Observations with the Swift satellite of X-ray afterglows of more than a hundred gamma-ray bursts (GRBs) with known redshift reveal ubiquitous soft X-ray absorption. The directly measured optical depth $\tau$ at a given observed energy is found to be constant on average at redshift $z > 2$, i.e., $(\tau(0.5\mathrm{keV}))_{z=2} = 0.40 \pm 0.02$. Such an asymptotic optical depth is expected if the foreground diffuse intergalactic medium (IGM) dominates the absorption effect and if the metallicity of the diffuse IGM reaches $0.2$–$0.4$ solar at $z = 0$. To further test the IGM absorption hypothesis, we analyze the 12 highest signal-to-noise ratio $(S/N) (>5000$ photons) $z > 2$ quasar spectra from the XMM-Newton archive, which are all extremely radio loud. The quasar optical depths are found to be consistent with the mean GRB value. The four lowest-$z$ quasars ($2 < z < 2.5$), however, do not show significant absorption. The best X-ray spectra of radio-quiet quasars at $z > 2$ provide only upper limits to the absorption, which are still consistent with the radio-loud quasars (RLQs), albeit with much lower $S/N$ ($\lesssim 1000$ photons at $z \approx 4$). Lack of quasar absorption poses a challenge to the smooth IGM interpretation and could allude to the opacity being rather due to the jets in RLQs and GRBs. However, the jet absorbing column would need to appear in RLQs only at $z \gtrsim 2.5$ and in GRBs to strongly increase with $z$ in order to produce the observed tendency to a constant mean $\tau$. High X-ray spectral resolution can differentiate between an absorber intrinsic to the source that produces discernible spectral lines, and the diffuse IGM that produces significant absorption, but no discrete features.

1. INTRODUCTION

Swift X-ray spectra of gamma-ray burst (GRB) afterglows reveal prevalent soft X-ray absorption, which is commonly assumed to originate in the host galaxy. The standard X-ray absorption measurement technique probes metal absorption, but quotes equivalent hydrogen column densities $N_{\text{H}}$ by assuming a neutral absorber at the host ($z$) and with solar abundances. Under these assumptions, $N_{\text{H}}$ toward GRBs shows a strong correlation with the host redshift $z$. The typical absorbing column rises from $N_{\text{H}} \sim 10^{21}$ cm$^{-2}$ at $z < 1$ up to $\approx 10^{23}$ cm$^{-2}$ at the highest observed redshifts (Jakobsson et al. 2006; Campana et al. 2006; Watson et al. 2007; Campana et al. 2010; Rau et al. 2010). Damped Ly$\alpha$ (DLA) absorption is also seen in some GRB afterglows. Unlike the X-ray absorber, the redshift of the Ly$\alpha$ absorber is well constrained. The implied column is usually still well below the X-ray derived column (see, e.g., Watson et al. 2007). If the abundances in the X-ray absorber are sub-solar, the X-ray derived $N_{\text{H}}$ values are even higher and the discrepancy with the Ly$\alpha$ column grows accordingly. Although an appreciable ionization range in a single medium can possibly account for such a discrepancy (recently, Schady et al. 2010), there is also the possibility that the X-ray and Ly$\alpha$ absorbers are physically distinct.

High-$z$ quasars also commonly reveal soft X-ray absorption (e.g., Fabian et al. 2001; Worsley et al. 2004a, 2004b; Page et al. 2005; Yuan et al. 2005; Grupe et al. 2006; Sambruna et al. 2007). The implied absorbing column, if intrinsic, is also of the order of $10^{23}$ cm$^{-2}$. In the case of quasars as well, metal and hydrogen line absorption in the UV imply significantly lower $N_{\text{H}}$ columns. In the case of low-luminosity active galaxies, partially ionized outflows are known to have more X-ray column with only a trace of UV absorbing ions (Crenshaw et al. 2003), a discrepancy that again can be partially reconciled with an ionization correction. The X-ray absorption profile in three different quasars at $z \sim 4.3–4.7$ was noted by Yuan et al. (2005) to be remarkably similar, while ionized quasar outflows are not necessarily expected to be so uniform. Indeed, partially ionized outflows have not been directly identified in such luminous quasars, and thus it is plausible that the X-ray and UV absorbers toward high-$z$ quasars are also physically distinct.

