Abstract

The fusion probability in “hot” fusion reactions leading to the synthesis of super-heavy nuclei is investigated systematically. The quasi-fission barrier influences the formation of the super-heavy nucleus around the “island of stability” in addition to the shell correction. Based on the quasi-fission barrier height obtained with the Skyrme energy-density functional, we propose an analytical expression for the description of the fusion probability, with which the measured evaporation residual cross sections can be reproduced acceptably well. Simultaneously, some special fusion reactions for synthesizing new elements 119 and 120 are studied. The predicted evaporation residual cross sections for $^{50}$Ti+$^{249}$Bk are $\sim 10 – 150$ fb at energies around the entrance-channel Coulomb barrier. For the fusion reactions synthesizing element 120 with projectiles $^{54}$Cr and $^{58}$Fe, the cross sections fall to a few femtobarns which seems beyond the limit of the available facilities.

*Electronic address: tianjunlong@gmail.com
Synthesis of super-heavy nuclei (SHN) through fusion reactions is a field of very intense studies in the recent decades [1–17]. Up to now, the superheavy elements \( Z = 107 \sim 118 \) have already been synthesized [1–6] through “cold” fusion reactions that use lead or bismuth targets with appropriate projectiles following the emission of one or two neutrons from a “cold” compound system, or “hot” fusion reactions that use actinide targets from uranium to californium with beams of \(^{48}\text{Ca}\) following the evaporation of 3 to 5 neutrons from a “hot” system. The reaction \(^{50}\text{Ti}^+ + ^{249}\text{Cf}\) for producing element 120 is currently being studied in GSI without a result up to now [18]. Besides the experiments, both the structure of SHN and the mechanism of fusion reactions are also being intensively investigated theoretically. On one hand, the precise calculation of the masses and the shell correction of SHN which plays a key role in determining the fission barrier and the center of the “island of stability” for SHN, is of great importance. Recently, Liu et al. [19] proposed an improved macroscopic-microscopic mass model (also called Weizsäcker-Skyrme mass model) with an rms error of 336 keV with respect to the 2149 known masses and 248 keV to the measured \( \alpha \)-decay energies of 46 super-heavy nuclei, with which they found that the SHN with the largest shell corrections are located around \( Z = 116 \sim 120 \) and \( N = 178 \) rather than at \( N = 184 \). It is found that the difference of the calculated evaporation residual cross sections for reactions leading to element 120 reaches two orders of magnitude by adopting two different mass tables for SHN [15]. It is therefore interesting to investigate the production cross sections of SHN in fusion reactions by using the Weizsäcker-Skyrme mass model.

On the other hand, the fusion probability of heavy nuclei and super-heavy nuclei should be systematically investigated for testing the models and for giving reliable predictions of fusion reactions leading to new super-heavy elements. Theoretical support for these very time-consuming and extremely-expensive experiments is vital for choosing the optimum target-projectile-energy combinations and for the estimation of cross sections. In the practical calculation of the evaporation residue cross section, the reaction process leading to the synthesis of SHN can be divided into three steps. Firstly, the projectile is captured by the target and a dinuclear system is formed which then evolves into the compound nucleus, and finally, the compound nucleus loses its excitation energy mainly by the emission of particles and \( \gamma \)-rays and goes to its ground state. The simplified version of the evaporation residue
The cross section is given by [14, 21]

$$\sigma_{ER}(E_{c.m.}) = \sigma_{\text{cap}}(E_{c.m.}) P_{\text{CN}}(E_{c.m.}) W_{\text{sur}}(E_{c.m.}).$$  \hspace{1cm} (1)$$

Here, $\sigma_{\text{cap}}$, $P_{\text{CN}}$ and $W_{\text{sur}}$ denote the capture cross section of the colliding nuclei overcoming the Coulomb barrier, the probability of the compound nucleus formation (i.e., the fusion probability) after the capture and the survival probability of the excited compound nucleus, respectively. The most unclear part may be the value of $P_{\text{CN}}$ which is usually calculated by different models for the dynamics [10, 12, 13] based on the potential energy surface of the reaction system or by empirical formulas [12, 20]. In Refs.[21–24], the methods for the calculation of $\sigma_{\text{cap}}$ and $W_{\text{sur}}$ are well established in general, with the Skyrme energy-density functional and an empirical barrier distribution for describing the capture cross sections and with the HIVAP code [25–27] for describing the survival probability of the compound nuclei. Based on the previous work [21], the fusion probability in reactions leading to SHN will be further systematically investigated in this work by applying the Weizsäcker-Skyrme mass model for describing the masses of SHN.

