that Player 1 has a winning strategy in $G(\mathcal{T}, b)$ iff $\mathcal{L}_{uc,B}(\mathcal{T})$ is non-empty. The game $G(\mathcal{T}, b)$ is obtained by extending the classical automata subset construction with counters which count, up to $b$, the maximal number of times all the runs, up to the current point, have visited accepting states. If $Q$ is the set of states of $\mathcal{T}$, the set of states of the safety game $G(\mathcal{T}, b)$ is all the functions $F : Q \to \{-1, 0, \ldots, b + 1\}$. The value $F(q) = -1$ means that no run have reached $q$ and $F(q) \in \{0, \ldots, b\}$ means that the maximal number of accepting states that has been visited by the runs reaching $q$ is $F(q)$. The safe states are all the functions $F$ such that $F(q) \leq b$ for all $q \in Q$. The set of states can be partially ordered by the pairwise comparison between functions and it is shown that the sets of states manipulated by the fixpoint algorithm are downward closed for this order.
Consider now the UCT $T_ϕ$ constructed from the KLTL$^{+}$ formula $ϕ$. Its state space is of the form $Q \times 2^{S_e}$ where $S_e$ is the set of states of the environment, because the construction also take into account the knowledge the system has from the environment. Given a bound $b$, the state space of the safety game $G(T_ϕ, b)$ is therefore functions from $Q \times 2^{S_e}$ to $\{-1, \ldots, b + 1\}$. However, we can reduce this state space thanks to the following result:

**Proposition 3.** For all runs $(T_ϕ, r)$ of $T_ϕ$ on some tree $T$, for all branches $π, π'$ in $T$, of the same length such that they follow the same sequence of observations, if $τ(π) = (q, I)$ and $τ(π') = (q, I')$, then $I = I'$.

In other words, given the same sequence of observations, the tree automaton $T_ϕ$ computes, for a given state $q$, the same knowledge.

Based on this proposition, it is clear that reachable states $F$ of $G(T_ϕ, b)$ satisfy, for all states $q \in Q$ and knowledges $I, I'$, if $F(q, I) \neq -1$ and $F(q, I') \neq -1$ then $I = I'$. We can therefore define the state space of $G(T_ϕ, b)$ as the set of pairs $(F, K)$ such that $F : Q \rightarrow \{-1, \ldots, b + 1\}$ and $K : Q \rightarrow 2^{S_e}$ associates with each state $q$ a knowledge (we let $G(q) = \emptyset$ if $F(q) = -1$). This state space is naturally ordered by $(F_1, K_1) \preceq (F_2, K_2)$ if for all $q \in Q$, $F_1(q) \leq F_2(q)$ and $K_1(q) \subseteq K_2(q)$. We show that all the sets manipulated during the fixpoint computation used to solve the safety games are downward closed for this order and therefore can be represented by the antichain of their maximal elements. A detailed analysis of the size of the safety game shows that $G(T_ϕ, B)$ is doubly exponential in the size of $ϕ$, and therefore, since safety games can be solved in linear time, one gets a 2Exptime upper bound for KLTL$^{+}$ realizability. The technical details are given in Appendix.

### 7 Implementation and Case Studies

In this section we briefly present our prototype implementation Acacia-K for KLTL$^{+}$ synthesis [1], and provide some interesting examples on which we tested the tool, on a laptop equipped with an Intel Core i7 2.10Ghz CPU. Acacia-K extends the LTL synthesis tool Acacia+[5]. As Acacia+, the implementation is made in Python together with C for the low level operations that need efficiency.

As Acacia+, the tool is available in one version working on both Linux and MacOsX and can be executed using the command-line interface. As parameters, in addition to the files containing the KLTL$^{+}$ formula and the partition of the signals and actions, Acacia-K requires a file with the environment model. The output of the tool is a winning strategy, if the formula is realizable, given as a Moore machine described in Verilog and if this strategy is small, Acacia-K also outputs it as a picture.

In order to have a more efficient implementation, the construction of the automata for the LTL formulas $γ$ is made on demand. That is, we construct the UCT $T_γ$ incrementally by updating it as soon as it needs to be triggered from some state $(q, I)$ which has not been constructed yet.

As said before, the synthesis problem is reduced to the problem of solving a safety game for some bound $b$ on the number of visits to accepting states. The tool is incremental: it tests realizability for small values of $b$ first and increments it as long as it cannot conclude for realizability. In practice, we have observed, as for classical LTL synthesis, that small bounds $b$ are sufficient to conclude for realizability. However if the
formula is not realizable, we have to iterate up to a large upper bound, which in practice is too large to give an efficient procedure for testing unrealizability. We leave as future work the implementation of an efficient procedure for testing unrealizability.

Taking now Example 1, the strategy provided by the tool is depicted in Figure 2. It asks to play first "toggle" and then keep play "skip" and, depending on the observation he gets, the system goes in a different state. The state 0 is for the start, the state 1 is the "error" state in which the system goes if he receives a wrong observation. That is, the environment gives an observation even if he cannot go in a state having that observation. Then, if the observation is correct, after playing the action "toggle" from the initial states \{s_1, s_2\}, the environment is forced to go in \(s_3\) and by playing the action "skip", the system forces the environment to stay in \(s_3\) and he will know that \(t\) is false. In the strategy, this situation corresponds to the state 2.

For this example, Acacia-K constructed a UCT with 31 states and the total running time is 0.2s.

Example 2 (The 3-Coin Game). Another example that we tried is a game played using three coins which are arranged on a table with either head or tail up. The system doesn’t see the coins, but knows at each time the number of tails and heads. Then, the game is infinitely played as follows. At the beginning the environment chooses an initial configuration and then at each round, the system chooses a coin and the environment has to flip that coin and inform the system about the new number of heads and tails. The objective of the system is to reach, at least once, the state in which all the coins have the heads up and to avoid all the time the state in which all the coins are tails. Depending on the initial number of tails up, the system may or may not have a winning strategy.

In order to model this, we considered an environment model whose states are labelled with atomic propositions \(c_1, c_2, c_3\) for the three coins, which are not visible for the system, and two other variables \(b_1, b_0\) which are visible and represent the bits encoding the number of heads in the configuration. The actions of the system are \(C_1, C_2, C_3\) with which he chooses a coin and the environment has to flip the coin chosen by the system by playing only the action done. A picture of the environment is in Figure 3 from Appendix.