Intrigued by the aforementioned puzzles associated with soft X-ray absorption of high-$z$ sources, we wish to explore the similarities of X-ray absorption of high-$z$ GRBs and quasars and their possible origin. In Section 2, we present the X-ray opacities toward GRB afterglows from the Swift sample (Evans et al. 2009; Campana et al. 2010), but now without assuming either a redshift, or an ionization, or a metallicity for the X-ray absorber. We then discuss in Section 3 the viability of X-ray absorption by the diffuse intergalactic medium (IGM). In Section 4, we present a comparison sample of the highest signal-to-noise ratio $(S/N) z > 2$ quasar spectra drawn from the XMM-Newton archive. Realizing that our selection criterion based on the number of detected photons allows only radio-loud quasars (RLQs) into the sample, in Section 4.1 we also present the best $S/N$ high-$z$ radio-quiet quasars (RQQs) from the works of Shemmer et al. (2008, 2006, 2005). In Section 5, we conclude and compare the expected absorption signature in the X-ray spectra of high-$z$ sources of a diffuse IGM versus that of jets and propose future tests that can reveal whether the observed absorption is indeed due to the IGM or intrinsic to the sources.

2. OBSERVED-FRAME OPACITY OF GRBs

Soft X-ray absorption below 1 keV is mostly due to photoionization of heavy elements (e.g., C, N, O, Fe) and has been measured with the Swift X-ray Telescope (XRT) in over a
hundred GRBs with an identified redshift (Gehrels 2004; Evans et al. 2009; Campana et al. 2010). It is preferable to use late photon arrival times when spectral variability is minimal in order to obtain the most reliable absorption measurements. In this work, we therefore use only the photon counting (PC) mode data available from the Swift/GRB spectrum repository (Evans et al. 2009)1. This choice of data is not as sophisticated as the careful time cuts of Campana et al. (2010), but on the other hand, it provides a uniformly reduced sample. We include all of the bursts up to 2010 July. We use only the 144 that have an identified redshift, out of a total of 520 GRBs. The sample greatly varies in S/N, but in order not to introduce any biases, we do not exclude any objects from the analysis. Out of the sample of 144 GRBs, absorption at the 90% confidence level is measurable for 113, while the other 31 have only upper limits.

The column density \( N_H(z) \) in the repository is conveniently given as an equivalent hydrogen column density assuming a neutral solar-abundance absorber at the host redshift. The strong correlation of these absorbing columns with \( z \) was noted by Campana et al. (2010). Here, we wish to carefully study the observed X-ray absorption effect, relaxing these assumptions as much as possible. We thus convert the quoted column into an optical depth at the observed energy \( E \) using

\[
\tau(E) = \tau_0(E) + \Delta \tau(E) = \frac{E}{\sigma(E)} N_H(z),
\]

where \( \sigma(E) = \sigma(1+z)E \) is the total photoionization cross section per hydrogen atom at a photon energy of \( [1+z]E \) and for solar metallicity gas. In Equation (1), we use the exact same cross section used by the repository team, namely that provided by the phabs model in Xspec2 for a neutral solar-composition (Anders & Grevesse 1989) absorber. Importantly, the intrinsic column densities provided in the repository are those in excess of the nominal local Galactic column \( N_H^{\text{Gal}} \) based on H I 21 cm measurements (Kalberla et al. 2005), which is also given there. However, we note that the use of the solar abundances of Anders & Grevesse (1989) for the Galactic column leads to an overestimate of the local X-ray absorption effect and, thus, to an underestimate of the residual (GRB) absorption, as these abundances are somewhat high compared to more up to date estimates of interstellar abundances (Wilms et al. 2000). At 0.5 keV, e.g., the photoionization cross section per H atom based on Anders & Grevesse (1989) abundances would be \( 7.14 \times 10^{-22} \text{ cm}^2 \) compared to the preferred value of \( 6.22 \times 10^{-22} \text{ cm}^2 \) obtained with the Wilms et al. (2000) abundances. This difference is demonstrated in Figure 1. We therefore introduce a small correction (increase) to the optical depth in Equation (1) as follows:

\[
\tau(E) = \tau_0(E) + \Delta \tau(E) = \frac{E}{\sigma(E)} N_H(z),
\]

where \( \sigma_0(E) = \sigma_0(E) + \Delta \sigma(W) \) is the (positive) difference in the inferred cross section deduced from using the Anders & Grevesse (1989, AG) and Wilms et al. (2000, W) abundances. On average, this correction to \( \tau \) is \( \sim 10\% \), but can reach \( 50\% \) for high Galactic column GRBs.

