Gamma-ray bursts (GRBs) have been regarded as standard candles at very high redshift for cosmology research. We have proposed a new method to calibrate GRB distance indicators with Type Ia supernova (SNe Ia) data in a completely cosmology-independent way to avoid the circularity problem that had limited the direct use of GRBs to probe cosmology [N. Liang, W. K. Xiao, Y. Liu, and S. N. Zhang, Astrophys. J. 685, 354 (2008)]. In this paper, a simple method is provided to combine GRB data into the joint observational data analysis to constrain cosmological models; in this method those SNe Ia data points used for calibrating the GRB data are not used to avoid any correlation between them. We find that the ΛCDM model is consistent with the joint data in the 1-σ confidence region, using the GRB data at high redshift calibrated with the interpolating method, the Constitution set of SNe Ia, the cosmic microwave background radiation from Wilkinson Microwave Anisotropy Probe five year observation, the baryonic acoustic oscillation from the spectroscopic Sloan Digital Sky Survey Data Release 7 galaxy sample, the x-ray baryon mass fraction in clusters of galaxies, and the observational Hubble parameter versus redshift data. Comparing to the joint constraints with GRBs and without GRBs, we find that the contribution of GRBs to the joint cosmological constraints is a slight shift in the confidence regions of cosmological parameters to better enclose the ΛCDM model. Finally, we reconstruct the acceleration history of the Universe up to z > 6 with the distance moduli of SNe Ia and GRBs and find some features that deviate from the ΛCDM model and seem to favor oscillatory cosmology models; however further investigations are needed to better understand the situation.

I. INTRODUCTION

Gamma-ray bursts (GRBs) are the most intense explosions observed so far and likely to occur in high redshift range. Recently, GRB 090423 has been observed at a very high redshift, z > 8 [1]. The early universe can be explored by using GRBs at the high redshift which is hardly achievable by Type Ia supernova (SNe Ia). In recent years, several GRB luminosity relations between measurable properties of the prompt gamma-ray emission with the luminosity or energy have been proposed as distance indicators, many of which are the two-dimensional (2D) luminosity relations, such as the isotropic energy (Eiso) - peak spectral energy (Epeak) relation (i.e., the so-called Amati relation) [2], the luminosity (L) - spectral lag (τlag) relation [3], the L - variability (V) relation [4], the L - Epeak relation [5], the L - minimum rise time (τRT) relation [6], and the collimation-corrected energy (Eiso) - Epeak relation (i.e., the so-called Ghirlanda relation) with small scattering [7]. In order to reduce the large scattering in some of these 2D relations, several 3D luminosity relations are also presented [8–10]. Liang and Zhang first proposed the relation among Eiso, Epeak and tiso (i.e., the so-called Liang-Zhang relation) [8], where tiso is the break time of the optical afterglow light curves; and Firmani et al. found the relation among L, Epeak and T0.45 (i.e., the so-called Firmani relation) [9], where T0.45 is the “high-signal” timescale of the prompt emission. Both of the 3D luminosity relations above could reduce the scattering in the luminosity or energy versus the Epeak relation. More recently, Yu et al. find that, for the 3D luminosity relations between the luminosity and an energy scale Epeak and a timescale (τlag or τRT), the intrinsic scattering is considerably smaller than that of those corresponding 2D luminosity relations [10]. Other GRB luminosity relations have been proposed in many works [11–13]. For reviews of GRB luminosity relations, see e.g. [14–17].
However, all the luminosity relations of GRBs presented above are always empirical, but still without solid physical interpretations [16]. Moreover, the luminosity relations can not be calibrated with a sufficiently large low-redshift GRB sample. Therefore, previous calibrations have been usually obtained by assuming a particular cosmological model. Once these GRB luminosity relations are calibrated, GRB data could be considered as standard candles at very high redshift for cosmology research [8, 10, 13] (see e.g. 10 and 17 for reviews). In 2003, Schaefer derived the luminosity distances of nine GRBs with known redshifts by using two GRB luminosity relations \((\mathcal{L} - \tau_{\text{lag}}, \mathcal{L} - V)\) to construct the first GRB Hubble diagram [18]. For 16 GRBs with redshift measurements, Bloom et al. found a narrow clustering of geometrically-corrected Gamma-ray energies within the framework of the uniform conical jet model [19]. Dai et al. proposed an approach to consider the Ghirlanda relation to constrain cosmological parameters and dark energy [20]. Because of the small scatter, the 3D luminosity relations have been used for cosmological constraint, including the Liang-Zhang relation [8], and the Firmani relation [21, 22]. In 2007, Schaefer used five 2D relations \((\mathcal{L} - \tau_{\text{lag}}, \mathcal{L} - V, \mathcal{L} - E_{\text{peak}}, \mathcal{L} - \tau_{\text{RT}}\) and \(E_{\gamma} - E_{\text{peak}}\)) to construct the Hubble diagram of 69 GRBs [17]. These GRB data have been widely used to constrain cosmology and dark energy models in many recent works [23, 24], and joint constraints by combining these GRB data with SNe Ia and the other cosmological probes have been derived in [30, 33]. Instead of a hybrid sample over the whole redshift range of GRBs, Takahashi et al. [34] firstly calibrated GRB relations \((\mathcal{L} - \tau_{\text{lag}}, \mathcal{L} - V)\) at low redshift where distance-redshift relations have been already determined from SNe Ia. This method was adopted by Bertolami and Silva for considering the use of GRBs at \(1.5 < z < 5\) calibrated with the bursts at \(z \leq 1.5\) as distance markers to study the generalized Chaplygin gas model [35]. All the calibration methods above carried out have been derived usually from the \(\Lambda\)CDM model with particular model parameters according to the concordance cosmology.

An important point related to the use of GRBs for cosmology is the dependence on the cosmological model in the calibration of GRB relations, which had limited the direct use of GRBs for cosmology research. In order to investigate cosmology, the relations of standard candles should be calibrated in a cosmology-independent way; otherwise, the circularity problem cannot be avoided easily [17]. Recently, the possibility of calibrating GRBs in a low-dispersion in redshift near a fiducial redshift has been proposed [26, 37], which has been developed further based on Bayesian theory [28]. However, the GRB sample available now is far from what is needed to calibrate the relations in this way [16, 38]. Many of the works treat the circularity problem with statistical approaches [18, 23, 39, 41]. A simultaneous fit of the parameters in the calibration curves and the cosmology is carried out to find the optimal GRB relation and the optimal cosmological model in the sense of a minimum scattering in both the luminosity relations and the Hubble diagram [18]. Firmani et al. proposed a Bayesian method to get around the circularity problem [23]. Li et al. presented a global fitting analysis for the Ghirlanda relation to deal with the problem [30]. Amati et al. used the \(E_{\text{iso}} - E_{\text{peak}}\) relation to measure the cosmological parameter by adopting a maximum likelihood approach [40]. More recently, Wang has shown that the current GRB data can be summarized by a set of model independent distance measurements, with negligible loss of information [41], which is followed by [42, 43]. However, an input cosmological model is still required in doing the joint fitting, the circularity problem can not be circumvented completely by means of these statistical approaches.

