In the framework of the tight binding approximation, we study a non-interacting model on the three-component dice lattice with real nearest-neighbor and complex next-nearest-neighbor hopping subjected to A- or V-type sublattice potentials. By analyzing the dispersions of corresponding energy bands, we find that the system undergoes a metal-insulator transition which can be modulated not only by the Fermi energy but also the tunable extra parameters. Furthermore, rich topological phases, including the ones with high Hall plateau, are uncovered by calculating the associated band’s Chern number. Besides, we also analyze the edge-state spectra and discuss the correspondence between Chern numbers and the edge states by the principle of bulk-edge correspondence.

I. INTRODUCTION

Quantum Hall effect is discovered under the condition with a low temperature and strong magnetic fields [1]. Since this finding, enormous attention has been poured into the study on the topological properties of the quantum systems [2–4], particularly on those quantum-engineered systems with quantum anomalous Hall effect (QAHE) [5–9], which are free from the extra magnetic fields.

One class of insulators realizing the QAHE breaking the time reversal symmetry [10], is Chern insulator in condensed matter physics. Their topological properties are directly characterized by the Hall conductance first proposed by Thouless-Kohmoto-Nightingale-den Nijs (TKNN) in a two-band system [11]. Through TKNN’s work, we know that the mathematical concept of Chern number (C) plays an important role in the topology of Bloch systems. That is, a separated Bloch band corresponds to a well-defined Chern number. In a multiple-band system, the associated Chern number is equal to the quantized Hall conductance in unit of $e^2/h$. For multiple occupied bands, which determines the topological phases of the system. For instance, the nonzero $C$ is indicative of a non-trivial phase, whereas $C = 0$ is of a topologically trivial phase, demonstrating that the system is a normal insulator. For multiple occupied bands, although the Chern number is not directly related to the Hall conductance, the summation of the Chern numbers corresponding to these bands finally share the same value of the observable quantized Hall conductance [12].

In the topological classification, Chern insulator belongs to the topological class $A$ [13]. In general, it is possible to geometrically engineer a Chern insulator with arbitrary topological index $C$. In addition, higher Hall conductance is accompanied by larger $C$ with reducing channel resistance in the field of interface transport, possessing more potential for applications. However, there remains a great challenge to observe the QAHE in real materials [14–17]. Optical-lattice experiments have the advantage of being highly flexible and adjustable, offering a platform for manipulating trapped ultracold atoms to realize the topological non-trivial phases. Accordingly, some attention has been paid to the optical-lattice experiments in recent years [5–9, 18–28]. With the benefits of quite a few efforts [5–9, 21, 24, 29–31], two quintessential models with rich topological phenomena, i.e., Haldane model [25, 32] and Haper-Hofstadter model [26, 33] have been well implemented. These mature techniques have had a significant impact on subsequent researches [34–40] and will increase the feasibility to realize the higher Hall conductance or larger Chern number with QAHE.

In this paper, we focus on a non-interacting model on the three-component dice lattice [41–50] with real nearest-neighbor and complex next-nearest neighbor hopping under A- or V-shaped sublattice potentials. We focus on the $1/3$ filling and $2/3$ filling cases, corresponding to the lowest band occupied and lower two bands occupied, respectively. By analyzing the band structures, we find that the system will have two kinds of phases, metallic phase and bulk insulating phase, thus, experiencing a metal-insulator phase transition. The metal-insulator phase diagram is plotted in the $\Delta$-$\phi$ parameter space, with $\Delta$ the strength of the tunable on-site potentials and $\phi$ the phase of the next-nearest-neighbor hopping. Further, we investigate the topological properties in the bulk insulating phase. Results suggest that there exist non-trivial topological phases with Hall conductance equal to $\pm 1$, $\pm 2$, in units of $e^2/h$. Furthermore, the quantization of the Hall conductance can be seen from the edge-state energy spectra and the large Chern numbers are self-consistently analyzed by the principle of bulk-edge correspondence [51].