In Figure 2 we present the PC-mean results for the optical depth \( \tau(0.5 \text{ keV}) \) at the observed energy of 0.5 keV, where photoelectric absorption is significant and the instrument response is sufficiently high. The errors on \( \tau \) correspond to the 90% confidence errors quoted in the repository. For bursts whose absorption measurements are consistent with zero to within these errors, we plot only the +90% confidence (upper) limit. We stress that the optical depth is the directly measurable model-independent quantity, unlike column density. The scatter in \( \tau(0.5 \text{ keV}) \) in Figure 2 is substantial, but there is no evolution with \( z \), especially not at high \( z \). Indeed, the error-weighted mean optical depth in \( \Delta z = 1 \text{ bin} \) is also shown in the figure, and its constancy with \( z \) is strikingly tight. For \( z > 2 \) bursts, the error-weighted mean optical depth is \( \langle \tau(0.5 \text{ keV}) \rangle_{z=2} = 0.40 \pm 0.02 \). The upper limits cannot be included in an error-weighted mean, but a simple mean with no weighting yields \( \langle \tau(0.5 \text{ keV}) \rangle_{z=2} = 0.7 \pm 0.1 \) with the upper limits and \( \langle \tau(0.5 \text{ keV}) \rangle_{z=2} = 0.55 \pm 0.09 \) without them; quoted errors are standard errors of the mean. Using the late-time PC spectra from the repository instead of the mean PC data increases the unweighted mean by \( \approx 0.1 \). This could be a result

---

1 http://www.swift.ac.uk/xrt_spectra/
2 http://heasarc.gsfc.nasa.gov/docs/xanadu/xspec/
of the 2%–3% steeper spectral slopes in the late-time spectra. On the other hand, excluding GRB 060202, a rare outlier with \( \tau(0.5 \text{ keV}) > 5 \), which also has a very steep spectral slope of \( \Gamma = 2.7 \) and is not fitted by the model very well, reduces the unweighted mean by \( \approx 0.1 \). All of these give a general idea of the systematic uncertainties that can be expected from the X-ray absorption measurements of the transient GRB afterglows. Given the wide range in the quality of the measurements, their detection limits, and the fact that including upper limits tends to increase the mean (i.e., largely inadequate measurements rather than low absorption), we prefer the error-weighted unweighted mean by
\[
\langle \tau(0.5 \text{ keV}) \rangle = 0.40 \pm 0.02.
\]

keeping in mind, however, the large (–0.2) systematic errors. The column densities required to produce an opacity \( \tau \) that is fixed with \( z \) increase roughly as \((1 + z)^{2.5}\) due to the corresponding decrease of the photoionization cross section with energy, as can be seen in Figure 1 and as explained in more detail below. These columns then exceed \( 10^{25} \text{ cm}^{-2} \) as reported by Campana et al. (2010). In the present work, we explore an alternative explanation for the observed constancy of optical depth with \( z \).

The opacity at high \( z \) and its apparent independence of \( z \) raises the suspicion that the absorption is not intrinsic to the GRB, but is due to a rather uniform foreground. We focus on the high-\( z \) population where host absorption is strongly quenched (as \( \sigma \) sharply declines with \( E \), see Figure 1). Therefore, at such a high \( z \) the possibility that the GRB environment or host galaxy contribute to the observed absorption is small, unless the intrinsic column is of the order of \( N_H \sim 10^{20}–10^{25} \text{ cm}^{-2} \), well above the typical galactic column in the local universe. In order to further illustrate the similarities of the absorption spectra irrespective of \( z \), in Figure 3 we plot spectral ratio plots for the 12 highest-\( z \) GRBs with absorption within the 90% level. This sub-sample is drawn from the full Swift/XRT sample shown in Figure 2, but is not necessarily representative of it. For Figure 3, each spectrum is fitted to an absorbed power law (with Wilms et al. 2000 abundances), after which the excess (extragalactic) absorption is removed. The ratio of the model (with only Galactic absorption) to the data, i.e., transmission, is plotted. The apparent drop of the ratio at low energies \( (E < 1 \text{ keV}) \) thus reflects the additional photoelectric non-Galactic absorption toward each GRB. GRB 060202 is exceptional in Figure 3 with its excessive absorption and can be seen also in Figure 2 at \( 1 + z = 5.05 \) far above the mean GRB opacity. On the other hand, GRB 081029 at \( 1 + z = 4.85 \) is less absorbed \( (\tau \approx 0.16^{+0.14}_{-0.08}) \), although, formally, not as well constrained. For the most part, absorption sets in at \( E < 1 \text{ keV} \), and the transmission \( (e^{-\tau}) \) at \( E = 0.5 \text{ keV} \) reaches \( \approx 0.5–0.7 \), i.e., \( \tau \approx 0.3–0.7 \).