Then, the specification is translated into the KLTL formula \(K \diamond (c_1 \land c_2 \land c_3) \land \Box \neg (c_1 \lor c_2 \lor c_3)\). Then, assuming that the initial state of the environment has two heads, the synthesized strategy proposes to "check" the position of every coin by double
flipping. If after one flip, the winning state is not reached, the system flips back the coin and at the third round he chooses another coin to check. A picture of the strategy can be found in Figure 4 of Appendix. For this example, Acacia-K constructs a UCT with 79 states, synthesises a strategy with 10 states, and the total running time is 3.9s.

Finally, we have designed an example (the prisoners enigma). It is not presented in the paper but can be found in Appendix. We have tried 3/4/5/6 prisoners versions (including the protagonist) of this problem, obtaining a one hour timeout for 6 agents. The statistics we obtained are the following:

| Pris # | | M_E | UCT | tb − UCT | Aut constr (s) | | M_A | Total time(s) |
|---|---|---|---|---|---|---|---|
| 3 | 21 | 144 | 692 | 1.79s | 12 | 1.87s |
| 4 | 53 | 447 | 2203 | 1.98s | 16 | 13.20s |
| 5 | 129 | 1310 | 6514 | 199.06s | 20 | 553.45s (≃ 9 min) |
| 6 | 305 | 3633 | 18125 | 6081.69s | N/A | N/A |

Again, Acacia-K generates strategies that are natural, the same that one would synthesise intuitively. This fact is remarkable itself since, in synthesis, it is often a difficult task to generate small and natural strategies.

8 Conclusion
In this paper, we have defined a Safraless procedure for the synthesis of KLTL+ specifications in environment with imperfect information. This problem is 2ExpTime-com but we have shown that our procedure, based on universal co-Büchi tree automata, can be implemented efficiently thanks to an antichain symbolic approach. We have implemented a prototype and run some preliminary experiments that prove the feasibility of our method. While the UCT constructed by the tool are not small (around 1300 states), our tool can handle them, although in theory, the safety games could be exponentially larger than the UCT. Moreover, our tool synthesises small strategies that correspond to the intuitive strategies we would expect, although it goes through a non-trivial automata construction. As a future work, we want to see if Acacia-K scales well on larger examples. We also want to extend the tool to handle the full KLTL logic in an efficient way. This paper is an encouraging (and necessary) step towards this objective. In a first attempt to generalise the specifications, we plan to consider assume-guarantees specifications $K \phi \rightarrow \psi$, where $\phi$ is an LTL formula and $\psi$ a KLTL+ formula.

A Correctness of the UCT construction for LTL formulas (proof of Lemma 1)

Proof. If $\psi$ is realizable in $M_E$, there exists a strategy $\lambda : (\Sigma_1 \times O)^* \rightarrow \Sigma_1$ for the system such that $exec(M_E, \lambda) \models \psi$. Let’s see this strategy as a $\Sigma_1$-labelled $O$-tree $\langle T_\lambda, \tau \rangle$ and prove that $T_\lambda \in \mathcal{L}(T)$.

The run on $T_\lambda$ of the automaton $T$ is a $Q \times O^*$-labelled $N$-tree $\langle T_r, \tau_r \rangle$. Therefore, each branch $\pi$ of $T_r$ induces an infinite sequence $\tau_r(\pi) = ((q_0, I(0)), (q_1, I(1)), (q_2, I(2)), \ldots)$, where $(q_0, I(0)) \in Q_0$ and $I(i+1) = post_{\tau_r(\pi)}(I(q_i, q_{i+1}, o_{i+1}))$, by definition of the transition relation of $T$.

Since $I_q(i)$ is the subset of environment state in $I(i)$ whose labels can fire transitions from $q_i$ to $q_{i+1}$ in $A$, $r = q_0q_1q_2\ldots$ is a run in $A$ on the traces of the executions $\rho = s_0s_1s_2\ldots$ where $s_i \in I_i$. Hence, from the fact that $exec(M_E, \lambda) \models \psi$ and $\rho \in exec(M_E, \lambda)$, $r$ is an accepting run and then $\tau_r(\pi)$ visits a finite number of accepting states in $T$. Therefore, $T_\lambda \in \mathcal{L}(T)$ and $\mathcal{L}(T) \neq \emptyset$.

In the other direction, if $\mathcal{L}(T) \neq \emptyset$, there exists a $\Sigma_1$-labelled $O$-tree $\langle T_\lambda, \tau \rangle$ such that $T_\lambda \in \mathcal{L}(T)$. We have to prove that the strategy $\lambda$ defined by $T_\lambda$ realizes $\psi$, i.e., for all executions $\rho \in exec(M_E, \lambda)$, we have $exec(M_E, \lambda, \rho, 0) \models \psi$. Let $\rho \in exec(M_E, \lambda)$. Since $\psi$ is an LTL formula, the sets of executions in which $\psi$ is evaluated does not matter, and therefore we have to prove that $\rho, 0 \models \psi$ (where $\models$ here denotes the classical LTL semantics). In other words, we have to show that $trace(\rho) \in \mathcal{L}(A)$, i.e., all the runs of $A$ on $trace(\rho)$ visit finitely many accepting states. Let $r = q_0q_1\ldots$ be a run of $A$ on $trace(\rho)$.

Let $\langle T_r, \tau_r \rangle$ be the (accepting) run of $T$ on $\langle T_\lambda, \tau \rangle$. It is a $Q \times O^*$-labelled $N$-tree. By definition of $exec(M_E, \lambda)$, there exists a sequence $u = a_0a_1\ldots \in \Sigma_1 \times O$ such that $\rho = s_0s_1s_2\ldots$ is compatible with $u$. Let define $t$ as the infinite sequence $t = (q_0, I(0)), (q_1, I(1)), (q_2, I(2)), \ldots$ such that $s_i \in I(i) \subseteq S$ for all $i \geq 0$, $I(0) = (q_0, s_0)$ and $I(i+1) = post_{t(i)}(I(q_i, q_{i+1}, o_{i+1}))$ for all $i \geq 0$. It is easily shown that this sequence is such that there exists a branch $\pi$ in $\langle T_r, \tau_r \rangle$ with $\tau_r(\pi) = t$ since the automata $A$ and $T$ are complete and $\forall i, \bigcup_{\rho' \in Q_{o_i}} post_{t(i)}(I(q_i, q_{i+1}, o_{i+1})) = post_{t(i)}(I(q_i, q_{i+1}, o_{i+1}))$. Therefore there are finitely many accepting states in $q_0q_1\ldots$, since $T_r$ is accepting. Therefore $\text{trace}(\rho) \in \mathcal{L}(A)$.