In our previous paper [45], we presented a new method to calibrate several GRB luminosity relations in a completely cosmology-independent manner. Our method avoids the circularity problem more clearly than previous cosmology-dependent calibration methods. It is obvious that objects at the same redshift should have the same luminosity distance in any cosmology. Therefore, the luminosity distance at any redshift in the redshift range of SNe Ia can be obtained by interpolating (or by other mathematical approach) directly from the SNe Ia Hubble diagram. Using the interpolation method, we calibrated seven GRB luminosity relations \((\mathcal{L} - \tau_{\text{lag}}, \mathcal{L} - V, \mathcal{L} - E_{\text{peak}}, \mathcal{L} - \tau_{\text{RT}}, E_{\gamma} - E_{\text{peak}}, E_{\text{iso}} - E_{\text{peak}}\) and \(E_{\text{iso}} - E_{\text{peak}}, t_b)\) with the data compiled by Schaefer [17]. Then if further assuming these calibrated GRB relations valid for all long GRB data, we can use the standard Hubble diagram method to constrain the cosmological parameters from the GRB data at high redshift obtained by utilizing the relations [45]. These distance data of GRBs are so far the most cosmology-independent GRB distance indicators. Following this cosmology-independent GRB calibration method from SN Ia [45], the derived GRB data at high redshift can be used to constrain cosmological models without circularity problem [45, 47, 49, 51]. Capozziello and Izzo first used the \(E_{\text{iso}} - E_{\text{peak}}, t_b\) relation and the \(E_{\gamma} - E_{\text{peak}}\) relation calibrated with the so-called Liang method to derive the related cosmography parameters \((\text{deceleration parameters (} q\text{), jerk parameters (} j\text{), and snap parameters (} s\text{))}\), which are only related to the derivatives of the scale factor without any a priori assumption [46]. Wei and Zhang used the Amati relation calibrated with the interpolation method to reconstruct the acceleration history of the Universe and constrain cosmological models [48, 50].

Furthermore, we proposed another approach to calibrate GRB relations by using an iterative procedure [52], which is a nonparametric method in a model independent manner to reconstruct the luminosity distance at any redshift in the redshift range of SNe Ia [53, 55]. Similar to the interpolation method, Cardone et al. constructed an updated GRBs Hubble diagram on six 2D relations calibrated by local regression from SNe Ia [56]. This method and GRB data have been used to cosmo-
logical constraints with SNe Ia in some following works \cite{42, 67}. Kodama et al. presented that the $L - E_{\text{peak}}$ relation can be calibrated with the empirical formula fitted from the luminosity distance of SNe Ia \cite{59}. This method has been used to constrain cosmological parameters by combining these GRB data with SNe Ia in a following work \cite{59}. However, it is noted that this calibration procedure depends seriously on the choice of the formula and various possible formulas can be fitted from the SNe Ia data that could give different calibration results of GRBs. As the cosmological constraints from GRBs are sensitive to GRBs calibration results \cite{41}, the reliability of this method should be tested carefully. Moreover, as pointed out in \cite{41}, the GRB luminosity relations which are calibrated by this way are no longer completely independent of all the SNe Ia data points; therefore these GRB data cannot be used to directly combine with the whole SNe Ia dataset to constrain cosmological parameters and dark energy.

It is easy to find that the number of SNe Ia data points that have been used in the linear interpolating procedure to obtain the GRB data is relatively small compared to the whole SNe Ia sample. In order to combine GRB data obtained by our interpolation method into the joint observational data analysis to constrain cosmological models, we can exclude the SNe points that have been used in the interpolating procedure from the SNe Ia sample used to the joint constraints. In this work, with the updated distance moduli of the 42 GRBs at $z > 1.4$ obtained by the interpolating method \cite{45} from the Union set of 307 SNe Ia \cite{64}, we provide a simple method to ensure that the calibrated GRB data are independent of the SNe Ia data used in the joint data fitting to constrain cosmological models, by using the Constitution set of 397 SNe Ia \cite{65}, along with the cosmic microwave background radiation (CMB) observation from the five-year Wilkinson Microwave Anisotropy Probe (WMAP5) result \cite{60} ($R, \Omega_b h^2$); the baryonic acoustic oscillation (BAO) \cite{67} observation from the spectroscopic Sloan Digital Sky Survey (SDSS) Data Release 7 (DR7) galaxy sample \cite{66} ($d_{0.2}, d_{0.35}$); the 26 baryon mass fraction in clusters of galaxies (CBF) from the x-ray gas observation ($f_{\text{gas}}$) \cite{69} and the 11 Hubble parameter versus redshift data, $H(z)$ \cite{70, 71}. Our goal is to determine the contribution of GRBs to the joint cosmological constraints in the confidence regions of cosmological parameters by comparing to the joint constraints with GRBs and without GRBs. Finally we also reconstruct the acceleration history of the Universe up to $z > 6$ with the distance moduli of SNe Ia and GRBs.

II. OBSERVATIONAL DATA ANALYSIS

The updated distance moduli of the 42 GRBs at $z > 1.4$ are obtained by the five GRB luminosity relations that are calibrated from the 27 GRBs at $z < 1.4$ with the interpolating method \cite{45} using the Union set of 307 SNe Ia \cite{64}. The Union set includes the Supernova Legacy Survey (SNLS) \cite{60} and the ESSENCE Survey \cite{61}, the extended dataset of distant SNe Ia observed with the Hubble Space Telescope \cite{62}, and the formerly observed SNe Ia data. For the SNe Ia data in joint analysis, we use the new Constitution set of 397 SNe Ia \cite{65}, which combine 90 CfA3 SNe Ia sample with the Union set \cite{64}. We also consider the shift parameters set ($R, \Omega_b h^2$) \cite{66}, the BAO \cite{67} parameters set ($d_{0.2}, d_{0.35}$) from SDSS DR7 \cite{68}, the 26 $f_{\text{gas}}$ data from the x-ray gas observation in clusters of galaxies \cite{69}, and the 11 $H(z)$ data from the differential ages of passively evolving galaxies \cite{70} and from the BAO peak position \cite{71}.

In our previous paper \cite{45} we used the data for 69 GRBs compiled by Schaefer \cite{17} and adopted the data for 192 SNe Ia compiled by Davis et al. \cite{62} to calibrate seven GRB luminosity relations ($L - \tau_{\text{lag}}, L - V, L - E_{\text{peak}}, L - \tau_{\text{RT}}, E_{\gamma} - E_{\text{peak}}, E_{\text{iso}} - E_{\text{peak}}$, and $E_{\text{iso}} - E_{\text{peak}}$) at $z < 1.4$ by using the interpolation method. In this work, we use the Union set of 307 SNe Ia \cite{64} to determine the values of the intercepts and the slopes of GRBs luminosity relations calibrated with the GRB sample at $z < 1.4$ by using the linear interpolation method. We do not include the 90 SNe Ia data from CfA3 \cite{65} due to their extremely low redshift ($z < 0.1$), which would not affect the calibrated results for GRB luminosity relations at $0.17 \leq z \leq 1.4$. The 2D luminosity relation of GRBs can be generally written in the form

$$\log y = a + b \log x,$$

where $y$ is the luminosity ($L/\text{erg s}^{-1}$) or energy ($E_{\gamma} / \text{erg}$); $x$ is the GRB parameters measured in the rest frame, e.g., $\tau_{\text{lag}}(1+z)^{-1}/(0.1 \text{s}), V(1+z)/0.02, E_{\text{peak}} (1+z)/(300 \text{keV}), \tau_{\text{RT}} (1+z)^{-1}/(0.1 \text{s})$, for the corresponding 2D relations. We adopt the data for these quantities from Ref. \cite{17} including five 2D GRB luminosity relations ($L - \tau_{\text{lag}}, L - V, L - E_{\text{peak}}, L - \tau_{\text{RT}}, E_{\gamma} - E_{\text{peak}}$). For the $E_{\gamma} - E_{\text{peak}}$ relation, in order to calculate the total collimation-corrected energy $E_{\gamma}$, one needs to know the beaming factor, $F_{\text{beam}} = (1 - \cos \theta_{\text{jet}})$, where the value of the jet opening angle $\theta_{\text{jet}}$ is related to the jet break time ($t_b$) and the isotropic energy for an Earth-facing jet, $E_{\gamma, \text{iso}} = E_{\gamma, \text{iso}_0}/10^{52} \text{erg}$ \cite{72}. When calculating $E_{\gamma, \text{iso}}$, we also use the interpolation method from SNe Ia to avoid the circularity problem. We determine the values of the intercept ($a$) and the slope ($b$) with their 1-$\sigma$ uncertainties calibrated with the GRB sample at $z < 1.4$ by using the linear interpolation methods from the Union set of 307 SNe Ia.