3. SOFT X-RAY OPACITY OF THE DIFFUSE IGM

A natural origin of universal, isotropic X-ray opacity that saturates at high \( z \) is the diffuse IGM. In this section, we describe a simple diffuse IGM model, based on well-established cosmological parameters, that can explain a tendency to a constant X-ray opacity for high-\( z \) sources. Since the photoionization cross section per H atom in the photon energy range of \( 0.5 \text{ keV} < E < 10 \text{ keV} \) scales roughly as \( \alpha(E) \propto E^{-2.5} \) (Figure 1), for a redshifted absorber at a fixed observed energy \( E, \sigma(E, z) \propto (1 + z)^{-2.5} \). Also, since the absorption at X-ray energies is dominated by metals, one can assume \( \sigma(E, z) \propto Z_\odot \sigma(E, z) \) scales approximately with the IGM metallicity \( Z_\odot \) (in solar units) that can evolve with redshift as \( Z_\odot(z) = Z_\odot \eta(z) \). We can thus write for the IGM photoelectric optical depth
\[
\tau_{\text{IGM}}(E, z, Z_\odot) = \int_0^z n_H(z') \sigma(E, z', Z_\odot) c \left( \frac{d\tau}{dz'} \right) dz'.
\]

\[
\approx \frac{n_0 c Z_\odot}{H_0} \int_0^z (1 + z')^3 \eta(z') dz',
\]

where \( n_0 \) and \( Z_\odot \) are the \( z = 0 \) mean IGM hydrogen number density and metallicity (in solar units), \( c \) is the speed of light, and \( H_0 \) is the Hubble constant. \( \Omega_M \) and \( \Omega_\Lambda \) are, respectively, the present-day matter and dark energy fractions of the critical energy density of the universe. Even with no metallicity evolution, i.e., \( \eta(z) \equiv 1 \), the differential optical depth \( d\tau/dz \rightarrow (1 + z)^{-2} \) at \( z \gg 1 \) and the integral in Equation (3) thus saturate at the high-\( z \) limit. This is starkly different from the more intuitive continuous increase of optical depth with \( z \), e.g., for Compton scattering and line absorption. The likely decrease of metallicity with \( z \) makes \( \tau_{\text{IGM}}(E, z) \) saturate even faster with \( z \). The behavior of \( \tau_{\text{IGM}}(E, z) \) both without metallicity evolution and with \( \eta(z) \propto (1 + z)^{-2} \) is shown in Figure 4, overlaid on the measured opacities. These curves are not fits to the data, but are plotted to give a rough idea of how the IGM contribution to the opacity saturates at high \( z \).

The mean density of hydrogen in the IGM is \( n_0 \approx 0.67 \Omega_M(3 H_0^2/8 \pi G m_H) = 1.7 \times 10^{-7} \text{ cm}^{-3} \), where \( \Omega_M = 0.045 \) is the universe’s baryon energy fraction (Komatsu et al. 2010), \( G \) is the gravitational constant, and \( m_H \) is the hydrogen mass. The pre-factor of 0.67 comes from the fact that \( \approx 74\% \) of the universe mass is in hydrogen atoms, \( \approx 90\% \) of which reside in the IGM (Fukugita & Peebles 2004). The Hubble constant is \( H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1} \) and the cross section at 0.5 keV \( \sigma(0.5 \text{ keV}, 0) = 6.22 \times 10^{-22} \text{ cm}^{-2} \). For \( \eta(z) \equiv 1 \) (no metallicity evolution), and using the standard cosmological parameters \( \Omega_M = 0.27 \) and \( \Omega_\Lambda = 0.73 \) (Komatsu et al. 2010), the integral in Equation (3) up to \( z \approx 10 \) attains a value of \( \approx 1.4 \). It is interesting that this estimate results in the simple asymptotic expression
\[
\tau_{\text{IGM}}(0.5 \text{ keV}, z \gg 1) \approx 2\Omega_H/1 + k.
\]

In other words, a reasonable \( z = 0 \) metallicity of \( Z_\odot \approx 0.2 \) could explain the measured asymptotic value of \( \tau \approx 0.4 \).