B Correctness of the UCT construction for KLTL$^+$

In the following, we prove that the automaton $T^i$ accepts exactly the strategies that realize $\varphi^i$ in the extended runs of the environment $M_E$. A strategy of the system in this case can be seen as a $\Sigma_1 \times 2^\mathcal{E}$-labelled $O$-tree $T$. A branch of $T$ is a sequence $\pi = a_1a_2a_3\ldots$, where $\forall i, \bar{a}_i \in \Sigma_1 \times 2^\mathcal{E}$ and $o_i \in \mathcal{O}$.

As we mentioned before, we start our construction with the LTL formula $\varphi^d$ and construct the universal co-Büchi tree automaton $T^d = T_{\varphi^d, s_0}$ for the LTL formula $\varphi^d$.

Then, we construct the sequence of automata $T^d, T^{d-1}, \ldots, T^0$ such that $T^i$ checks for the satisfaction of $\varphi^i$ on the branches of accepted trees. In other words, $\forall T' \in \mathcal{L}(T^i), \forall \rho \in exec(M_E, T)$, we have that

$$exec(M_E, T), \rho, 0 \models \varphi^i$$
In order to prove that the invariant holds, let define

\[ \text{exec}(\mathcal{M}_E, T, \pi, j) = \bigcup_{\pi'\in T: \pi'[0...j]=\pi[0...j]} \text{exec}(\mathcal{M}_E, \pi') \]

be the set of all extended executions that are compatible with the branch \( \pi \) of the tree \( T \) up to position \( j \). This runs are indistinguishable from the runs in \( \text{exec}(\mathcal{M}_E, \pi) \) up to position \( j \). Observe that by definition we have \( \text{exec}(\mathcal{M}_E, T, \pi, 0) = \text{exec}(\mathcal{M}_E, T) \).

**Definition 2.** A \( \Sigma_1 \times 2^K \)-labelled \( \mathcal{O} \)-tree is called fair with respect to a \( K \)-positive one-agent \( \mathcal{K}LTL \) formula \( \phi \) if:

\[
\forall \pi = (a_0, K_0)\circ_0 (a_1, K_1)\circ_1 ... \forall j, \forall k_\pi \in K_j \cap \text{sub}(\phi), \\
\forall \pi' \text{ s.t. } \pi'[0...j] = \pi[0...j], \\
\forall \rho \in \text{exec}(\mathcal{M}_E, \pi'), \text{ we have } \text{exec}(\mathcal{M}_E, \pi'), \rho, j \models \gamma
\]

Intuitively, whenever we have \( \psi \) where \( \psi \) is by induction on the structure of \( \pi \)...

**Lemma 3.** If a \( \Sigma_1 \times 2^K \)-labelled \( \mathcal{O} \)-tree \( T \) is fair with respect to \( \phi \), then

\[
\forall \psi \in \text{sub}(\phi), \forall \pi \text{ branch of } T, \forall j, \forall \rho \in \text{exec}(\mathcal{M}_E, T, \pi, j), \\
\text{if } \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi, \\
\text{then } \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi^{-1}
\]

where \( \psi^{-1} \) is obtained from \( \psi \) by replacing the atomic propositions \( k_\pi \) with the formulas \( K\gamma \).

**Proof.** Let fix a branch \( \pi = (a_0, K_0)\circ_0 (a_1, K_1)\circ_1 ... \) of \( T \). Then, the proof is by induction on the structure of \( \psi \).

- if \( \psi = p \in \mathcal{P} \), \( \psi^{-1} = \psi \) and then, \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models p \).
- if \( \psi = k_\pi \), since \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models k_\pi \), \( k_\pi \in \text{proj}_2(\rho[j]) = K_j \). Then, because \( k_\pi \in \text{sub}(\psi) \), we have \( k_\pi \in K_j \cap \text{sub}(\psi) \).

Because \( T \) is a fair tree with respect to \( \phi \) and \( \psi \in \text{sub}(\phi) \), \( \forall \pi' \in T \text{ s.t. } \pi'[0...j] = \pi'[0...j], \forall \rho' \in \text{exec}(\mathcal{M}_E, \pi') \), we have that \( \text{exec}(\mathcal{M}_E, T), \rho', j \models \gamma \). Then, since \( \text{exec}(\mathcal{M}_E, T, \pi, j) = \bigcup_{\pi' \text{ s.t. } \pi'[0...j] = \pi'[0...j]} \text{exec}(\mathcal{M}_E, \pi') \), we have \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models K\gamma \).
- if \( \psi = \psi_1 \land \psi_2 \), \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi_1 \land \psi_2 \). That is, \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi_1 \) and \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi_2 \). From the induction, we have \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi_1^{-1} \) and \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi_2^{-1} \) which means that \( \text{exec}(\mathcal{M}_E, T, \pi, j), \rho, j \models \psi_1^{-1} \land \psi_2^{-1} \) and the proof is the same for \( \psi = \psi_1 \lor \psi_2 \).
Lemma 4. Let $\pi \subseteq T$ be a subtree of $T$ with the root at position $j$ and $\pi$ is fair with respect to $\varphi^{i+1}$. Then, denoting by $\text{exec}(M_E, T, \pi, j)$ the set of $e$-executions in $M_E$ that are compatible with $\pi$ and start when the current possible states of $M_E$ are $X$, we can prove that:

**Lemma 4.** For all $i \in \{0, \ldots, d - 1\}$, $\forall T \in \mathcal{L}(T^i), T$ is fair with respect to $\varphi^{i+1}$.

**Proof.** The proof of this theorem comes directly from the construction of $T^i$ from $T^{i+1}$. Let $T \in \mathcal{L}(T^i)$. By the construction, $T^i$ is $T^{i+1}$ to which is “plugged” the automata $T_\gamma,X$ for the LTL formulas $\gamma$ where $k_\gamma \in \text{sub}(\varphi^{i+1})$ appears on a transition of $T^{i+1}$.