Further assuming that these GRB luminosity relations do not evolve with redshift, we are able to obtain the luminosity ($L$) or energy ($E_{\gamma}$) of each burst at high redshift ($z > 1.4$). Therefore, the luminosity distance ($d_L$) can be derived. A distance modulus can be calculated as $\mu = 5 \log(d_L/\text{Mpc}) + 25$. The weighted average distance modulus from the five relations for each GRB is $\mu = (\sum_i \mu_i/\sigma_{\mu_i}^2)/(\sum_i \sigma_{\mu_i}^2)$, with its uncertainty $\sigma_\mu = (\sum_i \sigma_{\mu_i}^2)^{-1/2}$, where the summations run from 1 to 5 over the five relations with available data. For more de-
where the equation of state (EoS) of dark energy $w(z)$ is determined by the choice of the specific dark energy model. The $\chi^2$ value of the observed distance moduli can be calculated by

$$\chi^2_\mu = \sum_{i=1}^{N} \frac{(\mu_{\text{obs}}(z_i) - \mu(z_i))^2}{\sigma_{\mu,i}^2},$$

(5)

where $\mu_{\text{obs}}(z_i)$ is the observed distance modulus for the SNe Ia and/or GRBs at redshift $z_i$, with its error $\sigma_{\mu,i}$; $\mu(z_i)$ is the theoretical value of distance modulus from a dark energy model which can be calculated from Eqs. -(4). The nuisance parameter $\mu_0$ (or $h$) can be obtained by marginalizing the likelihood functions of over $\mu_0$ (or $h$) for all values 20 or treated by following an effective approach 73 to expand the $\chi^2_\mu$ to $\chi^2_a$ by $\chi^2_a(\mu_0) = A\mu_0^2 - 2B\mu_0 + C$, with $A = \sum 1/\sigma_{\mu,i}^2$, $B = \sum [\mu_{\text{obs}}(z_i) - 5\log_{10} D_L]/\sigma_{\mu,i}^2$, and $C = \sum [\mu_{\text{obs}}(z_i) - 5\log_{10} D_L]^2/\sigma_{\mu,i}^2$. Thus the $\chi^2_a$ has a minimum value for $\mu_0 = B/A$ at $\chi^2_a$, which given by

$$\chi^2_a = C - B^2/A.$$  

(6)

Therefore we can minimize $\chi^2_a$ instead of minimizing $\chi^2_\mu$.

For the CMB observation from the WMAP5 results 66, the two shift parameters $R$ and $l_a$, together with the baryon density fraction of the Universe ($\omega_b = \Omega_b h^2$) can provide an efficient summary of CMB data to constrain cosmological models. The shift parameter $R$ can be expressed as

$$R = \Omega_{M0}^{1/2} \Omega_k^{-1/2} \sin \left[ \Omega_k^{1/2} \int_{0}^{z_{\text{rec}}} \frac{dz}{E(z)} \right],$$

(7)

where $z_{\text{rec}}$ is the redshift of recombination which is given by 74, $z_{\text{rec}} = 1048[1 + 0.00124(\omega_b^{0.738} + 1 + g_1(\Omega_{M0} h^2))^{-1}], g_1 = 0.0783(\omega_b^{0.238} + 1 + 3.95\omega_b^{0.706})^{-1}$ and $g_2 = 0.560(1 + 21.1\omega_b^{0.81})^{-1}$. The shift parameter $l_a$ can be expressed as

$$l_a = \frac{\Omega_k^{-1/2} \sin \left[ \Omega_k^{1/2} \int_{0}^{z_{\text{rec}}} \frac{dz}{E(z)} \right]/H_0}{r_s(z_{\text{rec}})}.$$  

(8)

where $r_s(z_{\text{rec}})$ is the comoving sound horizon at photodecoupling epoch,

$$r_s(z_{\text{rec}}) = \frac{1}{H_0} \int_{z_{\text{rec}}}^{\infty} \frac{c_s(z)}{E(z)} dz = a_{\text{rec}} \int_{\Omega_{M0}}^{\Omega_{M0} h^2} \frac{c_s}{\Omega_{M0} h^2 + a}^{-1/2} da,$$  

(9)

with the sound speed $c_s = (1/\sqrt{3})(1 + a(31500\omega_b(T_{\text{CMB}}/2.7 K)^{-4})^{-1/2}$ 44, and $T_{\text{CMB}} = 2.725 K$. From the WMAP5 measurement, the best-fit values of ($R$, $l_a$, $100\omega_b$) for a flat prior are 66

$$\vec{P}_{\text{CMB}} = \begin{pmatrix} \tilde{R} \\ \tilde{l}_a \\ 100\omega_b \end{pmatrix} = \begin{pmatrix} 1.710 \pm 0.019 \\ 302.10 \pm 0.86 \\ 2.2765 \pm 0.0596 \end{pmatrix}.$$  

(10)

FIG. 1: Hubble Diagram of 397 SNe Ia (red dots) and the 69 GRBs (circles) obtained using the interpolation methods. The 27 GRBs at $z < 1.4$ are obtained by linear interpolating from SNe Ia data (black circles), and the 42 GRBs at $z > 1.4$ (blue circles) are obtained with the five relations calibrated with the sample at $z \leq 1.4$ using the interpolation method. The curve is the theoretical distance modulus in the concordance model ($w = -1$, $\Omega_{M0} = 0.27$, $\Omega_{\Lambda} = 0.73$), and the vertical dotted line represents $z = 1.4$.}

tails of the calculation, see 17 and 45. We have plotted the Hubble diagram of 397 SNe Ia 65 which combine 90 CfA3 SNe Ia sample with the Union set 64, and the 69 GRBs obtained using the interpolation methods in Fig 1. The distance moduli of the 27 GRBs at $z \leq 1.4$ are obtained by using the linear interpolation method directly from the Union SNe data. The 42 GRB data at $z > 1.4$ are obtained by utilizing the five relations calibrated with the sample at $z \leq 1.4$ using the interpolation method.