We first investigate the relation between the fission barrier height, the quasi-fission barrier height and the evaporation residual cross sections for some fusion reactions leading to SHN. The fission barrier height $B_f$ of a nucleus can be approximately estimated by the shell correction $\Delta E^{\text{shell}}$ and the macroscopic fission barrier $B_f^{\text{Mac}}$ of the nucleus [21], i.e.,

$$B_f \approx B_f^{\text{Mac}} + \Delta E^{\text{shell}} = B_f^{\text{Mac}} + (E_{\text{exp}} - E_{\text{LD}}).$$  \hspace{1cm} (2)$$

Here, $E_{\text{exp}}$ and $E_{\text{LD}}$ denote the measured binding energy and the liquid drop energy of the nucleus (positive values), respectively. Fig. 1(a) shows the measured evaporation residual cross sections for some $^{48}$Ca-induced reactions as a function of the charge number of the compound nucleus. The data are extracted from a figure in Oganessian’s talk [28], and these data are also shown in Ref.[29]. At $Z \approx 114 – 116$ there exists a peak for the cross sections, which seems to be an evidence of the center of the “island of stability” for super-heavy nuclei being located at $Z \leq 120$. Fig. 1(b) shows the sum of the fission barrier height and the quasi-fission barrier height for some fusion reactions leading to the synthesis of SHN. Here, the quasi-fission barrier height $B_{qf}$ is defined as the depth of the capture pocket in the entrance-channel potential (see the sub-figure in Fig. 2), which is calculated by using the Skyrme energy-density functional [30] together with the extended Thomas-Fermi approximation including all terms up to the second order in the spatial derivatives.
FIG. 1: (Color online) (a) Measured evaporation residual cross-sections of some $^{48}$Ca-induced reactions. The data are extracted from a figure in Oganessian’s talk [28]. (b) Sum of fission barrier height and quasi-fission barrier height for some fusion reactions leading to the synthesis of super-heavy nuclei as a function of the charge number of SHN. The dot-dashed curves are to guide the eyes. The vertical dashed line shows the position of $Z = 118$ and the squares on its right side denote the results for $^{50}$Ti+$^{249}$Bk and $^{50}$Ti+$^{249}$Cf. (3) Quasi-fission barrier height for these reactions. The open and filled circles denote the results for “cold” and “hot” fusion reactions, respectively.

(ETF2) as mentioned in [22]. For calculating the shell corrections in Fig. 1(b), the obtained binding energies and the corresponding liquid-drop energies $E_{LD}$ of the SHN in Ref.[19] are adopted. One sees that the dependence of $B_f + B_{qf}$ on the charge number is very similar
to the dependence of the evaporation residual cross sections on the charge number. The peak around $Z \approx 116$ in Fig.1(b) comes from the contributions of the shell correction and the quasi-fission barrier height. The quasi-fission barrier height decreases linearly with the charge number of the compound nucleus [see Fig. 1(c)], and the largest shell corrections are located around $Z = 116 \sim 120$ according to the Weizsäcker-Skyrme mass model. The sum of the shell correction $\Delta E_{\text{Shell}}$ and the quasi-fission barrier height results in the peak at $Z \approx 114 \sim 116$ of the evaporation residual cross sections. Fig. 1 indicates that the quasi-fission barrier influences the formation of the super-heavy nuclei around the known “island of stability” in addition to the shell correction. For very asymmetric fusion reactions leading to intermediate and heavy nuclei rather than the SHN, the quasi-fission barrier height is relatively high. With the increase of the charge number of the projectile or target nuclei in the fusion reactions leading to the synthesis of SHN, the quasi-fission barrier height decreases gradually.

It is known that the fission barrier height strongly influences the survival probability of super-heavy nuclei. In addition, one expects that the fusion probability increases with increasing of the quasi-fission barrier height and the incident energies in the reactions leading to the SHN [16]. To consider the contribution of the quasi-fission barrier, we propose an analytical formula for description of the fusion probability $P_{\text{CN}}$:

$$P_{\text{CN}}(E^*) = \frac{1}{C} \exp\left(3B_{\text{qf}} + 0.3E^*\right).$$

(3)