There are two strong, oversimplifying assumptions in this estimate that have to do with the metallicity and the ionization of the IGM. First, there is most definitely a metallicity evolution in the IGM (e.g., Simcoe et al. 2004). If one assumes a universal metallicity evolution of \( Z_\odot(z) = Z_\odot(1 + z)^{-k} \), the saturation of \( \tau_{\text{IGM}}(E, z) \) occurs at even lower \( z \) than without evolution. In that case, for \( z' \gg 1 \text{, } d\tau/dz' \rightarrow (1 + z')^{-2-k} \), and the integral in Equation (3) is approximately \( (1 + k) \) times smaller. In other words, the corresponding expression is
\[
\tau_{\text{IGM}}(0.5 \text{ keV}, z \gg 1) \approx 2\Omega_H/(1 + k).
\]

For example, if one adopts for the IGM the metallicity trend of \( Z_\odot \approx (0.54 \pm 0.10)(1 + z)^{-1.25^{+0.25}_{-0.25}} \) (i.e., \( Z_\odot \approx 0.5 \) and \( k \approx 1.25 \)) observed for Fe in the X-ray emitting gas of galaxy clusters up to \( z \approx 1 \) (Balestra et al. 2007), the above relation suggests \( \tau_{\text{IGM}}(0.5 \text{ keV}, z \gg 1) \approx 0.45 \pm 0.15 \), which is consistent with both the GRB mean value (above) and with the quasar results (next section). Alternatively, \( Z_\odot \approx (0.2 \pm 0.1)(1 + z)^{-1} \) derived for Fe from the measured supernova rate (Graur et al. 2011) suggests \( \tau_{\text{IGM}}(0.5 \text{ keV}, z \gg 1) \approx 0.2 \pm 0.1 \), slightly less than the clusters or the above estimated GRB values.

The second caveat is the ionization correction, which is more difficult to deal with, as the ionization state of the diffuse IGM
Figure 3. Data to model ratio plots for the 12 highest-$z$ GRBs with confirmed absorption. Data are binned to represent conveniently the extragalactic transmission functions. Note the overall similar absorption amplitude irrespective of $z$.

(A color version of this figure is available in the online journal.)

is not directly observed and is a matter of ongoing debate (e.g., Bolton & Haehnelt 2007). The above estimates are all based on the photoionization cross section of a neutral absorber. An ionized absorber would have a somewhat lower cross section at X-ray energies, and therefore a larger column density would be required to produce the same $\tau$. Calculating cross sections for different ionization states and different metallicities in the IGM is beyond the scope of this paper. However, in Figure 1 we plot separately the contributions to the photoionization cross section of H and He, and that of the metals with solar composition. It can be seen that below the O edge, the metal contribution is dominated by that of H and He up to 0.54 keV, where it overtakes the H and He contribution. For redshifted absorption, it is thus the metal contribution that mostly determines $\tau(0.5 \text{ keV})$ unless the metallicity is radically sub-solar. The pure metal contribution can also be thought of as an upper limit to the cross section for ionized plasma in which H and He are totally ionized (although in reality the metal contribution also somewhat decreases with ionization). A $z = 1$ absorber in which H and He are totally transparent (ionized) would still retain more than 70% of its opacity at 0.5 keV (observed) mostly due to C and O, and that fraction of course needs to be further scaled with the metallicity.

To summarize this section, the mean high-$z$ opacity for the diffuse IGM within the standard cosmological model can explain the soft X-ray opacity measured from spectra of high-$z$ GRBs (and quasars) as long as the gas is not too highly ionized, and as long as the metallicity is a reasonable fraction of the solar value and does not decrease too quickly with redshift. The low ionization is possible since the truly diffuse IGM suffered
The Astrophysical Journal, 734:26 (9pp), 2011 June 10

behavior in the high-redshift regime. We find the 13 quasars listed in Table 1, most of which were already individually reported in the literature. We used the standard EPIC PN pipeline products and fitted all the quasar spectra in the exact same manner as the GRB spectra, namely with a host (z) absorber. The column density N_H(z) obtained from this measurement was then translated into the optical depth τ(0.5 keV) according to Equation (1). No abundance correction was needed (Equation (2)) as we used the abundances of Wilms et al. (2000) for both the Galactic and host absorbers. The best-fit τ(0.5 keV) values are listed in Table 1 and plotted in Figure 4 and can be seen to compare well with the mean GRB opacities. Quoted and plotted errors correspond to the 90% confidence limits. When more than one XMM-Newton observation is available, we fit all observations simultaneously with a single absorbing column.