Therefore, if at position $j$ on a branch $\pi = (a_0, K_0)_{0\ldots1}(a_1, K_1)_{0\ldots1} \ldots$ of $T$ we have $k_\gamma \in K_j \cap \text{sub}(\varphi^{i+1})$, there also starts the execution of $T_\gamma,X$ that accepts the “maximal” subtree of $T$ with the root at position $j$ on branch $\pi$. Let denote this subtree $T_{\pi,j}$ and observe that it is formed from the suffixes $\pi'[j \ldots]$ of all the branches $\pi'$ of $T$ such that $\pi'[0 \ldots j] = \pi[0 \ldots j]$. Therefore, since $T_{\pi,j} \in \mathcal{L}(T_\gamma,X)$ for some $X$ and $\gamma$ is an
LTL formula, using the results in Section 4 we have that exec($M_E[X], \pi'[\ldots]) \models \gamma$. That is, \( \forall \pi^i \) branch of \( T \) such that \( \pi^i[0\ldots j] = \pi[0\ldots j] \), \( \forall \rho \in \text{exec}(M_E, \pi') \), we have \( \text{exec}(M_E, \pi'), \rho, j \models \gamma \). This means that \( T \) is fair with respect to \( \varphi^{i+1} \).

**Proposition 4.** For all \( i \in \{0,\ldots,d\} \), \( \forall T \in L(T^d) \), \( \forall \pi \) branch of \( T \), \( \forall \rho \in \text{exec}(M_E, \pi) \),

\[
\text{exec}(M_E, \pi), \rho, 0 \models \varphi^i
\]

**Proof.** We do the proof of the theorem by induction on \( i \). For the case base, if \( i = d \), \( T^d = T_{\varphi^d, S_0} \) and a sample adaptation of the proof of Lemma 1 yields that \( \forall \pi \) a branch of \( T \in L(T^d) \), we have directly that \( \text{exec}(M_E, \pi) \models \varphi^d \).

For the inductive step, we suppose that the theorem holds for \( T^{i+1} \) and prove it for \( T^i \). From the inductive hypothesis, we have that \( \forall T \in L(T^{i+1}) \), \( \forall \pi \) branch of \( T \), \( \forall \rho \in \text{exec}(M_E, \pi), \text{exec}(M_E, \pi'), \rho, 0 \models \varphi^{i+1} \).

But, since \( L(T^{i+1}) \supseteq L(T^i) \), it is true that \( \forall T \in L(T^i) \), \( \forall \pi \) branch of \( T \), \( \forall \rho \in \text{exec}(M_E, \pi) \), we have \( \text{exec}(M_E, \pi), \rho, 0 \models \varphi^i \).

Let fix \( T \in L(T^i) \) and a branch \( \pi \) of \( T \). By Theorem 4, \( T \) is fair with respect to \( \varphi^{i+1} \). Then, since \( \text{exec}(M_E, \pi) \subseteq \text{exec}(M_E, T, \pi, 0) \) and since all the runs \( \rho \in \text{exec}(M_E, \pi) \) are distinguishable from the other runs from \( \text{exec}(M_E, T, \pi, 0) \) \( \subseteq \text{exec}(M_E, \pi) \) (because they are compatible with different sequences \( \pi' \) of actions \( a_i \) and observations \( o_i \)), we have that \( \forall \rho \in \text{exec}(M_E, \pi), \text{exec}(M_E, T, \pi, 0), \rho, 0 \models \varphi^{i+1} \).

Then, by applying Lemma 3, results that \( \text{exec}(M_E, T, \pi, 0), \rho, 0 \models \varphi^i \) and because of the inclusion \( \text{exec}(M_E, \pi) \subseteq \text{exec}(M_E, T, \pi, 0) \) and because the runs \( \rho \in \text{exec}(M_E, \pi) \) are distinguishable from the other runs from \( \text{exec}(M_E, T, \pi, 0) \) \( \subseteq \text{exec}(M_E, \pi) \), we have that \( \text{exec}(M_E, \pi), \rho, 0 \models \varphi^i \).

## C Proof of corollary 1

**Proof.** From left to right, if \( L(T^0) \neq \emptyset \), there exists a tree \( T \in L(T^0) \) that, by Theorem 4, satisfies the property that \( \forall \pi = (a_0, K_0)_{0 \leq i < l} \) branch of \( T \), \( \forall r \in \text{exec}(M_E, \pi), \text{exec}(M_E, \pi), \rho, 0 \models \varphi^0 \). This means that all paths in the model \( M_E \) compatible with the branches of the tree \( T \) satisfy the formula \( \varphi^0 = \varphi \). That is, since \( \varphi \) is a \( K \)-positive KTL formula over \( 2^P \), \( \forall r \in \text{exec}(M_E, T), \) we have that \( \text{proj}_1(\text{exec}(M_E, T)), \text{proj}_1(r), 0 \models \varphi \).

Then, there exists a strategy \( \lambda_1 : (\Sigma_1 \times O)^* \rightarrow \Sigma_1 \) of the system, represented by the tree \( T \), that, since \( \text{exec}(M_E, \lambda_1) = \bigcup_{\pi \in T} \text{proj}_1(\text{exec}(M_E, \pi)) \), satisfies the property that \( \forall r \in \text{exec}(M_E, \lambda_1), \) we have \( \text{exec}(M_E, \lambda_1), \rho, 0 \models \varphi \). That is, \( \varphi \) is realizable in \( M_E \).

From right to left, if \( \varphi \) is realizable in \( M_E \), there exists a strategy \( \lambda_1 : (\Sigma_1 \times O)^* \rightarrow \Sigma_1 \) of the system such that \( \forall r \in \text{exec}(M_E, \lambda_1), \) we have \( \text{exec}(M_E, \lambda_1), \rho, 0 \models \varphi \). This strategy can be seen as a \( \Sigma_1 \)-labelled \( O \)-tree \( T \). Note that any branch \( a_0 \rightarrow a_1 \rightarrow a_2 \ldots \) of \( T \) can be seen as a sequence \( \hat{\pi} = a_0 a_1 a_2 a_3 \ldots \) where \( a_i \in \Sigma_1 \times O \) and \( o_i \in O \). Therefore, \( \forall r \in \text{exec}(M_E, \hat{\pi}), \) we have \( \text{exec}(M_E, \hat{\pi}), \rho, 0 \models \varphi \).