The paper proceeds as follows. Section II describes the model and its Hamiltonian in both the real and momentum space. Section III contains the analysis of the band structures, the topological phases, as well as the edge-state spectra and Chern numbers. Section IV summarizes the results of these investigations.
II. MODEL AND HAMILTONIAN

In this paper, we consider a non-interacting model based on the dice lattice, shown in Fig. 1, with three interpenetrating triangle sublattices [denoted by R (red dots), B (blue dots) and G (green dots)]. The single-particle Hamiltonian of the model consists of three terms:

$$\hat{H} = \hat{H}_1 + \hat{H}_2 + \hat{H}_3.$$  \hspace{1cm} (1)

The first term $\hat{H}_1$ describes the hopping between adjacent sites which belong to different sublattices and is expressed as

$$\hat{H}_1 = \sum_{\langle \text{R}, \text{B} \rangle} t \left( \hat{c}^\dagger_{\text{R}} \hat{c}_{\text{B}} + \text{H.c.} \right) + \sum_{\langle \text{R}, \text{G} \rangle} t_1 \left( \hat{c}^\dagger_{\text{R}} \hat{c}_{\text{G}} + \text{H.c.} \right) + \sum_{\langle \text{B}, \text{G} \rangle} t_1 \left( \hat{c}^\dagger_{\text{B}} \hat{c}_{\text{G}} + \text{H.c.} \right), \hspace{1cm} (2)$$

where $t$ is the hopping amplitude between adjacent R sites and B sites, $t_1$ is the real hopping amplitude between adjacent R (or B) and G sites, $\hat{c}_{\text{R}}, \hat{c}_{\text{B}}, \text{ and } \hat{c}_{\text{G}}$ are the corresponding fermionic annihilation operators defined on the relevant sites $\text{R}, \text{B}, \text{ and G}$ of sublattice R, B, and G, respectively. $\langle \cdots \rangle$ means the nearest-neighbor hopping.

Figure 1: (a) The schematic diagram of the three-band $\Lambda$- or $V$-type dice model. The red, blue and green dots denote the R, B, G sublattice sites, respectively. The vectors $\mathbf{a}_n \ (n = 1, 2, 3)$ connect the nearest neighbors which belong to different sublattices. The vectors $\mathbf{b}_n \ (n = 1, 2, 3)$ connect the nearest neighbors which belong to the same R and B sublattice sites. The circle arrows show the direction of hopping with a phase factor $\phi$ in $e^{i\phi}$. (b) The first Brillouin zone, $\Gamma$, K, and M are high-symmetry points which are connected by three red dashed arrows. The distance between adjacent sites has been set as unit length.

Furthermore, we consider the hopping between two nearest neighbor sites only in R and B sublattice site.

Then the Hamiltonian $\hat{H}_2$ is written as

$$\hat{H}_2 = \sum_{\langle \text{R}, \text{R} \rangle} \left( t_2 e^{i\phi} \hat{c}^\dagger_{\text{R}} \hat{c}_{\text{R}} + \text{H.c.} \right) + \sum_{\langle \text{B}, \text{B} \rangle} \left( t_2 e^{i\phi} \hat{c}^\dagger_{\text{B}} \hat{c}_{\text{B}} + \text{H.c.} \right), \hspace{1cm} (3)$$

where $t_2 e^{i\phi}$ is the hopping amplitude, $\pm$ correspond to the clockwise (anticlockwise) direction of the hopping, $t_2$ is a real number and $\phi$ denotes the phase. These flux configurations can be obtained by the artificial gauge field $[5–9, 18–20]$.