The simple model of an absorbed (Galactic and host) power law fits most of the sources well as can be seen by the reduced χ^2/dof values quoted in Table 1 and which are mostly close to unity. Three quasars in our sample, however, did not yield a satisfactory fit, namely QSO B0014+810, QSO B0438−43, and PKS 1830−210. The first two suffer from low count statistics at high energies, but are fitted well up to E < 3 keV. C-statistic fits (Cash 1979) of the entire spectra of these two sources are good and yield spectral parameters that are well within the errors of the limited band χ^2 fitting. We could not satisfactorily fit the complex spectrum of the gravitationally lensed quasar PKS 1830−210 (Zhang et al. 2008) with the same simple model, not even when the high energy region was ignored. Henceforth, we refer to our sample as the 12 targets in Table 1, excluding PKS 1830−210. The sense of the absorption effect in this sample can be obtained from Figure 5. In this figure, we plot the data to best-fit-model ratios for all targets of Table 1 except PKS 1830−210, but after the excess column has been removed from the model, i.e., N_H(z) is set to zero. When a source was observed more than once, we plot each spectrum separately (in color in the electronic version). The absorption effect can be seen to be consistent between different observations.

For the most part, the optical depth toward quasars is well within the scatter of the GRB optical depths (Figure 2) and consistent with its mean trend (Figure 4). However, the four lowest redshift targets with 2 < z < 2.5 do not show significant absorption. The three lowest-z ones have τ(0.5 keV) ≤ 0.1 at 90% confidence (Table 1). Formally, the quasar absorption effect is relatively uniform with an error-weighted mean of ⟨τ(0.5 keV)⟩_z<2 = 0.19 ± 0.01, 0.35 ± 0.09 with no weights, and 0.32 ± 0.08 if the one upper limit is also included, all of

4. OBSERVED-FRAME OPACITY OF X-RAY SELECTED HIGH-z QUASARS

We wish to further explore whether soft X-ray absorption of high-z GRBs is due to the peculiar environment of the GRBs or whether there is a significant intervening IGM contribution. A natural place to check for IGM absorption is with high-z steady X-ray sources, namely quasars. For this, we searched the XMM-Newton archive for all quasars with z > 2 for which the EPIC PN camera recorded more than 5000 source photons to ensure high S/N. We found the 13 quasars listed in Table 1, most of which were already individually reported in the literature. We used the standard EPIC PN pipeline products and fitted all the quasar spectra in the exact same manner as the GRB spectra, namely with a host (z) absorber. The column density N_H(z) obtained from this measurement was then translated into the optical depth τ(0.5 keV) according to Equation (1). No abundance correction was needed (Equation (2)) as we used the abundances of Wilms et al. (2000) for both the Galactic and host absorbers. The best-fit τ(0.5 keV) values are listed in Table 1 and plotted in Figure 4 and can be seen to compare well with the mean GRB opacities. Quoted and plotted errors correspond to the 90% confidence limits. When more than one XMM-Newton observation is available, we fit all observations simultaneously with a single absorbing column.
which are lower than the respective GRB values (Section 2). The error-weighted mean optical depth of the eight quasars with 
z > 2.5 is \( \langle \tau(0.5 \text{ keV}) \rangle_{z>2.5} = 0.41 \pm 0.02 \), which is consistent with the GRB value, and 0.43 \( \pm 0.10 \) with no weights. RBS 315 (\( z = 2.69 \)) has somewhat high absorption (see also Piconcelli & Guainazzi 2005) with respect to the quasars with \( \tau(0.5 \text{ keV} = 1.08 \pm 0.06 \), although this too is still well within the GRB scatter. It has been suggested that perhaps the spectral curvature in RBS 315 is intrinsic to the source and not due to absorption (Tavecchio et al. 2007). However, no definitive conclusion could be drawn.