Now, we annotate all the nodes \( a_j \) of the tree \( T \) with fresh atomic propositions \( k_j \in K \) whenever on the branch \( \hat{\pi} \), the formula \( K \gamma \) has to be true at position \( j \), i.e., whenever for all the branches \( \pi'[\ldots] \) of \( T \) such that \( \hat{\pi}[0\ldots j] = \pi'[0\ldots j] \),
∀ r ∈ exec(\(M_E, \pi^r\)), it is true that exec(\(M_E, \pi^r\), r, j \models \gamma\). Then, all branches of the obtained tree \(\tilde{T}\) will be of the form \(\pi = (a_0, K_0) o_0 (a_1, K_1) o_1 (a_2, K_2) o_2 \ldots\) where \(K_j = \{k_\gamma \mid K \gamma \text{ is true at position } j\}\). Also, \(∀ r ∈ exec(\(M_E, \pi\)), exec(\(M_E, \pi\), r, 0 \models \varphi^d\) thanks to the annotations. Therefore, the annotated tree \(\tilde{T}\) is accepted by \(T^d\) and then, by the construction of the chain of over-approximations and by the fact that \(k_\gamma\) appears only where \(K \gamma\) is true, we have that \(\tilde{T}\) is also accepted by \(T^0\). This means that \(\mathcal{L}(T^0) \neq \emptyset\).

### D Reduction to Safety Games and Complexity

In the following, the aim is to reduce the emptiness problem to a safety game between the environment and the system. Following the approach in [8], we turn the universal Co-Büchi tree automaton \(T^0\) into an universal B-Co-Büchi tree automaton \((T^0, B)\) (in which at most \(B\) accepting states are visited) and check for the emptiness. For doing this, we construct a two-player game \(G_\varphi\) with a safety winning condition. This is done via a determinization of the universal B-Co-Büchi tree automaton.

In order to simplify the notations, in the next sections we will use \(T = \langle Q, Q_0, \Delta, \alpha, \Sigma_1 \times 2^E \rangle\) instead of \(T^0\) since the others automata in the chain of over-approximations are not needed in the following.

#### D.1 Reduction to Universal B-Co-Büchi tree automaton

Before reducing the universal co-Büchi tree automaton \(T\) to a universal \(B\)-co-Büchi tree automaton, we mention the fact that a finite-state strategy can be represented by a Moore machine as in [8] where the transition relation is extended to simulate a strategy.

**Lemma 5.** Let \(T\) be a UCT over \(\Sigma\) with \(n\) states constructed for the KLTLL\(^+\) formula \(\varphi\) and a strategy \(\lambda\) represented by a Moore machine \(M_\lambda\) with \(m\) states. Then, \(T_\lambda \in \mathcal{L}_{uc}(T)\) iff \(T_\lambda \in \mathcal{L}_{uc, 2nm}(T)\), where the strategy \(\lambda\) is viewed as the tree \(T_\lambda\).

**Proof.** It is obvious that if \(T_\lambda \in \mathcal{L}_{uc, 2nm}(T)\), then \(T_\lambda \in \mathcal{L}_{uc}(T)\). Now, if \(T_\lambda \in \mathcal{L}_{uc}(T)\), intuitively, the infinite runs in \(T\) on \(T_\lambda\) are accepting. That is, each path of the runs on \(T_\lambda\) visits finitely many accepting states. Therefore, in the product of \(M_\lambda\) with \(T\), there are no cycle visiting accepting states of \(T\) which bounds the number of visited accepting states on a path by the number of states in the product.

Further, in [14] is shown that if a UCT automaton with \(n\) states is not empty, then it accepts a finite state machine of width bounded by \(2n! n^{2n} (n+1)/n!\). An improved upper bound result mentioned in [13] shows that the width reduces to \(2n(n!^2)\). Then, using this results we can turn the emptiness problem for the UCT automaton \(T\) into the emptiness problem of the UBCB automaton \((T, B)\) as follows:

**Theorem 3.** Given the UCT \(\bar{T}\) over \(\Sigma_1 \times 2^E\) with \(n\) states and \(B = 4n^2(n!)^2\), \(\mathcal{L}_{uc}(\bar{T}) \neq \emptyset\) iff \(\mathcal{L}_{uc, B}(\bar{T}) \neq \emptyset\).

**Proof.** If \(\mathcal{L}_{uc}(\bar{T}) \neq \emptyset\), then there exists a regular tree \(T_\lambda \in \mathcal{L}_{uc}(\bar{T})\) generated by a finite state machine with \(m\) states \(m < 2n(n!)^2\). Then, by the Lemma 5, \(T_\lambda \in \mathcal{L}_{uc, 2nm}(\bar{T})\) and \(\mathcal{L}_{uc, B}(\bar{T}) \neq \emptyset\). In the other sense, the proof is obvious since \(\mathcal{L}_{uc, B}(\bar{T}) \subseteq \mathcal{L}_{uc}(\bar{T})\).
D.2 Reduction to Safety Game

In the previous subsection we reduced the emptiness problem of the universal Co-Büchi tree automaton $T$ to the emptiness problem of the universal $B$-Co-Büchi tree automaton $(T, B)$. Further, we show the reduction of the new problem to a safety game. This is done via an determinization of the universal $B$-Co-Büchi tree automaton $(T, B)$. Note that we explain the reduction for self-containeness reasons, the construction being very similar to [9,17].

In the determinization step, we construct a complete deterministic 0-Co-Büchi tree automaton by extending the subset construction with counters. The states of the automaton are functions $F$ that count (up to $B+1$) for each state $q \in Q$ the maximum number of accepting states visited by the paths that lead to $q$. Formally, $F : Q \rightarrow \{-1, 0, \ldots, B+1\}$ where $F(q) = -1$ means that no runs on the prefix read so far end in $q$. Also, $0, \ldots, B$ are safe states for which $F(q) = i, 0 \leq i \leq B$ means that the maximal number of visits of final states by runs that end in $q$ is $i$, and $B+1$ is the unsafe state where the number of visits to final states of runs that end in $q$ is greater or equal to $B+1$.

Then, the determinization of $(T, B)$ is the universal 0-co-Büchi tree automaton $\text{Det}(T, B) = \{ F, F_0, \alpha^\prime, \delta \}$ where $F$ is the set of states, $F_0$ is the initial state, $\alpha^\prime$ is the set of final states and $\delta$ is the transition relation with:

- $\forall q, I \in F, F_0(q, I) = -1$ if $(q, I) \notin Q_0$ and $F_0(q, I) = ((q, I) \in \alpha)$ otherwise
- $\alpha^\prime = \{ F \in F \exists q, I \in Q \text{ s.t. } F(q, I) > B \}$
- $\forall o \in O, \delta(F, (a, K), o) = (F', o) \text{ if } F'(q', I') = \max \{ \min \{ B + 1, F(q, I) + ((q', I') \in \alpha) - 1 \} \}$
- $((q', I'), o) \in \Delta(\delta(F(q, I), (a, K), o) \text{ and } F(q, I) \neq -1)$

where $\max(\emptyset) = -1$ and, for all states $(q, I) \in Q$, $(q, I) \in \alpha) = 1$ if $(q, I)$ is in $\alpha$ and 0 otherwise. We say that a state $F$ is unsafe if there exists $(q, I) \in Q$ such that $F(q, I) = B + 1$.