The final term, $\hat{H}_3$, describes an on-site potential of the form $[52]$

$$\hat{H}_3 = \gamma_1 \Delta \sum_{\text{R}} \hat{c}^\dagger_{\text{R}} \hat{c}_{\text{R}} + \gamma_1 \Delta \sum_{\text{B}} \hat{c}^\dagger_{\text{B}} \hat{c}_{\text{B}} + \gamma_2 \Delta \sum_{\text{G}} \hat{c}^\dagger_{\text{G}} \hat{c}_{\text{G}}, \hspace{1cm} (4)$$

where $\Delta$ is the tunable parameter of the potential and $\gamma_1$ ($\gamma_2$) is modulation slope of $\Delta$. This shape of the potential can be viewed as a three-band model in the lattice case of three discrete levels forming a $\Lambda$- ($\gamma_1 < \gamma_2$) or $V$-type ($\gamma_1 > \gamma_2$) structure. Such on-site potentials are a bit different from previous works on the dice model $[48–50]$ and can also be realized by tuning single-beam lattice depths $[18, 21, 25, 26]$.

In our research, we consider a sufficiently large system such that the translational symmetry is preserved. Then we map the single-particle Hamiltonian $\hat{H}$ onto the momentum space $[53–55]$. The Bloch Hamiltonian is written as

$$\hat{H}(\mathbf{k}) = I(\mathbf{k}) + \mathbf{d}(\mathbf{k}) \cdot \vec{\lambda}, \hspace{1cm} (5)$$

where $I(\mathbf{k})$ is a scalar leading to a overall shift of three eigenvalues of $\hat{H}(\mathbf{k})$, $\mathbf{d}(\mathbf{k})$ is an eight-dimensional real vector, and $\vec{\lambda}$ is a vector of Gell-Mann matrices $[56]$. In fact, the Chern number will not be influenced by the scalar $I(\mathbf{k})$, and is only determined by the coefficient vectors $\mathbf{d}(\mathbf{k})$. The discrete Fourier transformation is performed in the three-component basis $(\hat{c}_{\text{R}}, \hat{c}_{\text{B}}, \hat{c}_{\text{G}})^T$, with

$$\hat{c}_{\text{R}} = \frac{1}{\sqrt{N}} \sum_{\mathbf{R}} e^{-i \mathbf{k} \cdot \mathbf{R}} \hat{c}_{\mathbf{R}},$$
$$\hat{c}_{\text{B}} = \frac{1}{\sqrt{N}} \sum_{\mathbf{B}} e^{-i \mathbf{k} \cdot \mathbf{B}} \hat{c}_{\mathbf{B}},$$
$$\hat{c}_{\text{G}} = \frac{1}{\sqrt{N}} \sum_{\mathbf{G}} e^{-i \mathbf{k} \cdot \mathbf{G}} \hat{c}_{\mathbf{G}}, \hspace{1cm} (6)$$

where $N$ is the number of the cells. The components of
the vector \( \mathbf{d}(k) \) are obtained as follows,

\[
d_1 = t \sum_s \cos (k \cdot a_s), \quad d_2 = t \sum_s \sin (k \cdot a_s),
\]
\[
d_4 = d_6 = t \frac{1}{\sqrt{3}} \sum_s \cos (k \cdot a_s),
\]
\[
d_7 = -d_5 = t \frac{1}{\sqrt{3}} \sum_s \sin (k \cdot a_s), \quad (7)
\]
\[
d_3 = -2t \sin \phi \sum_s \sin (k \cdot b_s),
\]
\[
d_8 = \frac{\gamma_1 - \gamma_2}{\sqrt{3}} \Delta + \frac{2t}{\sqrt{3}} \cos \phi \sum_s \cos (k \cdot b_s),
\]

where the six vectors \( a_n \) and \( b_n \) \((n = 1, 2, 3)\), shown in Fig. 1(a), are expressed as

\[
a_1 = \begin{pmatrix} 0 \\ -1 \end{pmatrix}, \quad a_2 = \begin{pmatrix} \frac{\sqrt{3}}{2} \\ 1 \end{pmatrix}, \quad a_3 = \begin{pmatrix} 1 \\ -\frac{\sqrt{3}}{2} \end{pmatrix},
\]
\[
b_1 = \begin{pmatrix} \sqrt{3} \\ 0 \end{pmatrix}, \quad b_2 = \begin{pmatrix} -\frac{\sqrt{3}}{2} \\ 3 \end{pmatrix}, \quad b_3 = \begin{pmatrix} 1 \\ -\frac{\sqrt{3}}{2} \end{pmatrix}. \quad (8)
\]

In the next section, we will study the properties of the band structures and topology of the system under 1/3 and 2/3 fillings with the lowest and lower two bands occupied, respectively. We set \( t = 1 \) as the unit of energy, and choose \( t_1 = 0.5, t_2 = 0.526, \gamma_1 = 5, \) and \( \gamma_2 = 7 \).