The emergence of absorption at \( z > 2.5 \) raises an interesting connection with the re-ionization of He \( \text{I} \) in the IGM observed from UV spectroscopy to occur at \( z = 2.7 \pm 0.2 \) (Shull et al. 2010). The contribution of He to the observed opacity at 0.3–1 keV (1–4 keV in the rest frame for \( z = 2–3 \) targets) is small (Figure 1), while the contribution of heavier elements such as C and O is appreciable. The ionization energy of He \( \text{I} \) is 54.4 eV, which is comparable to that of L-shell C and O charge states. For example, the ionization energy of O \( \text{I} \) is 54.9 eV and that of C \( \text{II} \) is 47.9 eV. Thus, these elements are expected to be ionized into their L-shell when He \( \text{I} \) is ionized. The L-shell ionization of C and O results in their K-edge (responsible for the X-ray absorption) being pushed to higher energies and in a slightly reduced photoionization cross section in the sub-keV regime. This was demonstrated recently for N in Figure 8 of Garcia et al. (2009). The IGM X-ray opacity due to these metals will decrease more drastically once they become ionized down to their H-like state. This occurs for C and O at much higher ionization energies of 392.1 eV and 739.3 eV, respectively. If the reduced absorption observed along the lines of sight to the quasars at \( 2 < z < 2.5 \) is due to the intervening material being highly ionized, it would conflict with ubiquitous IGM absorption, which is expected to nearly saturate by \( z \approx 2.5 \) (see Section 3 and Figure 4). Admittedly, the current quasar sample is small. A larger sample is needed to conclusively determine whether indeed X-ray absorption of high-\( z \) quasars increases significantly around \( z = 2.5 \).

### 4.1. Radio-quiet Quasars

Although the above sample was selected based on the availability of high-S/N X-ray spectra in the XMM-Newton archive, the radio brightness of these bright X-ray sources creates a strong bias in the sample toward extremely RLQs, which are only a small fraction of the total quasar population. Are RQQs absorbed in the soft X-rays as much as the RLQs and GRBs? The answer to this question cannot benefit from the high S/N available for the RLQs. Nevertheless, it is of considerable importance for assessing IGM absorption. Comprehensive studies of high-\( z \) RQQs have been carried out by Shemmer et al. (2005, 2006, 2008), who find the observed soft X-ray spectrum of RQQs in these studies to be essentially featureless. In other words, significant absorption (or soft excess) is not detected. We obtained from the XMM-Newton archive the highest S/N spectra for RQQs. The data reduction and handling are similar to that of the RLQs in Section 4. We find similar results to those of Shemmer et al. (2005, 2006, 2008) and include these four data points in Figure 4.

In Figure 6, we show the four RQQs with the most EPIC PN counts. The parameters of these sources are given in Table 2 and plotted in Figure 4. It can be seen that the RQQ spectra are much noisier than those of the RLQs and that none of the sources reveals significant absorption. The two RQQs with the most counts (bottom of Figure 6) are also at \( z < 2.5 \), where the RLQs do not show any significant absorption either (Figures 4 and 5). The two other RQQs at \( z > 4 \) suffer from even poorer S/N. Therefore, their spectra only poorly constrain the optical depth at 0.5 keV. The mean optical depth of \( \sim 0.3 \) found for the RLQs is still within the errors for these two sources, although their best-fit values are lower.

Despite the limited S/N compared to the RLQs (and many GRBs), the lack of absorption in RQQs (11 sources in Shemmer et al. 2008) appears to be in contrast with the (diffuse IGM?) absorption effect observed in GRBs and RLQs. RQQs in the local universe are known to have soft X-ray excess emission that can offset the absorption effect. However, this excess that

Notes.

a Measured assuming an absorber at the host at redshift $z$.

b Deduced from $N_H(z)$ using Equation (1).
Figure 6. Data to model ratio plots for the highest-count RQQs listed in Table 2. Data are binned to conveniently represent the extragalactic transmission functions. The lack of absorption seen for the two $z < 2.5$ sources is consistent with the RLQ results (Figure 5), while for $z > 4$ it is not. This result, however, needs to be taken with caution due to the low-S/N RQQ spectra.

(A color version of this figure is available in the online journal.)

reaches $\sim 1$ keV in the quasar rest frame is not expected to affect the observed $0.5$ keV opacity for sources with $z > 2$, unless its strength increases with $z$. To summarize this section, the sense of no absorption in RQQs is visible in Figure 6 (see also the plots in Shemmer et al. 2005, 2006, 2008), although some of the opacity upper limits are still high.