**Theorem 4.** Let $T$ be the UCT for the KLTL$^+$ formula $\varphi$ and $B \in \mathbb{N}$. Then, $\text{Det}(T, B)$ is complete, deterministic and $L_{uc, 0}(\text{Det}(T, B)) = L_{uc, B}(T)$.

**Proof.** It is obvious that the constructed automaton is complete by construction and from the completeness of $(T, B)$. Also, it is deterministic because of the construction. From a state $F$, for one action of the agent and one observation we get only one successor state $F'$.

Then, we prove the language equality by double inclusion. From right to left, if $(T, \tau)$ is a $\Sigma_1 \times 2^K$-labelled $O$-tree accepted by $(T, B)$, there exists an accepting run on $(T, \tau)$ in $(T, B)$. Let it be $(T, \tau)$ such that $\tau_\epsilon(q_0) \in Q_0 \times \{ \epsilon \}$ and $\forall x \in T$ s.t. $\tau(x) = ((q, I), v)$ and $\tau(v) = (a, K)$, if $\Delta((q, I), \alpha, K) = \{ ((q_1, I_1), o_1), \ldots, ((q_n, I_n), o_n) \}$, then $\forall 0 < j \leq n, x_j \in T, \text{ and } \tau(x_j) = ((q_j, I_j), v, o_j)$.

Since the run on $T$ is accepting, each branch $\pi$ of $t_\lambda$ induces an infinite sequence $\tau_\epsilon(\pi) = ((q_0, I_0), \epsilon)((q_1, I_1), v_1)((q_2, I_2), v_2)\ldots$ which visits at most $B$ times the final states. Then, by the construction of $\text{Det}(T, B)$ using subset construction on the states with the same observation, there exists a run on $(T, \tau)$ which is accepting since the set of final state $\alpha^\prime = \{ F \in F \exists q, I \in Q \text{ s.t. } F(q, I) > B \}$ is not reached.
From left to right, let $\langle T, \tau \rangle$ be a $\Sigma_1 \times 2^K$-labelled $O$-tree accepted by $\text{Det}(T, B)$. Then, there exists a run on $\langle T, \tau \rangle$ in $\text{Det}(T, B)$. Let it be $(T_r, \tau_r)$ such that $\tau_r(\epsilon) \in F_0 \times \{\epsilon\}$ and $\forall x \in T_r$ s.t. $\tau_r(x) = (F, v)$ and $\tau(v) = (a, K)$, if $\delta(F, (a, K)) = \{(F_1, o_1), \ldots, (F_n, o_n)\}$, then $\forall 0 < j \leq n, x_j \in T_r$ and $\tau_r(x_j) = (F_j, v \cdot o_j)$.

Since the run is accepting in the 0-Co-Büchi tree automaton, it means that it doesn’t visit any $F$ such that $\exists(q, I)$ for which $F(q, I) \geq B + 1$. This means that, using the construction of $\text{Det}(\mathcal{F}, B)$, the branches of the run in $\langle T, \tau \rangle$ on $\langle T, \tau \rangle$ visit at most $B$ times the final states in $\alpha$. Therefore, $T \in \mathcal{L}_{uc,B}(\bar{T})$.

A two-player safety game is played on a game arena. To reflect the game point of view, the automaton $\text{Det}(T, B)$ can be seen as a game arena $G(T, B) = (\mathcal{F}_E, \mathcal{F}, \varphi_0, T = T_1 \cup T_E, \text{Safe})$ with $|\mathcal{F}| + |\delta|$ states where $\mathcal{F}_E \cup \mathcal{F}$ is the set of states of the game, $\mathcal{F}$ being the set of states controlled by the system and $\mathcal{F}_E$ the set of states controlled by the environment, $\varphi_0 = F_0 \in \mathcal{F}$ is the initial state, $T \subseteq \mathcal{F} \times \mathcal{F}_E \cup \mathcal{F}_E \times \mathcal{F}$ is the transition relation and $\text{Safe} \subseteq \mathcal{F}$ is the safety winning condition defined by

- $\mathcal{F}_E = \{F_a, K | F \in \mathcal{F} \text{ and } (a, K) \in \Sigma_1 \times 2^K\}$
- $T_1 = \{(F, F_a, K) | F \in \mathcal{F} \text{ and } (a, K) \in \Sigma_1 \times 2^K\}$
- $T_E = \{(F_a, K, F') | \forall F' \in \delta(F, (a, K))\}$
- $\text{Safe} = \mathcal{F} \setminus \alpha'$

Then, $\mathcal{F}_E \cup \mathcal{F}$ is the total set of states of the game and $T = T_1 \cup T_E$ is the transition relation.

An infinite play on $G(T, B)$ is a path $\rho = \rho_0\rho_1\rho_2\ldots \in (\mathcal{F}\mathcal{F}_E)^\omega$ such that $\forall i \geq 0, (\rho_i, \rho_i + 1) \in T$. Finite plays are similarly defined and they belong to $(\mathcal{F}\mathcal{F}_E)^\ast$. A strategy for the system is a mapping $\lambda_1 : (\mathcal{F}\mathcal{F}_E)\ast \rightarrow \mathcal{F}_E$ that maps every finite play $\rho$ whose last state is $\rho_n \in \mathcal{F}$ to a state $\rho_{n+1}$ such that $(\rho_n, \rho_{n+1}) \in T_1$. A strategy for the environment is a mapping $\lambda_2 : (\mathcal{F}\mathcal{F}_E)\ast \rightarrow \mathcal{F}$ that maps an infinite play ending in $\rho_n \in \mathcal{F}_E$ to a state $\rho_{n+1} \in \mathcal{F}$ such that $(\rho_n, \rho_{n+1}) \in T_E$. The outcome of a strategy $\lambda_1$ of the system is a set $\text{Outcome}_{G(T, B)}(\lambda_1)$ of infinite plays $\rho = \rho_0\rho_1\rho_2\ldots \in (\mathcal{F}\mathcal{F}_E)^\omega$ such that if $\rho_i \in \mathcal{F}$ then $\rho_{i+1} = \lambda_1(\rho_0\ldots\rho_i)$. A strategy for the system is winning if $\text{Outcome}_{G(T, B)}(\lambda_1) \subseteq (\text{Safe} \mathcal{F}_E)^\omega$.