III. RESULTS AND DISCUSSIONS

A. Band structures

![Figure 2: \( \Delta-\phi \) phase diagram for the case of 1/3 filling (a) and 2/3 filling (b). The metallic phase (M) is separated from the bulk insulating phase (I). In each case, we choose four typical parameter points \( a, b, c, \) and \( d \) discussed in details in the main text. For 1/3 filling, system is in the metallic phase at the \( a \) point, while it is in the bulk insulating phase at the \( b \) and \( d \) points. The opposite is obtained for the ones at 2/3 filling. For the \( c (d) \) point, the system is always in the metallic (insulating) phase, no matter what the filling is.](image)

First, we numerically investigate the band structures of this system by analysing the dispersions of three bands.

The first Brillouin zone is shown in Fig. 1(b) and the \( \Gamma, K, \) and \( M \) are high-symmetry points [57]. By diagonalizing the Hamiltonian \( \hat{\mathbf{H}}(k) \) with the known components of \( \mathbf{d}(k) \) in Eq. (7), we obtain the energy dispersions along the high-symmetry \( k \)-points along the path \( \Gamma-K-M-\Gamma \) at a chosen parameter point \((\phi, \Delta)\), where \( \phi \) has been converted to radians.

![Figure 3: Dispersion relations of the three bands along the high-symmetry \( k \)-points along the path \( \Gamma-K-M-\Gamma \). The red, blue, and black lines correspond to the dispersion relations of the three bands from the bottom to the top, respectively. (a) \( \phi_a = 0.25, \Delta_a = 1 \); (b) \( \phi_b = -0.25, \Delta_b = -0.5 \); (c) \( \phi_c = 0, \Delta_c = -0.25 \); (d) \( \phi_d = \pi/2, \Delta_d = 0.5 \). The lower Fermi energy (magenta dot-dashed line) and higher Fermi energy (green dashed line) correspond to the case of 1/3 and 2/3 filling, respectively.](image)

Based on the relative position of the valance band and the conduction band, we notice that there are two different phases in this model, the metallic phase and bulk insulating phase. To be precise, when the top of the valance band is higher than the bottom of the conduction band, the system is in the metallic phase (M). Otherwise, the system is in the bulk insulating phase (I). According to this feature, the metal-insulator phase diagrams are shown in Figs. 2(a) and 2(b), corresponding to 1/3 filling and 2/3 filling, respectively. These phases are symmetrically distributed with respect to \( \phi \). Four typical parameter points, \( a, b, c \) and \( d \) (red dots), are chosen in each of the \( \Delta-\phi \) phase diagram. For 1/3 filling case, system is in the metallic phase at the \( a \) point, while it is in the bulk insulating phase at the \( b \) and \( d \) points. The situations are opposite for the ones for 2/3 filling. For the \( c (d) \) point, the system remains in the metallic (insulating) phase, no matter what the filling is. One can adjust the Fermi energy \( E_f \) or the parameters of \( \Delta \) and \( \phi \) to change the system from the metallic to bulk insulating phases. For instance, if the system is initially in the
metallic phase (a point), we can increase \( E_f \) by adding the filling up to 2/3, or change the parameters up to the b (d) point, to achieve the bulk insulating phase.