Constraints from the SNe Ia data and the GRB data can be obtained by fitting the distance moduli $\mu(z)$. A distance modulus can be calculated as

$$\mu = 5 \log \frac{d_L}{\text{Mpc}} + 25 = 5 \log_{10} D_L - \mu_0,$$  

(2)

where $\mu_0 = 5 \log_{10} h + 42.38$, $h = H_0/(100 \text{km/s/Mpc})$, $H_0$ is the Hubble constant, and the luminosity distance $D_L$ can be calculated by

$$D_L \equiv H_0 d_L = (1 + z)\Omega_k^{-1/2} \sin \left[ \Omega_k^{1/2} \int_{0}^{z} \frac{dz'}{E(z')} \right],$$  

(3)

where $\Omega_k = 1 - \Omega_{M0} - \Omega_{\Lambda}$, $\sin(x)$ is sinh for $\Omega_k > 0$, sin for $\Omega_k < 0$, and $x$ for $\Omega_k = 0$; and $E(z)$ can be given by

$$E(z) = \frac{H_0}{H} = [\Omega_{M0}(1 + z)^3 + \Omega_{\Lambda}] \exp \left[ 3 \int_{0}^{z} \frac{1 + w(z')}{1 + z'} dz' \right] + \Omega_k (1 + z)^2]^{1/2},$$  

(4)

The 27 GRBs at $z < 1.4$ are obtained by linear interpolating from SNe Ia data (black circles), and the 42 GRBs at $z > 1.4$ (blue circles) are obtained with the five relations calibrated with the sample at $z \leq 1.4$ using the interpolation method.
The $\chi^2$ value of the CMB observation from WMAP5 can be expressed as

$$\chi^2_{\text{CMB}} = \Delta P^T_{\text{CMB}} C_{\text{CMB}}^{-1} \Delta P_{\text{CMB}},$$

(11)

where

$$\Delta P_{\text{CMB}} = \begin{pmatrix} R - 1.710 \\ l_a - 302.10 \\ 100\omega_b - 2.2765 \end{pmatrix},$$

(12)

and the corresponding inverse covariance matrix is

$$C_{\text{CMB}}^{-1} = \begin{pmatrix} 2809.73 & -0.133381 & 158.356 \\ -0.133381 & 2.21908 & 19.7195 \\ 158.356 & 19.7195 & 465.728 \end{pmatrix}.$$  

(13)

It is noted that we use the priors following 76, $\Omega_b = 0.022765/h^2$ and $h = 0.705$, when calculating the value of $\chi^2_{\text{CMB}}$.

For the BAO observation 67, from the SDSS DR7 galaxy sample 68, we use the measurement of $d_z$ at $z = 0.2$ and $z = 0.35$, where $d_z$ can be expressed as

$$d_z = \frac{r_s(z_d)}{D_V(z_{\text{BAO}})},$$

(14)

where $z_d$ is the drag epoch at which baryons were released from photons which is given by 77, $z_d = 1291(\Omega_{M0}h^2)^{0.251}(1 + b_1 \omega_b^{1/2})/[1 + 0.659(\Omega_{M0}h^2)^{0.828}]$, $b_1 = 0.313(\Omega_{M0}h^2)^{0.419}[1 + 0.607(\Omega_{M0}h^2)^{0.674}]^{-1}$, and $b_2 = 0.238(\Omega_{M0}h^2)^{0.223}$, and $D_V$ can be given by 67

$$D_V(z_{\text{BAO}}) = \frac{1}{H_0} \left[ \frac{z_{\text{BAO}}}{E(z_{\text{BAO}})} \left( \int_0^{z_{\text{BAO}}} \frac{dz}{E(z)} \right)^2 \right]^{1/3}. $$

(15)

From the SDSS DR7 measurement, the best-fit values are

$$P_{\text{BAO}} = \begin{pmatrix} 0.1905 \pm 0.0061 \\ 0.1907 \pm 0.0036 \end{pmatrix}. $$

(16)

The $\chi^2$ value of the BAO observation from SDSS DR7 can be expressed as

$$\chi^2_{\text{BAO}} = \Delta P^T_{\text{BAO}} C_{\text{BAO}}^{-1} \Delta P_{\text{BAO}},$$

(17)

where

$$\Delta P_{\text{BAO}} = \begin{pmatrix} d_{0.2} - 0.1905 \\ d_{0.35} - 0.1097 \end{pmatrix},$$

(18)

and the corresponding inverse covariance matrix is

$$C_{\text{BAO}}^{-1} = \begin{pmatrix} 30124 & -17227 \\ -17227 & 86977 \end{pmatrix}. $$

(19)

The baryon mass fraction in clusters of galaxies from the x-ray gas observation can be used to constrain cosmological parameters on the assumption that the gas mass fraction in clusters is a constant and thus independent of redshift. The baryon gas mass fraction $f_{\text{gas}}$ can be presented as

$$f_{\text{gas}}(z) = \lambda \left( \frac{d_{A}^{\text{SCDM}}(z)}{d_A(z)} \right)^{2/3},$$

(20)

where $\lambda = [b\Omega_b(2h)^{3/2}]/[(1 + \alpha)\Omega_{M0}]$, $a = 0.19\sqrt{h}$, $b$ is a bias factor motivated by gas dynamical simulations, and $d_A \equiv d_L/(1 + z)^2$ is the theoretical value of the angular diameter distance corresponding to cosmological models, $d_A^{\text{SCDM}}$ is the angular diameter distance corresponding to the standard cold dark matter (SCDM) universe ($\Omega_{M0} = 1$ for a flat universe). Here we adopt the usually used 26 observational $f_{\text{gas}}$ data 69 to constrain cosmological models. The $\chi^2$ value of cluster’s baryon gas mass fraction is

$$\chi^2_{\text{CFB}} = \sum_{i=1}^{N-26} \left[ \frac{f_{\text{gas}}(z_i) - f_{\text{gas}}(z_i)}{\sigma_{f_{\text{gas}},i}} \right]^2. $$

(21)

Following 71, 78, we treat $\lambda$ as a nuisance parameter to expand the $\chi^2_{\text{CFB}}$ to $\chi^2_{\text{CFB}}(\lambda) = A\lambda^2 - 2B\lambda + C$, with $A = \sum [f_{\text{gas},i}/\sigma_{f_{\text{gas}},i}]^2$, $B = \sum [f_{\text{gas},i}/\sigma_{f_{\text{gas}},i}]^2$, and $C = \sum [f_{\text{gas},i}/\sigma_{f_{\text{gas}},i}]^2$, where $f_{\text{gas},i} = [d_A^{\text{SCDM}}(z)/d_A(z)]^{2/3}$. Thus the $\chi^2_{\text{CFB}}$ has a minimum value at $\lambda_{\text{CBF}}$ which is given by

$$\lambda_{\text{CBF}} = C - B^2/A. $$

(22)

The Hubble parameter $H(z)$ can be derived from the derivative of redshift with respect to the cosmic time,

$$H(z) = -\frac{1}{1 + z} \frac{dz}{dt}. $$

(23)

From the Gemini Deep Deep Survey (GDDS) 79 observations of differential ages of passively evolving galaxies and other archival data 80, the $H(z)$ data at nine different redshifts (0.09 ≤ $z$ ≤ 1.75) have been obtained 70. Recently, using the BAO peak position as a standard ruler in the radial direction, $H = 83.2 \pm 2.1 \text{km/s/Mpc}$ at $z = 0.24$, and $H = 90.3 \pm 2.5 \text{km/s/Mpc}$ at $z = 0.43$ have been obtained 71, 72. To constrain cosmological models, the $\chi^2$ value of the 11 $H(z)$ data is

$$\chi^2_{H} = \sum_{i=1}^{N=11} \left[ \frac{H_{\text{obs}}(z_i) - H(z_i)}{\sigma_{H,i}} \right]^2. $$

(24)

The nuisance parameter $H_0$ is also marginalized following the procedure used in calculating $\chi^2_{\mu}$ and $\chi^2_{\text{CFB}}$ 73, 77, 78.