Where, $E^* = E_{\text{c.m.}} + Q$ denotes the excitation energy of the compound nucleus (in MeV). In addition, we introduce a truncation for the value of $P_{\text{CN}}$, i.e. $P_{\text{CN}}$ should not be larger than 1. The parameters in Eq. (3) with $C = \exp(50|\eta|)$ are determined by fitting the measured evaporation residual cross sections of $^{48}\text{Ca}+^{248}\text{Cm}$ and $^{48}\text{Ca}+^{249}\text{Cf}$. Here, $\eta = (A_1 - A_2)/(A_1 + A_2)$ denotes the mass asymmetry of the reaction system. For $^{48}\text{Ca}$-induced “hot” fusion reactions leading to SHN, $|\eta| \approx 0.67$. The calculation for the capture cross sections and the survival probability of compound nucleus are the same as those in Ref.[21] except that the masses of unknown nuclei are given by the Weizsäcker-Skyrme mass model [19] rather than by the finite range droplet model (FRDM) [31]. Fig. 2 shows the fusion probability in reactions leading to SHN as a function of the quasi-fission barrier height $B_{\text{qf}}$. The solid squares denote the results for “hot” fusion reactions with an excitation energy of $E^* = 35$ MeV. The open and filled circles denote the calculated results for “cold”
FIG. 2: (Color online) Fusion probability in reactions leading to super-heavy nuclei as a function of quasi-fission barrier height. The open circles and the filled circles denote the calculated results for “cold” fusion reactions with excitation energy \( E^* = 15 \) MeV and the extracted fusion probability in Ref.[14] for the same reactions, respectively. The solid squares denote the results for “hot” fusion reactions with \( E^* = 35 \) MeV. Sub-figure: Calculated entrance-channel potential for \(^{48}\text{Ca}+^{208}\text{Pb}\). \( B_{qf} \) and \( B_0 \) denote the depth of the pocket and the height of the Coulomb barrier, respectively.

Fusion reactions with \( E^* = 15 \) MeV and the extracted fusion probability in Ref.[14] for the same reactions, respectively. Here the parameter \( C \) is slightly different for the “cold” fusion reactions which will be discussed later. The corresponding evaporation residual cross sections for these reactions will be shown in Fig. 3, Fig. 4 and Fig. 5. The shades show the estimated uncertainty of the calculated fusion probability with Eq.(3). With decreasing of the quasi-fission barrier height, the fusion probability decreases exponentially. The obtained fusion probabilities in this work and those in Ref.[14] are very close to each other for the “cold” fusion reactions. In addition, it seems that the obtained fusion probability for the “cold” fusion reaction and that for the “hot” fusion reaction are comparable when their quasi-fission barrier heights are close to each other.
FIG. 3: (Color online) Evaporation residual cross sections for some “hot” fusion reactions. The data are taken from Refs.[6, 32]. The dashed and solid lines denote the entrance-channel Coulomb barrier height $B_0$ under the sudden approximation for the densities and the mean barrier height $B_m$, respectively. The green and blue curves denote the corresponding calculation results for the 3n and 4n channels with $C = \exp(50|\eta|)$, respectively. The shades show the uncertainty of the calculated $\sigma_{ER}$ for the 4n channel [except (h) in which the shades are for the 3n channel].

Fig. 3 shows the evaporation residual cross sections for some “hot” fusion reactions. The open triangles and solid circles denote the experimental data for the 3n and 4n channels, respectively. The green and blue curves denote the corresponding calculated results. The dashed and solid lines denote the entrance-channel Coulomb barrier height $B_0$ from the Skyrme energy-density functional and the mean barrier height $B_m \approx 0.956B_0$ according to the empirical barrier distribution [22], respectively. The shades show the corresponding uncertainty of this approach due to the systematic errors in the calculation of $\sigma_{cap}$, $W_{sur}$ and $P_{CN}$, which is about a factor of 4.4 for $\sigma_{ER}$ at energies above the mean barrier height $B_m$. The estimated uncertainties [21] for $\sigma_{cap}$, $W_{sur}$ and $P_{CN}$ are about factors of 1.18, 1.85 and 2.0 at $E_{c.m.} > B_m$, respectively. We would like to state that the parameters in Eq.(3)
FIG. 4: (Color online) The same as Fig. 3, but for some “cold” fusion reactions. Here, we adopt $C = \exp(47|\eta|)$ in the calculations. The data are taken from Ref. [32]. The shades show the uncertainty of the calculated $\sigma_{ER}$ for the 1n channel.

are determined just by reactions $^{48}\text{Ca} + ^{248}\text{Cm}$ and $^{48}\text{Ca} + ^{249}\text{Cf}$. With the same parameters we find that the experimental data of other “hot” fusion reactions can also be reproduced reasonably well.