In order to comprehend these two phases intuitively, we plot the dispersion relations of the three bands at the four chosen parameter points \((\phi_a, \Delta_a), (\phi_b, \Delta_b), (\phi_c, \Delta_c)\) and \((\phi_d, \Delta_d)\), shown in Figs. 3(a), 3(b), 3(c), and 3(d), respectively. In each diagram, we select two Fermi energies for reference, corresponding to the case of 1/3 filling (magenta dot-dashed line) and 2/3 filling (green dashed line), respectively. The red, blue, and black solid lines represent the dispersions of the bands ranging from the bottom to the top, respectively. In Fig. 3(a), when the \( E_f \) is chosen at 1/3 filling, the fully occupied bottom band and a partially occupied middle band lead to a metallic phase, although the middle and the bottom band avoid touching each other. When the \( E_f \) is tuned up to 2/3 filling, there is a significant band gap between the top and the middle band, leading to a completely empty conduction and a fully occupied valence band. Therefore, the system is in the bulk insulating phase for 2/3 filling. With the same reasons, it is not difficult to interpret that the system is in the bulk insulating phase at 1/3 filling, and in the metallic phase at 2/3 filling for the case shown in Fig. 3(b). Moreover, the system is always in the metallic phase shown in Fig. 3(c) and in the bulk insulating phase shown in Fig. 3(d), respectively, no matter what the filling is. All these are manifested in the metal-insulator phase diagrams in Fig. 2. In the following, we will further investigate the topological properties in the \( \Delta - \phi \) phase diagram.

B. Topological phases

Motivated by the Haldane model [32] and the dice models [48–50], we try to understand whether there are any topological properties in the bulk insulating phase or not. For the three-band system considered, when \( E_f \) is within a band gap, the Hall conductance [11] can be defined as

\[
\sigma_H(E_f) = \frac{e^2}{h} \sum_{E_n < E_f} C_n,
\]

where \( C_n \) is Chern number of the \( n \)th fully occupied band and is expressed as

\[
C_n = \frac{1}{2\pi} \oint_{\partial BZ} A_n(k) \cdot dk,
\]

where \( n \epsilon \{1, 2, 3\} \) is the band index and its ascending order corresponds to three energy bands from bottom to top; \( \partial BZ \) is the boundary of the first Brillouin zone; \( A_n \) is the Berry connection with \( A_n = -i \langle \psi_n(k) | \nabla_k | \psi_n(k) \rangle \) and \( |\psi_n(k)\rangle \) is the corresponding eigenvector. Without loss of generality, we use two quantities, \( C_{\frac{1}{2}} \) and \( C_{\frac{3}{2}} \), to character the topological properties under 1/3 and 2/3 filling, respectively. The relationship between the topological number of the filling \( (C_{\frac{1}{2}}, C_{\frac{3}{2}}) \) and band Chern numbers \( (C_1, C_2) \) is that \( C_{\frac{1}{2}} = C_1 \) and \( C_{\frac{3}{2}} = C_1 + C_2 \).

The topological \( \Delta - \phi \) phase diagram is obtained shown in Figs. 4(a) and 4(b) by calculating the \( C_{\frac{1}{2}} \) and \( C_{\frac{3}{2}} \), corresponding to the topological numbers for the 1/3 and 2/3 filling of the system, respectively. In Fig. 4, there are several phase boundary lines shown in red and black dashed lines in the bulk insulating phase, accompanied by energy band closing [32, 58]. In fact, the band crossing lines also appear in the metallic phase without changing the intrinsic properties being a metal. Particularly, in each diagram, the topological non-trivial phase is separated from the topological trivial one by the red dashed lines, whereas the topological non-trivial phases are separated from the different nonzero Chern numbers by the black dashed lines.