### III. CONSTRAINTS ON COSMOLOGICAL MODELS FROM THE JOINT DATA WITH GRBS

The distance moduli of the 42 GRBs at $z > 1.4$ are obtained by the five GRB luminosity relations that are
calibrated from the 27 GRBs at z < 1.4 with the interpolating method using directly the distance moduli of adjacent SNe Ia. In the interpolating procedure to obtain the distance moduli of the 27 GRBs at z < 1.4, we have used only 40 SNe Ia data points from the Union set of 307 SNe Ia. In order to combine GRB data into the joint observational data analysis to constrain the dark energy models, we exclude the 40 SNe points from the SNe Ia sample used to the joint constraints. Therefore, the remaining SNe Ia data points are completely independent of the distance moduli of the 42 GRBs at z > 1.4. Those excluded 40 SNe are listed in the Appendix. Since the reduced 357 SNe Ia, 42 GRBs, CMB, BAO, as well as CBF and H(z) are all effectively independent, we can combine the results by simply multiplying the likelihood functions. Thus the cosmological parameters can be fitted with the combined observable data by the minimum \( \chi^2 \) method. The total \( \chi^2 \) with the SNe + GRBs + CMB + BAO + CBF + H(z) dataset is

\[
\chi^2 = \hat{\chi}^2_{\mu, (SN+GRB)} + \chi^2_{CMB} + \chi^2_{BAO} + \hat{\chi}^2_{CBF} + \chi^2_H. \tag{25}
\]

The best-fit values for these parameters can be determined by minimizing the total \( \chi^2 \). For comparison, SNe + CMB + BAO + CBF + H(z) without GRBs have been used to show the contribution of GRBs to the joint cosmological constraints, and we also consider the joint constraints with 397 SNe + CMB + BAO + CBF + H(z). In addition, some different data set such as SNe + GRBs + CMB + BAO, SNe + GRBs + CMB, and SNe + GRBs + BAO have also been used in the cosmological constraints.

We use the Akaike information criterion (AIC) \[81\] and the Bayesian information criterion (BIC, the so-called Schwarz information criterion) \[82\] to select the best-fit models. Liddle examined the use of information criteria in the context of cosmological observations \[83\]. The AIC is defined as \[81\] AIC = \(-2 \ln Z_{\text{max}} + 2k\), where \( Z_{\text{max}} \) is the maximum likelihood, and \( k \) the number of parameters of the model. Models with too few parameters give a poor fit to the data and hence have a low log-likelihood, while those with too many are penalized by the second term. The best model is the model which minimizes the AIC \[83\]. The BIC can be defined as \[82\] BIC = \(-2 \ln Z_{\text{max}} + k \ln N\), where \( N \) is the number of data points used in the fit. Note that for Gaussian errors, \( \chi^2_{\text{BIC}} = \Delta \chi^2_{\text{min}} + \Delta k \ln N\), and the difference in BIC can be simplified to BIC = \( \Delta \chi^2_{\text{min}} + \Delta k \ln N\). The AIC gives results similar to the BIC approach, although the AIC is not strict enough on models with extra parameters for any reasonably sized data set (in \( N > 2\)). Therefore, for comparing cosmological models from the joint data set, we only compare \( \Delta \text{BIC} \) measured with respect to the best model. A difference in BIC of 2 is considered positive evidence against the model with the higher BIC, while a \( \Delta \text{BIC} \) of 6 is considered strong evidence \[83\].

The combined data sets are used to constrain cosmological parameters and dark energy. Here we consider three cosmological models, the \( \Lambda \)CDM model with dark energy \( EoS \ w = -1 \), the \( w \)CDM model with a constant \( EoS \), and the Chevallier-Polarski-Linder (CPL) model in which dark energy with a parameterization \( EoS \) as

\[
w(z) = w_0 + w_a \frac{(1 - a)}{1 + z}. \tag{26}\]

For the \( \Lambda \)CDM model, Eq. \[14\] becomes

\[
E(z) = \left[ \Omega_{M0}(1 + z)^3 + \Omega_{\Lambda} - \Omega_k(1 + z)^2 \right]^{1/2}, \tag{27}\]

where \( \Omega_{M0} + \Omega_{\Lambda} + \Omega_k = 1 \). For the \( w \)CDM model with a constant \( EoS \) for a flat universe prior,

\[
E(z) = \left[ \Omega_{M0}(1 + z)^3 + (1 - \Omega_{M0})(1 + z)^{3(1 + w_0)} \right]^{1/2} \tag{28}\]

and considering \( w(z) \) as CPL parameterization model for a flat universe prior, Eq. \[14\] becomes

\[
E(z) = \left[ \Omega_{M0}(1 + z)^3 + (1 - \Omega_{M0}) (1 + z)^3(1 + w_0 + w_a) e^{-3w_a \frac{z}{1 + z}} \right]^{1/2}. \tag{29}\]

In Fig. 2, we show the joint confidence regions in the \((\Omega_{M0}, \Omega_{\Lambda})\) plane for the \( \Lambda \)CDM model. With 357SNe + GRBs + CMB + BAO + CBF + H(z), the 1σ confidence region for \((\Omega_{M0}, \Omega_{\Lambda})\) of the \( \Lambda \)CDM model are \((0.275^{+0.016}_{-0.015}, 0.723^{+0.017}_{-0.016})\), with \( \chi^2_{\text{min}} = 494.476 \) for 438 degrees of freedom. For comparison, fitting results from the joint data without GRBs are also given in Fig. 2. With 357SNe + CMB + BAO + CBF + H(z), the best-fit values are \((\Omega_{M0}, \Omega_{\Lambda}) = (0.270^{+0.016}_{-0.015}, 0.730^{+0.017}_{-0.017})\) with \( \chi^2_{\text{min}} = 449.001 \) for 396 degrees of freedom. We present the best-fit value of \( \Omega_{M0}, \Omega_{\Lambda} \) with 1σ uncertainties, and \( \chi^2_{\text{min}}, \chi^2_{\text{min}}/\text{dof} \), as well as AIC, BIC for the \( \Lambda \)CDM model in Table 1.

From comparing to the joint constraints with GRBs and without GRBs, we can see that the contribution of GRBs to the joint cosmological constraints is a slight shift between the best-fit values near the line that represents a flat universe, towards a higher matter density Universe by \( \Delta \Omega_{M0} = 0.005 \), compared to the joint constraints without GRBs. It is noted that the obtained errors for these parameters with and without GRBs are essentially unchanged, because the number of SNe Ia data points dropped is similar to the number of GRBs when including GRBs in the joint fitting. This model has the lowest BIC compared to other models tested from the joint data \([357\text{SNe} + \text{CMB} + \text{BAO} + \text{CBF} + H(z)]\) with GRBs, so \( \Delta \text{BIC} \) are measured with respect to this model.

Figure 3 shows the joint confidence regions in the \((\Omega_{M0}, w)\) plane for the \( w \)CDM model with a constant
TABLE I: The best-fit value of $\Omega_{M0}$, $\Omega_\Lambda$, and $w$ with 1σ uncertainties, and $\chi^2_{\text{min}}$, $\chi^2_{\text{min}}$/dof, as well as AIC, BIC for the $\Lambda$CDM model and for the flat $w$CDM model with SNe+GRBs+CMB+BAO+CBF+$H(z)$ (with GRBs) and SNe+CMB+BAO+CBF+$H(z)$ (without GRBs).

|          | $\Lambda$CDM model (with GRBs) | $\Lambda$CDM model (without GRBs) | $w$CDM model (with GRBs) | $w$CDM model (without GRBs) |
|----------|--------------------------------|----------------------------------|--------------------------|-----------------------------|
| $\Omega_{M0}$ | $0.275^{+0.014}_{-0.015}$ | $0.270^{+0.014}_{-0.015}$ | $0.269^{+0.013}_{-0.014}$ | $0.267^{+0.013}_{-0.014}$ |
| $\Omega_\Lambda$ | $0.723^{+0.017}_{-0.016}$ | $0.730^{+0.017}_{-0.016}$ | $\Omega_\Lambda = 1 - \Omega_{M0}$ | $\Omega_\Lambda = 1 - \Omega_{M0}$ |
| $w$      | $w = -1$ | $w = -1$ | $w = -0.99^{+0.07}_{-0.07}$ | $w = -0.98^{+0.07}_{-0.07}$ |
| $\chi^2_{\text{min}}$ | 494.476 | 449.001 | 494.532 | 448.808 |
| $\chi^2_{\text{min}}$/dof | 1.129 | 1.134 | 1.129 | 1.133 |
| AIC      | 500.476 | 454.001 | 500.532 | 454.008 |
| BIC      | 512.736 | 466.960 | 512.792 | 466.767 |

FIG. 2: The joint confidence regions in the $(\Omega_{M0}, \Omega_\Lambda)$ plane for the $\Lambda$CDM model with SNe+GRBs+CMB+BAO+CBF+$H(z)$. The contours correspond to $1$-σ and $2$-σ confidence regions, and the red point is the best-fit value [SNe+GRBs+CMB+BAO+CBF+$H(z)$]. The results for the cases with and without GRBs are indicated by the solid lines and the dot-dashed lines, respectively. The blue line represents a flat universe $(\Omega_{M0} + \Omega_\Lambda = 1)$.