**Theorem 5.** $\mathcal{L}_{uc,0}(\text{Det}(T, B)) \neq \emptyset$ iff the system has a winning strategy $\lambda_1$ in the game $G(T, B)$.

**Proof.** If $\mathcal{L}_{uc,0}(\text{Det}(T, B)) \neq \emptyset$, then there exists a $\Sigma_1 \times 2^K$-labelled $O$-tree $T$ which is accepted by $\text{Det}(T, B)$. Then, there exists an accepting run $(T_r, \tau_r)$ on $T$ whose paths don’t visit the final states in $\alpha'$. Then, by the construction of the game $G(T, B)$, there exists a strategy (represented by the tree $T$) which is winning in $G(T, B)$ because all the paths in the game arena that follow it visit exactly the same states in $\mathcal{F}$ as $\langle T_r, \tau_r \rangle$ does and the safe set is defined as $\text{Safe} = \mathcal{F} \setminus \alpha'$.

Now, if there exists a winning strategy $\lambda_1$ in $G(T, B)$ (which can be seen as a $\Sigma_1 \times 2^K$-labelled $O$-tree $T$), then all the outcomes of $\lambda_1$ will stay in the set $\text{Safe}$. Then, by construction of the game arena, there exists a run on $T$ in the automaton $\text{Det}(T, B)$ which is also accepting because $\text{Safe} = \mathcal{F} \setminus \alpha'$ which means that the run doesn’t visit the set $\alpha'$.

Therefore, by Theorems 2, 3, 4 and 5, we have that the KTLT$^+$ formula $\varphi$ is realizable in the environment model $M_E$ if and only if the system has a winning strategy in the game $G(T, B)$. 
D.3 Complexity

In the following, we study the complexity of the realizability algorithm for the KLTL$^+$ formulas. First, using the way the game arena is constructed, we have the following lemma:

**Lemma 6.** For all states $F \in \mathcal{F}$, if there exist $(q, I), (q', I') \in Q$ such that $F(q, I) \neq -1$ and $F(q', I') \neq -1$, if $I \neq I'$, then $F$ is not reachable from the initial state.

**Proof.** We prove the lemma by induction on the length of the path leading to a state $F$.

If $F = F_0$, then since $F(q, I) \neq -1$, we have $(q, I) \in Q_0 = \{(q_0, S_0) \mid q_0 \in Q_0\}$.

Then, the proposition is true by definition.

Now, suppose that there is reached a state $F_i \in \mathcal{F}$ such that for all $(q, I), (q', I') \in Q$ with $F_i(q, I) \neq -1$ and $F_i(q', I') \neq -1$, we have $I = I'$. Let this set be denoted by $I_i$. We then prove that, after one round in the game, the state $F_{i+1}$ that is reached satisfy the property that for all $(q, I), (q', I') \in Q$ such that $F_{i+1}(q, I) \neq -1$ and $F_{i+1}(q', I') \neq -1$, we have $I = I'$.

From the construction of the game arena, $F_{i+1}$ is computed from $F_i$ using the action $(a, K)$ proposed by the agent and observation $o$ given by the environment. That is, $F_{i+1}(q, I') = \max(\min|(B + 1, F_i(q'', I_i) + ((q, I'), o) \in \Delta((q'', I_i), (a, K))\}$ from the definition, the states $(q, I')$ for which $F_{i+1}(q, I') \neq -1$ are states for which there exists $(q'', I_i)$ with $F_i(q'', I_i) \neq -1$ and $I' = \text{Post}_a(I''_{q', q}, o)$. Therefore, since the state $F_{i+1}$ is uniquely determined by a sequence of actions and observations, and the states $q$ and sets $I$ are synchronized along a path, we have that all the states $(q, I')$ with $F_{i+1}(q, I') \neq -1$ contain the same set $I_{i+1} = I'$ of states of the environment.

Since we are interested in reachable positions of the safety game only, we can just focus on functions $F$ such that for all $(q, I), (q', I') \in Q$, we have $I = I'$. We associate to each function $F$ a tuple $\tilde{K}$ of sets $I$ corresponding to the states $q$ (as in section 6) and denote by $\tilde{K}(q)$ the set $I$ associated to the state $q$ in $F$. Then, the safety game $G(T, B)$ is restricted to reachable states $(F, \tilde{K})$.

**Lemma 7.** The number of states of the safety game $G(T, B)$ built for the KLTL$^+$ formula $\varphi$ in the environment $M_E$ has at most $\frac{(B+3)^{|\varphi|+1}-1}{B+2} \times (1 + 2^{|O|}) \times (1 + |\Sigma| \times 2^{|I|})$ states.

**Proof.** $\mathcal{F} = \{F \mid F : Q \to \{-1, 0, \ldots, B + 1\}\}$. But, according to the previous lemma, $\forall(q, I), (q', I') \in Q$ such that $F(q, I) \neq -1$ and $F(q', I') \neq -1$, we have $I = I'$.

It means that, for a function $F$, there are at most $n = |Q| + \sum_{\gamma: \exists i, s.t. K \gamma \in \text{Sub}(\varphi^{i})} |Q_\gamma|$ states $(q, I)$ for which $F(q, I) \neq -1$.

Then, because of the way the set $I$ is computed using $\text{Post}_*(Y, o)$, excepting the initial state that may fall into several observations, there exists $o \in O$ such that $I \subseteq o$. This means that there exist $1 + \sum_{o \in O} 2^{|o|}$ sets of states of the environment that are reached, where 1 is for the initial state.

In conclusion, the number of functions $F$ is $\frac{(B + 2)^0 + (B + 2)^1 + \ldots (B + 2)^n}{B+2} \times (1 + \sum_{o \in O} 2^{|o|})$. That is, $\frac{(B+3)^{|\varphi|+1}-1}{B+2} \times (1 + \sum_{o \in O} 2^{|o|})$ functions.
Then, for each state \( F \), we have \( |\Sigma_1 \times 2^K| \) states \( F_{a,K} \) controlled by the environment. This gives a total number of \( \frac{(B+3)^{n+1} -1}{B+2} \times (1 + \sum_{o \in O} 2^{|o|}) \times (1 + |\Sigma_1 \times 2^K|) \) states of the game \( G(T, B) \).