To further test the model, the “cold” fusion reactions leading to SHN are also investigated systematically. In Fig. 4, we show the evaporation residual cross sections for some “cold” fusion reactions. The solid squares and open circles denote the experimental data for the 1n and 2n channels, respectively. The blue and green solid curves denote the corresponding calculated results. Here, we slightly change the parameter $C = \exp(47|\eta|)$ considering the differences between the “cold” fusion reactions and the “hot” fusion reactions. Carrying out the same calculations as for the “hot” fusion reactions, we can roughly reproduce the measured evaporation residual cross sections for the “cold” fusion reactions. The larger uncertainty for the “cold” fusion reactions at sub-barrier energies is due to the factor $g$ in the barrier distribution function for calculating the capture cross sections [21].
FIG. 5: (Color online) The same as Fig. 3 but for fusion reactions leading to the synthesis of elements 119 and 120 (in femtobarn). The green solid and blue dot-dashed curves denote the predicted results for the 3n and 4n channels with $C = \exp(50|\eta|)$, respectively.

TABLE I: The predicted optimal evaporation residual cross section (in femtobarn) for four reactions leading to elements 119 and 120.

The above calculations give us great confidence for investigating the evaporation residual cross sections of fusion reactions leading to the synthesis of new elements. Fig. 5 shows the predicted evaporation residual cross sections for the reactions $^{50}$Ti+$^{249}$Bk, $^{50}$Ti+$^{249}$Cf, $^{54}$Cr+$^{248}$Cm and $^{58}$Fe+$^{244}$Pu leading to the synthesis of the elements 119 and 120. The solid and dashed curves denote the results for the 3n and 4n channels, respectively. For the reaction $^{50}$Ti+$^{249}$ Bk $\rightarrow$ $^{295}$ 119 + 4n, the obtained evaporation residual cross sections $\sigma_{ER}$
are about $10 \sim 150$ femtobarn at incident energies around the entrance-channel Coulomb barrier $B_0$. For the reactions synthesizing element 120, the calculated $\sigma_{\text{ER}}$ are smaller than those for element 119, and the $\sigma_{\text{ER}}$ falls to a few femtobarns for the latter two reactions $^{54}\text{Cr}+^{248}\text{Cm}$ and $^{58}\text{Fe}+^{244}\text{Pu}$. Here, we would like to state that the parameter $C$ in Eq.(3) for the description of the fusion probability depends on the parameter sets for calculating the survival probability of super-heavy nuclei. If one takes a different liquid-drop formula for calculating the fission barrier, the parameter $C$ must be re-adjusted. Adopting different formulas for describing the liquid-drop energies [19, 33] and the binding energies of yet unmeasured nuclei [19, 31] (the parameter $C$ is re-adjusted to fit the measured $\sigma_{\text{ER}}$ of “hot” fusion reactions), we find that the calculated evaporation residual cross sections for the four reactions leading to the elements 119 and 120 are close to the corresponding results in Fig. 5, with deviations which are smaller than the uncertainty of this approach. To compare with the results from other models, we list in Table I the calculated optimal evaporation residual cross sections from four different models for the four reactions mentioned in Fig. 5. One sees that for $^{50}\text{Ti}+^{249}\text{Bk}$ and $^{50}\text{Ti}+^{249}\text{Cf}$ the results from Ref.[10] with the fusion-by-diffusion model and Ref.[34] with the dinuclear system model are in the same order of magnitude (hundreds of fb), while the results from Ref.[12] and those in this work are in the same order of magnitude (tens of fb). All models in Table I predict that the optimal evaporation residual cross sections for $^{50}\text{Ti}+^{249}\text{Cf} \rightarrow ^{299}_{-\text{n}} 120$ are smaller than those for $^{50}\text{Ti}+^{249}\text{Bk} \rightarrow ^{299}_{-\text{n}} 119$.

In summary, the entrance-channel Coulomb barrier determines the capture cross sections, the quasi-fission barrier due to the pocket in the entrance-channel potential influences the fusion probability and the fission barrier is related to the survival probability, all play an important role for a reliable calculation of the evaporation residual cross sections in fusion reactions leading to the synthesis of SHN. Of course the dynamics of the fusion process and the zero-point motion for fission process [35, 36] also influence the cross sections significantly, but it is beyond the scope of this work. Based on the previously established methods for the calculation of capture cross sections and the survival probability, we further proposed an analytical formula with only three fixed parameters for a systematic description of the fusion probability in reactions leading to SHN. With this formula the measured evaporation residual cross sections for the “hot” fusion reactions can be reproduced reasonably well. The predicted evaporation residual cross sections $\sigma_{\text{ER}}$ for the reaction $^{50}\text{Ti}+^{249}\text{Bk}$ are about
10 \sim 150 \text{ femtobarn at incident energies around the entrance-channel Coulomb barrier, and the predicted } \sigma_{\text{ER}} \text{ for the reactions } ^{54}\text{Cr}+^{248}\text{Cm} \text{ and } ^{58}\text{Fe}+^{244}\text{Pu} \text{ falls to a few femtobarns which seems beyond the limit of the available facilities.}