From the phase diagrams, we can see intuitively that there are abundant quantum phases in the system. In Fig. 4(a), besides the metallic phase regions, there are topological non-trivial phases with \( C_{\frac{1}{2}} = \pm 1 \) and \( C_{\frac{3}{2}} = \pm 2 \), as well as the topological trivial phase with \( C_{\frac{1}{2}} = 0 \). Moreover, when we tune the parameters continuously, the system goes through rich different phases. For instance, when \( \Delta = -0.25 \), by increasing of \( \phi \), the system can circularly undergo with six phases:

\[
\begin{align*}
C_{\frac{1}{2}} &= -1 &\Rightarrow C_{\frac{3}{2}} &= +2 \\
\uparrow & &\downarrow \\
M & &M \\
\uparrow & &\downarrow \\
C_{\frac{1}{2}} &= +1 &\Leftarrow C_{\frac{3}{2}} &= -2,
\end{align*}
\]
where $M$ is short for the metallic phase. When $\Delta = 0.5$, system will cycle through five phase regions with increasing $\phi$:

$$C_{\frac{3}{2}} = -1 \Rightarrow C_{\frac{3}{2}} = +2 \Rightarrow C_{\frac{3}{2}} = 0 \uparrow \uparrow$$

Similarly, for fixing $\phi$, the system experiences with rich phases when we change the tunable parameter $\Delta$ of the potential.

### C. Edge states and Chern numbers

![Figures showing zigzag and armchair edges](image)

Figure 5: Two schematic diagrams of the system with a periodic boundary condition in the $x$ direction and an open boundary condition in the $y$ direction. Two types of boundaries are studied: (a) zig-zag edge; (b) armchair edge. The lattice structures surrounded by the black dotted lines represent the periodic repeating units which contain $N_{\text{zigzag}}$ and $N_{\text{armchair}}$ lattice sites, respectively.

According to the research in Ref. [12], we know that the quantization of the Hall conductance or the total Chern number can be readily seen from the edge-state spectrum in static systems, known as the bulk-edge correspondence. In this subsection, we study the bulk-edge correspondence by considering a cylindrical geometry with a periodic boundary condition in the $x$ direction and an open boundary condition in the $y$ direction. Two types of lattice geometries with zigzag and armchair edge are studied, shown in Figs. 5(a) and 5(b), respectively, surrounded by the dashed boxes representing the periodic repeating units, each of them containing $N_{\text{zigzag}}$ and $N_{\text{armchair}}$ lattice sites. The Hamiltonian $\hat{H}(k_x)$ used for calculating the energy spectrum $E_{k_x}$ can be treated as a function of the good quantum number $k_x$.

![Figures showing edge-state spectra](image)

Figure 6: Two edge-state spectra of the system with a periodic boundary condition in the $x$ direction and an open boundary condition in the $y$ direction at the parameter point $(\phi_d, \Delta_d) = (\pi/2, 0.5)$. Magenta dot-dashed and green dashed lines denote the chosen $E_f$ for 1/3 filling and 2/3 filling, respectively. (a) Edge-state spectra for the zigzag-edge case. Q5 and Q6 are a pair of edge mode at $E_f = 1.80$ for 1/3 filling; Q1 and Q4, Q2 and Q3 are two pairs of edge modes at $E_f = 3.60$ for 2/3 filling. (b) Edge-state spectra for the armchair-edge case. P5 and P6 are a pair of chiral edge mode at $E_f = 1.535$ for 1/3 filling; P1 and P4, P2 and P3 are two pairs of edge modes at $E_f = 3.578$ for 2/3 filling. The results indicates that, no matter what kind of edge the system has, there is a pair of edge modes at 1/3 filling corresponding to $C_{\frac{3}{2}} = 1$, and two pairs of edge modes at 2/3 filling corresponding to $C_{\frac{3}{2}} = -2$.

By choosing $N_{\text{zigzag}} = 299$ and $N_{\text{armchair}} = 243$, two associated edge-state spectra at the parameter point $(\phi_d, \Delta_d) = (\pi/2, 0.5)$ are calculated, shown in Figs. 6(a) and 6(b), respectively. Intuitively, there is a pair of edge modes at 1/3 filling corresponding to a topological non-trivial phase with $C_{\frac{3}{2}} = 1$, and two pairs of edge modes at 2/3 filling corresponding to a topological non-trivial phase with $C_{\frac{3}{2}} = -2$ with no dependence on the edge of the system.