Now, since \( n \) can be bounded by \( 2^{\left| S \right| + \left| \varphi \right|} \) and \( \sum_{o \in O} 2^{|o|} \leq 2^{|S|} \), we get that the number of states of \( G(T, B) \) is bounded by \( \frac{(B+3)^{2|S| + |\varphi|} -1}{B+2} \times (1 + 2^{|S|}) \times (1 + |\Sigma_1 \times 2^K|) \).

**Proposition 5.** The realizability of a \( K \)-positive KLTL formula \( \varphi \) is decidable in 2EXPTIME.

**Proof.** As also showed in Section 5, the number of states if the co-Büchi tree automaton \( T \) is bounded by \( 2^{|S| + |\varphi|} \) and is built in EXPTIME since there is a polynomial number of formulas \( K\gamma \) in \( \varphi \).

Then, when transforming \( T \) into a \( B \)-co-Büchi tree automaton, the bound \( B \) equals \( 4n^2(2n!)^2 \). By applying Lemma 7, we have that the safety game \( G(T, B) \) is built in 2EXPTIME.

### E Implementation and Case Studies

![Fig. 3: The environment for 3-Coins Game](image)

In the Moore machine representing the strategy of Fig.4, the state 2 corresponds to the configuration in which there are only heads and the states 3 and 7 are the states in which he goes when the environment cheated. Then, the strategy has two parts. One that leads to the state 2 by checking the coins and the second part in which the system plays only \( c_3 \) and moves between the states \( s_1 \) and \( s_7 \).

Another example that illustrates the game with imperfect information in which we need the knowledge is based on the following enigma:

**Example 3 (n-Prisoners Enigma).** Consider that there are \( n \) prisoners in a prison, each one in his own cell and they cannot communicate. Also, there is a room with a light bulb
and a switch and a policeman that, at each moment of time, sends only one prisoner in that room and gives him the possibility to turn on or off the light. The prisoners can observe only the light when they are in the room. The guardians send the prisoners in the room in any order and infinitely many times if the game never stops (fairness assumption). At any time, any prisoner can stop the game. At that point, if every prisoner has visited the room at least once, then they are all free. Otherwise they will all stay in the jail for eternity. Of course all the prisoners want to be freed, and therefore if someone stops the game, he must be sure that all the prisoners have indeed visited the room at least once. Before the game starts, they are allowed to communicate, and they know the initial state of the light.

If you want to solve this puzzle by yourself, don’t read the following paragraph which gives the solution. Assume that the light is initially off. The solution is that there is a special prisoner, let say prisoner $n$, that will count up to $n-1$. For all $1 \leq j \leq n-1$, the fairness assumption ensures that prisoner $j$ will visit the room again and again until the game stops. The first time he visits the room while the light is off, it turns it on, otherwise it does nothing. Prisoner $n$ will turn the light off next time he enters the room, and increment his counter by 1. When the counter reaches $n-1$, prisoner $n$ stops the game because he is sure that all the prisoners have visited the room at least once.

To model this problem, it is natural to represent the guardians by the environment and the prisoners by multi-agents. However, our framework only allows for one agent. Therefore we fix the strategy of prisoners 1 to $n-1$ and encode them in the environment model. Prisoner $n$ (the system) must figure out a winning strategy (ideally the counting strategy described above). We have modelled this example in Acacia-K and indeed, our tool find the strategy described above. Let us now give more details about the formalization.

Fig. 4: The winning strategy for 3-Coins Game
For three prisoners, \( \mathcal{P} = \{ \text{on}, x_1, x_2, p_1, p_2, p_3 \} \) where the atomic proposition \( \text{on} \) corresponds to the light, values of \( x_i \) for \( i \in \{1, 2\} \) is true if the prisoner \( i \) already turned the light on, and the proposition \( p_i \) for \( i \in \{1, 2, 3\} \) indicates the prisoner that is inside the room. Then, \( \mathcal{P}_v = \{ \text{on}, p_3 \} \) and \( \mathcal{P}_i = \{ x_1, x_2, p_1, p_2 \} \) indicating that the last prisoner sees all the time the light and can observe when he is inside the special room but cannot see what the other prisoners do.

We assume that at the beginning there is no one in the room. Then, the environment can propose an action in \( \Sigma_2 = \{ P_1, P_2, P_3 \} \) deciding which prisoner is going in the room and prisoner 3 will decide if he wants the light on or off by choosing an action in \( \Sigma_1 = \{ t_{\text{on}}, t_{\text{off}} \} \). Note that the action of \( P_3 \) is ignored if he is not chosen by the environment. The transition relation asks that if the prisoner \( p_i, i \in \{1, 2\} \) finds for the first time the light off (\( x_1 = \text{false} \) and \( \text{on} = \text{false} \)), he turns on the light and the value of \( x_i \) changes and remains true for all the reachable states from there.

Then, assuming that the environment is restricted to send all the prisoners in the special room infinitely many times, the KLTL\(^+\) formula that translates the goal is \( \Box \land_{i=1}^n (\lozenge p_1) \rightarrow \lozenge K(\land_{i=1}^{n-1} x_i) \). A winning strategy for the prisoner \( n \) would be to turn off the light whenever he is sent to the special room and to let it off if it already is. Then, after he finds the light on \( n-1 \) times when he is sent in that room, thanks to the strategy of the other prisoners, he will know that all of them passed by that room, and even more, all of them switched the light. Assuming that the observations set \( \mathcal{O} = \{ o_0, o_1, o_2, o_3 \} \) where \( o_0 = \{ s \in S \mid \text{on} \in \tau(s) \text{ and } p_3 \notin \tau(s) \} \), \( o_1 = \{ s \in S \mid \text{on} \notin \tau(s) \text{ and } p_3 \in \tau(s) \} \), \( o_2 = \{ s \in S \mid \text{on} \in \tau(s) \text{ and } p_3 \in \tau(s) \} \) and \( o_3 = \{ s \in S \mid \text{on} \notin \tau(s) \text{ and } p_3 \in \tau(s) \} \), the strategy synthesized by Acacia-K for three prisoners and corresponds to the intuitive strategy is illustrated in Figure 5 where the state 10 in the generated Moore machine corresponds to the moment when the prisoner \( p_3 \) knows that all the other prisoners passed through the special room and turned on the light.

For this example, Acacia-K constructed a UCT with 144 states, synthesised a strategy with 12 states, and the total running time is 1.87s.
Fig. 5: The winning strategy for 3-Prisoners Game