FIG. 3: The joint confidence regions in the $(\Omega_{M0}, w)$ plane for the dark energy model with a constant $w$ for a flat universe with SNe+GRBs+CMB+BAO+CBF+$H(z)$. The contours correspond to $1$-σ and $2$-σ confidence regions, and the red point is the best-fit value [SNe+GRBs+CMB+BAO+CBF+$H(z)$]. The results for the cases with and without GRBs are indicated by the solid lines and the dot-dashed lines, respectively.

For a flat universe. With 357SNe + GRBs + CMB + BAO + CBF + $H(z)$, the 1-σ confidence region for $(\Omega_{M0}, w)$ of the flat $w$CDM model are $(\Omega_M, w) = (0.260^{+0.014}_{-0.015}, -0.99^{+0.06}_{-0.07})$, with $\chi^2_{\text{min}} = 494.532$ for 438 degrees of freedom. For comparison, fitting results from the joint data without GRBs are also given in Fig. 3. With 357SNe + CMB + BAO + CBF + $H(z)$, the best-fit values are $(\Omega_{M0}, w) = (0.267^{+0.013}_{-0.014}, -0.98^{+0.06}_{-0.07})$, with $\chi^2_{\text{min}} = 448.808$ for 396 degrees of freedom. We present the best-fit value of $\Omega_{M0}$, $\Omega_\Lambda$ with 1σ uncertainties, and $\chi^2_{\text{min}}$, $\chi^2_{\text{min}}$/dof, as well as AIC, BIC for the flat $w$CDM model in Table 1.

Comparing to the joint constraints with GRBs and without GRBs, we can see that the contribution of GRBs to the joint cosmological constraints is a slight shift that adding the best-fit value of $\Omega_{M0}$ to 0.002, and subtracting the best-fit value of $w$ to $-0.01$ to enclose the $\Lambda$CDM model ($w = -1$). From the joint data (357SNe + CMB + BAO + CBF + $H(z)$) with GRBs for the flat $w$CDM model, we obtain $\Delta \text{BIC} = 0.056$ with respect to the $\Lambda$CDM model. This has the lowest BIC compared to other models tested from the joint data (357SNe + CMB + BAO + CBF + $H(z)$) without GRBs, so $\Delta \text{BIC}$ are measured with respect to this model. Therefore, for the $\Lambda$CDM from the joint data without GRBs, we obtain $\Delta \text{BIC} = 0.193$ with respect to the flat $w$CDM model.
TABLE II: The best-fit value of the corresponding \((w_0, w_a)\) with 1σ uncertainties and the best-fit value of \(\Omega_{M0}\), and \(\chi^2_{\text{min}}, \chi^2_{\text{min}}/\text{dof}\), as well as AIC, BIC for the CPL model in a flat universe, with 357SNe+GRBs+others(CMB+BAO+CBF+H), 357SNe+others (without GRBs), 397SNe+others, and with 357SNe+GRBs+C(CMB)+B(BAO), 357SNe+GRBs+CMB, and 357SNe+GRBs+BAO.

|                | 357SNe+GRBs+others | 357SNe+others | 397SNe+others | 357SNe+GRBs+C+B | 357SNe+GRBs+C | 357SNe+GRBs+BAO |

| \(\Omega_{M0}\) | 0.269               | 0.269         | 0.269         | 0.269          | 0.269          | 0.263          |
| \(\chi^2_{\text{min}}\) | 494.530             | 448.726       | 504.496       | 458.857        | 455.544        | 452.839        |
| \(\chi^2_{\text{min}}/\text{dof}\) | 1.132              | 1.136         | 1.160         | 1.147          | 1.145          | 1.138          |
| AIC            | 502.530             | 456.726       | 512.496       | 464.857        | 463.554        | 460.839        |
| BIC            | 518.877             | 472.672       | 528.825       | 482.853        | 479.530        | 476.815        |

FIG. 4: The joint confidence regions in the \((w_0, w_a)\) plane for the CPL model in a flat universe with 357SNe+GRBs+others(CMB+BAO+CBF+H), 357SNe+others (without GRBs), and 397SNe+others. The contours correspond to 1-σ and 2-σ confidence regions, and the red point is the best-fit value (357SNe+GRBs+others(CMB+BAO+CBF+H)). The solid lines represent the results of 357SNe+GRBs+others(CMB+BAO+CBF+H). The dash-dotted lines represent the results of 357SNe+others (without GRBs). The dashed lines represent the results of 397SNe+others.

FIG. 5: The joint confidence regions in the \((w_0, w_a)\) plane for the CPL model in a flat universe with 357SNe+GRBs+CMB+BAO, 357SNe+GRBs+CMB and 357SNe+GRBs+BAO. The contours correspond to 1-σ and 2-σ confidence regions, and the red point is the best-fit value (357SNe+GRBs+CMB+BAO). The solid lines represent the results of 357SNe+GRBs+CMB+BAO. The dashed lines represent the results of 357SNe+GRBs+CMB. The dash-dotted lines represent the results of 357SNe+GRBs+BAO. The straight line near the top is given by \(w_a + w_0 = 0\).

For the flat CPL model, we find that the best-fit parameters with 357SNe + GRBs + CMB + BAO + CBF + \(H(z)\) are \((w_0, w_a, \Omega_{M0}) = (-0.98, -0.02, 0.269)\), with \(\chi^2_{\text{min}} = 494.53\) for 437 degrees of freedom. Figure 4 shows the joint confidence regions in the \((w_0, w_a)\) plane, while fixing \(\Omega_{M0} = 0.269\). For comparison, fitting results from the joint data without GRBs are also given in Fig. 4. With 357SNe + CMB + BAO + CBF + \(H(z)\), the best-fit values are \((w_0, w_a, \Omega_{M0}) = (-0.95, -0.14, 0.269)\), with \(\chi^2_{\text{min}} = 448.726/395\). Fitting results with 397SNe + CMB + BAO + CBF + \(H(z)\) are also given in Fig. 4 and the best-fit values are \((w_0, w_a, \Omega_{M0}) = (-0.99, 0.00, 0.269)\), with \(\chi^2_{\text{min}} = 504.496/435\). In addition, fitting results from the joint data with 357SNe + GRBs + CMB + BAO, 357SNe + GRBs + BAO, and 357SNe + GRBs + CMB are given in Fig 5. We note that the contours for 357SNe + GRBs + BAO are sharply cutoff at the top, near the line given by \(w_0 + w_a = 0\), as shown in the figure. This is due to \(w(z) ≫ 1\) < 0 or
\( w_0 + w_a < 0 \) in the CPL parameterization (i.e., the early universe is matter dominated) implicitly required by the BAO data; this was also noted by Kowalski et al.\cite{61}. We present the best-fit value of the derived \( w_0, w_a \) with 1\( \sigma \) uncertainties, and the best-fit value of \( \Omega_{M0}, \chi^2_{\text{min}}, \chi^2_{\text{min}}/\text{dof} \), as well as AIC, BIC with differently combined data set in Table 2.