As the principle of the bulk-edge correspondence tells [51], Chern number is closely related with the chiral edge modes. By choosing the same parameters used for edge-state spectra, we plot the spatial density distributions of the edge modes of Q1-Q6 in the zigzag-edge case and the edge modes of P1-P6 in the armchair one, in Fig. 7. We first analyze the zigzag-edge case. As the distributions show (up panels in Fig. 7), Q5 and Q6 are a pair of chiral edge modes at $E_f = 1.80$ for 1/3 filling; Q1 and Q4, Q2 and Q3 are two pairs of chiral edge modes at $E_f = 3.60$ for 2/3 filling. In particular, the spatial density distributions of the edge modes with positive group velocity are shown in red, while black for those with the negative group velocity. We analyze the Chern number by means...
of the edge modes localized at the site of $j = N_{\text{zigzag}}$. From the above calculation, $C_2 = 1$, that is, the edge mode Q5 carries $C = 1$. Naturally, we know that the edge modes Q3 and Q1 with the opposite group velocity both carry $C = -1$. Accordingly, we get $C_1 = 1$ and $C_2 = -1 + (-1) - 1 = -3$.

For the armchair-edge case, there are also six edge modes marked as P1-P6, in which P5 and P6 are a pair of chiral edge modes at $E_f = 1.535$ (magenta dot-dashed line), P1, P4 and P2, P3 are another two pairs of chiral edge modes at $E_f = 3.578$ (green dashed line). We notice that the edge mode P6 localized at the site of $j = N_{\text{armchair}}$ the armchair case has the same sign of the group velocity as the edge mode Q5 of the zigzag case. Hence, P6 carries $C = 1$, which leads to $C_1 = 1$. Meanwhile, the edge modes P1 and P3 with positive group velocity both carry $C = -1$, thus $C_2 = -1 + (-1) - 1 = -3$. All these analyses are self-consistent with the phase diagrams in Fig. 4.

Figure 7: Spatial density distributions of the edge modes. Top panel: the zigzag-edge case. The result shows that, Q5 and Q6 are a pair of chiral edge modes at $E_f = 1.80$ for 1/3 filling; Q1 and Q4, Q2 and Q3 are two pairs of chiral edge modes at $E_f = 3.60$ for 2/3 filling. The label $j$ is the site index of the periodic repeating unit shown in Fig. 5(a), as an artificial chain with the order of B-R-G-⋯-B-R. Bottom panel: the armchair-edge case. Intuitively, P5 and P6 are a pair of chiral edge modes at $E_f = 1.535$ for the 1/3 filling; P1 and P4, P2 and P3 are two pairs of chiral edge modes at $E_f = 3.578$ for the 2/3 filling. The label $j$ denotes the site index of the periodic repeating unit shown in Fig. 5(b), as an artificial chain with the order of R-B-G-R-B-⋯-R-G-B-R-B-G. Particularly, the distributions of the edge modes with positive group velocity are shown in red, whereas black for negative one.

IV. CONCLUSION

In conclusion, we have studied the three-band dice model which is composed of three types of sublattices. Firstly, we investigated the dispersion relations of the energy bands, and found that the system has the metallic and bulk insulating phases. The metal-insulator phase diagrams were plotted in the $\Delta \phi$ parameter space. Further, we evaluated the Chern numbers through the energy band theory in the bulk insulating phase. Interestingly, high Hall plateau was uncovered with $C_2 = \pm 2$. The quantizations of the Hall conductance were readily seen in the edge-state spectra. Finally, we verified the Chern numbers through the spatial density distributions of the edge modes according to the principle of the bulk-edge correspondence.

Although the similar lattice structure has been studies in several electronic materials [59–63], due to the high tunability of the parameters in the cold-atom experiments, it is now possible for experimentalists to research topological phases of neutral atoms which never appear in these aforementioned researches. Thus, we hope that the system with high Hall plateau proposed here can be realized in the near-future cold-atom experiment.