5. DISCUSSION AND CONCLUSIONS

The extragalactic soft X-ray opacity toward GRBs and quasars at low $z$ is dominated by absorption in the host galaxy. However, the contribution of a fixed host column to the optical depth $\tau$ at a given observed energy sharply drops with $z$, and the extragalactic opacity observed in the soft X-ray spectra of high-$z$ GRBs may thus have a dominant contribution from the diffuse IGM. Due to the redshift and energy dependence of the photoelectric cross section, the diffuse IGM opacity saturates at $z \gtrsim 2$ and is expected to be isotropic and relatively constant beyond that redshift. The redshift where saturation occurs depends on the IGM metallicity. The IGM opacity is not expected to directly correlate with the line absorption systems observed in the optical and UV that originate either in the host galaxy or in overdense IGM clumps. A large sample of Swift GRBs and a high-S/N sample of RLQs observed with XMM-Newton appear to be mostly consistent with this picture of diffuse IGM absorption. However, a few RLQs at $z < 2.5$ and a few low-S/N RQQs with very little absorption that nonetheless could represent a much larger quasar sample raise doubts.

For the IGM to produce the X-ray opacities observed toward high-$z$ GRBs and RLQs, it needs to be relatively enriched with metals and not too highly ionized. If indeed it is primarily the diffuse IGM responsible for this absorption, it can account for a significant fraction of the currently missing baryons, implied by big bang nucleosynthesis (Steigman 2007), the observed angular power spectrum of the cosmic microwave background radiation, and the Thomson opacity inferred from its polarization (Komatsu et al. 2010). Of these baryons, in the local universe only $\sim 50\%$ are present in the galaxies, galaxy clusters, and UV–optical IGM line systems known to date (for a review see Bregman 2007). Furthermore, if $90\%$ of the baryons are in the IGM and if the diffuse low-$z$ IGM metallicity is indeed $\sim 0.2–0.4$ solar as we postulate here, then the IGM contains the bulk of the metals in the present-day universe, compared to, say, solar metallicity in stars and galaxies that comprise only $10\%$ of the baryons.

The presence of absorption in GRBs and RLQs, that both harbor powerful jets, but less in RQQs, also raises the possibility that the absorption effect has something to do with the jet. It was discovered by ROSAT (Elvis et al. 1994; Fiore et al. 1998) that high-$z$ RLQs are much more absorbed in the X-rays than RQQs, which seems to support a jet effect. On the other hand, these authors also realized the absorption (if intrinsic) increases with $z$ and not with luminosity, which argues against a jet-physics origin. The fact that local RLQs generally do not have the high column densities that are found in the high-$z$ sources has been confirmed recently by Galbiati et al. (2005, Table 4 therein). Indeed, ascribing photoelectric absorption to the jet is
counterintuitive, as the jet is not expected to comprise atomic material with bound electrons, and especially not metals, that produce the observed X-ray opacity. Moreover, the little scatter of the observed optical depth found in this paper, and even more the tendency to an asymptotic opacity at high \( z \) that requires a putative intrinsic column to scale approximately with \((1 + z)^{2.5}\) to offset the decreasing cross section, calls into question the realistic role jets can play in determining the soft X-ray opacity.

Turning to the trends of intergalactic line absorption toward GRBs and quasars in the optical band does not provide a clear-cut answer to the uniqueness of absorption toward jetted sources either. On one hand, the number of Mg \( \text{ii} \) intervening absorption systems toward GRBs (Prochter et al. 2006) and blazars (Bergeron et al. 2010) is a few times higher than that toward RQQs. As there is no obvious reason for line sights toward GRBs to be different from those toward quasars, it would require metals to be entrained in the jets of GRBs and RLQs. On the other hand, line sights toward high-\( z \) RLQs seem to have a similar number density of intervening DLA systems as those toward optically selected (again, mostly RQQs) blazars (Bergeron et al. 2010) is a few times higher than that toward RQQs. E.B. is grateful to R. Mushotzky for insightful discussions on He \( \text{ii} \) absorption systems, and by O. Shemmer on X-ray absorption. We acknowledge important insights by D. Chelouche on Mg \( \text{ii} \) absorption systems, and by O. Shemmer of RQQs. The authors thank A. Heller for assistance with the GRB data extraction, and S. Kaspi and A. Nusser for early discussions.