Comparing to the joint constraints with GRBs and without GRBs, we can see that the contribution of GRBs to the joint cosmological constraints is a slight shift in the \((w_0, w_a)\) plane to enclose the \( \Lambda \)CDM model \((w_0 = -1, w_a = 0)\). From the joint data [357SNe + CMB + BAO + CBF + \( H(z) \)] with GRBs for the flat CPL model, we obtain \( \Delta \text{BIC} = 6.141 \) with respect to the \( \Lambda \)CDM model, indicating a strong preference for the \( \Lambda \)CDM model; while from the joint data without the iterative procedure and adopt results from Ref.\cite{55}, studied by an iterative method\cite{53, 54}. Here we follow the iterative procedure and adopt results from Ref.\cite{55},

\[
\ln f(z)_n = \ln f(z)_{n-1} + N(z) \sum_i \left[ \ln f^{\text{obs}}(z_i) - \ln f(z)_n \right] N_i(z)
\]

where \( f(z) \equiv D_L(z)/h, f(z)_n \) represents the smoothed luminosity distance at any redshift \( z \) after the \( n \)th iteration, \( f(z)_0 \) denotes a guess background model, and \( f^{\text{obs}}(z_i) \) is the observed one from the SNe Ia data, as well as the normalization parameter \( N(z)^{-1} = \sum_i N_i(z), N_i(z) = \exp \left[ -\left( \ln^2 \left( (1+z)/(1+z_i) \right) / \left( 2 \Delta^2 \right) \right) \right] \). It has been shown that the results are not sensitive to the chosen value of \( \Delta \) and the assumed initial guess model. Here we use a \( w \)CDM model with \( w = -0.9 \) and \( \Omega_{M0} = 0.28 \) as the guessed background model and we choose \( \Delta = 0.6 \).

The best iterative result is obtained by minimizing

\[
\chi_n^2 = \sum_i \left( \mu(z)_i - \mu^{\text{obs}}(z_i) \right)^2 / \sigma^{2}_{\mu^{\text{obs}}},
\]

Once the \( \chi_n^2 \) reaches its minimum value, we stop the iterative process and get the best result \((\chi^2_{\text{min}}, \Delta \text{BIC})\), with the 1-\( \sigma \) uncertainties corresponding to \( \chi^2 = \chi^2_{\text{min}} + 1 \). Figure 6 shows the computed \( \chi_n^2 \) for the reconstructed results at each iteration for the SNe Ia and GRB data. We find that when at \( n = 16 \) a minimum value of \( \chi_n^2 \) is obtained.

![FIG. 6: Computed \( \chi_n^2 \) for the reconstructed results at each iteration for the SNe Ia and GRB data. The minimum value of \( \chi_n^2 \) is obtained at \( n = 16 \), and the 1-\( \sigma \) uncertainties of reconstructed results can be obtained at \( n = 9, 41 \), corresponding to \( \Delta \chi^2 = 1 \), respectively.](image)

IV. RECONSTRUCTING THE ACCELERATION HISTORY OF THE UNIVERSE

Following a well-known procedure in the analysis of large scale structure, Shafieloo et al used a Gaussian smoothing function rather than the top hat smoothing function to smooth the noise of the SNe Ia data directly\cite{53, 54}. In order to obtain important information on interesting cosmological parameters expeditiously, when doing the Gaussian smoothing, \( \ln d_L(z) \), rather than the luminosity distance \( d_L(z) \) or distance modulus \( \mu(z) \), is studied by an iterative method\cite{53, 54}. Here we follow the iterative procedure and adopt results from Ref.\cite{55},

\[
\frac{d}{dz} \left[ \frac{100 f(z)}{(1+z)} \right]^{-1},
\]

By using the iterative approach to reconstruct the luminosity distance at any redshift in the redshift range of SNe Ia, we have calibrated GRB luminosity relations in a model independent manner\cite{52}. Here we reconstruct the Hubble parameter \( H(z) \), the deceleration parameter \( q(z) \), and the EoS of dark energy \( w(z) \) from the best iterative result of \( f(z) \) with the distance moduli of SNe Ia and GRBs obtained by the interpolating method. The Hubble parameter can be given by differentiating the smoothed luminosity distance \cite{55},

\[
H(z) = \left[ \frac{d}{dz} \left[ \frac{100 f(z)}{(1+z)} \right]^{-1} \right],
\]

where \( f(z) \equiv D_L(z)/h, f(z)_n \) represents the smoothed luminosity distance at any redshift \( z \) after the \( n \)th iteration, \( f(z)_0 \) denotes a guess background model, and \( f^{\text{obs}}(z_i) \) is the observed one from the SNe Ia data, as well as the normalization parameter \( N(z)^{-1} = \sum_i N_i(z), N_i(z) = \exp \left[ -\left( \ln^2 \left( (1+z)/(1+z_i) \right) / \left( 2 \Delta^2 \right) \right) \right] \). It has been shown that the results are not sensitive to the chosen value of \( \Delta \) and the assumed initial guess model. Here we use a \( w \)CDM model with \( w = -0.9 \) and \( \Omega_{M0} = 0.28 \) as the guessed background model and we choose \( \Delta = 0.6 \).

The best iterative result is obtained by minimizing

\[
\chi_n^2 = \sum_i \left( \mu(z)_i - \mu^{\text{obs}}(z_i) \right)^2 / \sigma^{2}_{\mu^{\text{obs}}},
\]

Once the \( \chi_n^2 \) reaches its minimum value, we stop the iterative process and get the best result \((\chi^2_{\text{min}}, \Delta \text{BIC})\), with the 1-\( \sigma \) uncertainties corresponding to \( \chi^2 = \chi^2_{\text{min}} + 1 \). Figure 6 shows the computed \( \chi_n^2 \) for the reconstructed results at each iteration for the SNe Ia and GRB data. We find that when at \( n = 16 \) a minimum value of \( \chi_n^2 \) is obtained.

![FIG. 6: Computed \( \chi_n^2 \) for the reconstructed results at each iteration for the SNe Ia and GRB data. The minimum value of \( \chi_n^2 \) is obtained at \( n = 16 \), and the 1-\( \sigma \) uncertainties of reconstructed results can be obtained at \( n = 9, 41 \), corresponding to \( \Delta \chi^2 = 1 \), respectively.](image)
which contains the information on $H_0$. Then the deceleration parameter $q(z)$ of the expanding universe and the EoS of dark energy can be obtained [55],

$$q(z) = (1 + z) \frac{H'(z)}{H(z)} - 1,$$

(33)

$$w(z) = \frac{-1 + \frac{2}{3}(1 + z) \cdot H'/H}{1 - (1 + z)^{3\Omega_{m0}H^2_0}/H^2},$$

(34)

where the prime ($'$) denotes the derivative with respect to $z$.

**FIG. 7:** The reconstructed $H(z)$ with the 1-σ uncertainties. The red line indicates the best-fit value of the reconstructed $H(z)$ which is obtained at $n = 16$ and the blue lines represent the fit values of the reconstructed $H(z)$ within 1-σ uncertainties at $n = 9, 14, 19, 24, 29, 34, 39, 41$. The dashed line is the theoretical values of the ΛCDM model.

The reconstructed $H(z)$ with the 1-σ uncertainties are shown in Fig. 7. For comparison, the theoretical values of the ΛCDM model are also shown in Fig. 7. We can find that there is a deviation between the reconstructed $H(z)$ and the theoretical values of the ΛCDM model with the 1-σ uncertainty at $1 \lesssim z \lesssim 4$, where the GRB data clearly dominate. The reconstructed $q(z)$ with the 1-σ uncertainties are shown in Fig. 8. We can find that the transition redshift at which the expansion of the universe from deceleration ($q(z) > 0$) to acceleration ($q(z) < 0$) is $z_T = 0.38^{+0.03}_{-0.03}$, at relatively low redshifts, where the SNe Ia data dominate, which is slightly later but more stringent than that reconstructed from the ESSENCE supernova data ($z \sim 0.55 – 0.73$) [55]. However, there is another transition redshift at which the expansion of the universe from acceleration to deceleration, $\tilde{z}_T \simeq 3$, at high redshift where GRB data dominate. However, this transition redshift has large 1-σ uncertainties ($2.4 < \tilde{z}_T < 3.5$) compared to the former one $0.35 < z_T < 0.41$, similar to that reconstructed from the GRB data using the Amati relation [49]. The reconstructed EoS of dark energy $w(z)$ with the 1-σ uncertainties are shown in Fig. 9. We can find that there is a singular point at $z \lesssim 5$ from the reconstructed $w(z)$. This phenomenon has been known to happen and just displays the fact that $w(z)$ [Eq 34] is nothing more than an effective parameter that (in this case) fails to describe the system correctly. On the other hand, the singular point may be caused by the absence of data in the Hubble diagram at $5 \lesssim z \lesssim 6$, i.e., between the GRB data at $z < 5$ and the only two GRBs at $z > 6$ as shown in Fig. 1.

![Image](image.png)

**FIG. 8:** The reconstructed $q(z)$ with the 1-σ uncertainties. The red line indicates the best-fit value of the reconstructed $q(z)$ which is obtained at $n = 16$ and the blue lines represent the fit values of the reconstructed $q(z)$ within 1-σ uncertainties at $n = 9, 14, 19, 24, 29, 34, 39, 41$. The dashed line is the theoretical values of the ΛCDM model.

From Fig. 7 - 9, we can read that $H_0 = 66$ km s$^{-1}$ Mpc$^{-1}$, $q_0 = -0.82$ and $w_0 = -1.19$. We can also find some features in the reconstructed $H(z)$, $q(z)$, and $w(z)$, which seem to favor the oscillating models [85–87]. However, it is noted that because the available data of GRBs at high redshift are still quite rare now, and their statistical scatters are relatively large compared to that of SNe Ia, these tentative results might be artifacts, but nevertheless deserve further investigations.
FIG. 9: The reconstructed EoS of dark energy $w(z)$ with the 1-σ uncertainties. The red line indicates the best-fit value of the reconstructed $w(z)$ which is obtained at $n = 16$ and the blue lines represent 1-σ uncertainties at $n = 9, 41$. The dashed line is the theoretical values of the ΛCDM model.

V. SUMMARY AND DISCUSSION

Because of the lack of enough low red-shift GRBs to calibrate the luminosity relation, GRBs could not be used reliably and extensively in cosmology until recently. In our previous paper, we have proposed a new method to calibrate GRB luminosity relations in a completely cosmology-independent manner to avoid the well-known circularity problem [45].

In this work, with the recent GRB data at high redshift whose distance moduli are calibrated with the interpolating method [45] from the Union set of 307 SNe Ia [64], as well as the Constitution set of SNe Ia [65], the CMB observation from the WMAP5 result ($R, l_a, \Omega_b h^2$) [66], the BAO observation from the spectroscopic SDSS DR7 galaxy sample ($d_{0.2}, d_{0.35}$) [68], the x-ray baryon mass fraction in clusters of galaxies [69], and the observational $H(z)$ data [71, 77], we find that the ΛCDM model is consistent with the joint data in 1-σ confidence region; this confirms the conclusion of many previous investigations. We also find that the current GRB data are substantially less accurate than the SNe Ia data, if each data set is used alone, consistent with previous investigations.

The new results and insights we have obtained in this work are briefly summarized as follows:

1. In order to combine GRB data into the joint observational data analysis to constrain cosmological models, we provide a simple method to avoid any correlation between the SNe Ia data and the GRB data; in this method those SNe Ia data points used for calibrating the GRB data are not used.

2. Comparing to the joint constraints with GRBs and without GRBs, we find that the contribution of GRBs to the joint cosmological constraints is a slight shift in the confidence regions of cosmological parameters to better enclose the ΛCDM model.

3. Finally we reconstruct the Hubble parameter $H(z)$, the deceleration parameter $q(z)$, and the EoS of dark energy $w(z)$ of the acceleration Universe up to $z > 6$ with the distance moduli of the Constitution set of SNe and GRBs and find some features that seem to favor oscillatory cosmology models; however further investigations are needed to better understand the situation.

For considering the use of GRBs for cosmology, the gravitational lensing effect may need to be considered [88]. However Schaefer found that the gravitational biases of GRBs are small [17]. Recently, some possible observational selection bias [88, 92] and evolution effects [93, 94] in GRB relations have also been discussed. However, Ghirlanda et al. confirmed the spectral-energy relations of GRBs observed by Swift [97]. Moreover, it is found that instrumental selection effects do not dominate for the Amati relation [98] and for the $E_{peak} - L$ relation [99], as well as no strong evolution with redshift of the Amati relation can be found [98, 100]. Nevertheless, for considering GRBs as standard candles to constrain cosmology, further examinations of possible selection bias and evolution effects should be required in a larger GRB sample.

Different dark energy models may have very different Hubble diagrams at high redshifts [17]. Therefore, the best plan to investigate the property of dark energy is measuring the dark energy over a wide range of redshifts. GRBs can extend the Hubble diagram to much higher redshifts beyond SNe Ia data [17]. It is worth noticing that GRBs are important potential probes for cosmic history up to $z > 6$. However, the contribution of GRBs to the cosmological constraints would not be sufficiently significant at present, due to the large statistical scatters of the relations and the small dataset of GRBs. As discussed in [17], GRBs are almost immune to dust extinction, whereas in the case of SNe Ia observations, there is extinction from the interstellar medium when optical photons propagate towards us. On the other hand, SNe Ia are substantially more accurate standard candles than GRBs, which will lead to tight constraints on cosmological parameters; whereas a single GRB at high redshift will provide more information than a single maximal redshift SNe Ia [17]. Through Monte Carlo simulations, future prospect of probing dark energy parameters with a larger sample of GRBs has been investigated [22, 51, 59]. It has been found that cosmological constraints would improve substantially with more simulated GRBs expected by future observations. Recently, Xiao and Schaefer have compiled 107 long GRBs with their spectroscopic/photometric redshifts measured [101], observed by BATSE, Konus, HETE, and Swift. Along with more and more GRBs observed from Fermi Gamma-ray Space Telescope (formerly known as GLAST) with much
smaller scatters, and its combination with the increasing Swift data, GRBs could be used as an additional choice to set tighter constraints on cosmological parameters of dark energy models.

Appendix A: The SN Ia data used in the interpolating procedure for calibrating the GRB data

Here we list the 40 SNe Ia data points that have been used to obtain the distance moduli of the 27 GRBs at $z < 1.4$ in the interpolating procedure, and have consequently been excluded from the SNe Ia sample used to the joint constraints.

Acknowledgments

We thank the anonymous referee for comments and suggestions.
