Quantifying the (X/Peanut)-Shaped Structure in Edge-on Disc Galaxies: Length, Strength, and Nested Peanuts

Bogdan C. Ciambur,* Alister W. Graham

Centre for Astrophysics and Supercomputing, Swinburne University of Technology, Hawthorn, VIC 3122, Australia

1 INTRODUCTION

Quite apart from the spheroid-shaped bulges observed at the cores of many disc galaxies, some galaxy bulges display a characteristic bi-lobed, boxy or X-like shape if viewed in projection close to edge-on (for example, the famous IC 4767 – ‘the X-galaxy’; Whitmore & Bell 1988). Shortly after this class of galaxy was noticed (Burbidge & Burbidge 1959) they were coined ‘peanut’ bulges by de Vaucouleurs & de Vaucouleurs (1972), and have since been found to occur in a significant fraction of galaxies (e.g., Lütticke, Dettmar & Pohlen 2000 found that > 40% of disc galaxies in close to edge-on orientation and ranging from S0 to Sd have (peanut/X)-shaped bulges; see also Jarvis 1986 and Buta et al. 2015). Additionally, more recent works suggest that the bulge of our own Galaxy is peanut-shaped ( Sellwood 1993; Dwek et al. 1995; Ness et al. 2012; Wegg, Gerhard & Portail 2015).

The early analyses (based on N-body simulations) of Combes & Sanders (1981), Combes et al. (1990) and Raha et al. (1991), suggested that peanuts arise naturally from the thickening and/or buckling of galactic bars, or vertical resonance mechanisms, such as the Inner Lindblad Resonance (ILR). Observational support for the peanut–bar link...
quickly followed (e.g., Shaw 1987; Dettmar & Barteldrees 1990; Kuijken & Merrifield 1995; Bureau & Freeman 1999; Bureau & Athanassoula 2005), the fraction of barred disc galaxies (~45%; Aguerri, Méndez-Abreu & Corsini 2009) being found to be close (within a few per cent) to that of X/P hosts. Other than their characteristic morphology, X/P bulges also exhibit specific kinematic signatures in face-on orientation (Debattista et al. 2005, Méndez-Abreu et al. 2008), as well as cylindrical rotation, i.e., almost constant rotational velocity in the direction perpendicular to the disc plane (e.g., Molaeinezhad et al. 2016 and references therein). The field has advanced significantly, with three-dimensional simulations becoming ever more refined (e.g., Quillen et al. 2014; Athanassoula et al. 2015; Li & Shen 2015) and peanuts being detected at lower inclinations (e.g., Erwin & Debattista 2013). For a more in-depth overview we refer the reader to the review articles of Laurikainen & Salo (2016) and Athanassoula (2016), and references therein.

Quantifying X/P structures in real galaxies has proved a challenging feat, with most observational studies relying on qualitative methods, such as visual inspection. Several quantitative diagnostics have been attempted, particularly: determining whether isophotes crossing the minor axis are ‘pinched’ or concave (Williams, Bureau & Cappellari 2009), examining one-dimensional cuts parallel to the disc plane (D’Onofrio et al. 1999; Athanassoula 2005) or looking for the peanut imprint in the fourth Fourier component (B4) of isophotes (Beaton et al. 2007; Erwin & Debattista 2013). However, all of these approaches are problematic. As we will show in Section 4, many peanut galaxies do not exhibit a very prominent X/P feature comparable to the disc and spheroid. As such, their photometric structure is dominated by the combination of the latter two, thus most often resulting in straight (parallel to the disc plane) or even convex isophotes which cross the minor axis1 (where the shape is dominated by the spheroid), despite the presence of an X/P. Taking cuts parallel to the disc plane also works best only for strong peanuts, and further suffers from noise from, e.g., substructure, seeing, etc. Finally, B4 usually measures the boxyness or discyness of isophotes. However, X/P structures are believed to be different to boxy ellipticals (Combes et al. 1990), and in fact for edge-on galaxies the disc makes the isophotes discy, i.e., when the isophote crosses the major axis, it is highly concave (not concave, as would be the case for boxy isophotes).

In this work we propose a method which is more accurate, easy to automate, can probe fainter peanuts and is well suited to compare observations (galaxy isophotes) with simulations (projected isodensity contours). Ciambrur (2015), hereafter C15, recently suggested that, just as B4 quantifies boxyness or discyness, so the sixth Fourier component of isophotes (B6) carries physical meaning, capturing the X/P feature. In this paper we show that B6 does trace X/P structures remarkably well and provides a wealth of information about them.

The paper is structured as follows. In Section 2 we define our five diagnostics, based on the radial B6 profile, and we additionally present them in the context of peanut formation theory. Section 3 details our sample of eleven galaxies with known X/P structures, obtained from the literature. Section 4 provides a detailed demonstration of X/P structure quantification using a well known peanut galaxy, NGC 128, as well as the results for the full sample. We interpret and discuss our results in Section 5, and finally, we re-iterate our main findings and conclude with Section 6. Throughout this paper, we assume a flat Universe cosmology with \( \Omega_m = 0.27 \) and \( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1} \).

2 THEORY AND QUANTITATIVE X/P PARAMETERS

Bars in discs are dynamically unstable, and are susceptible to buckling outside of the disc plane. Numerical simulations have shown that bar buckling is one channel through which disc galaxies can develop X/P structures (Raha et al. 1991; Merritt & Sellwood 1994). In such cases, the bar buckles and forms a peanut in the inner regions (Athanassoula & Martínez-Valpuesta 2009) and the stronger the buckling, the more pronounced is the resulting peanut. Another scenario which also arose from N-body simulations is that the peanut is actually due to a resonance mechanism (e.g., Combes & Sanders 1981; Combes et al. 1990), in particular a vertical Inner Lindblad Resonance (ILR). The X/P shape is given by stellar orbits undergoing a 2:1 vertical Lindblad Resonance:

\[
\Omega_{p,b} = \Omega - \frac{\nu_z}{2},
\]

where \( \Omega_{p,b} \) is the pattern rotation frequency of the bar, \( \Omega \) is the circular rotation frequency of stars in the disc, and \( \nu_z \) is their vertical oscillation frequency. Essentially, there is a ‘sweet spot’ in radius where the vertical component of stellar orbits is resonant with the bar’s pattern speed, and for the 2:1 resonance, the stellar orbits oscillate twice per bar rotation (i.e., each time the two ends of the bar pass underneath). As this is a resonance, this vertical motion enhancement causes the orbits of these stars to ‘puff’ out of the disc plane at these two points, thus leading to the observed peanut shape in an edge-on projection. Finally, Patsis et al. (2002) explore N-body simulations where X/P bulges develop without a bar at all.

In order to disentangle the various mechanisms and thus constrain galaxy dynamics, it is obviously interesting to measure a number of peanut properties: the radius where it is most prominent, how high above the disc plane it reaches, and how strong it is, in real galaxies. Our methodology provides a framework for measuring these quantities and thus allows to probe the theory via direct observations, as well as comparing real X/P galaxies among themselves. This framework is based on the azimuthal profiles of galaxy isophotes. Throughout our work, we employed the quasi-elliptical isophote fitting software ISOFIT, introduced in C15. As detailed in C15, ISOFIT provides a superior description of isophote deviations from pure ellipses (which real galaxy isophotes are observed to have), than its predecessor, ELLIPSE. These deviations are mathematically expressed as Fourier harmonics, and in ISOFIT, they are ex-

---

1 There are of course exceptions, most notably NGC 128, in which the peanut is the dominant component, and the isophotes crossing the minor axis are highly concave.
An isophote with the characteristic X/P shape (thick curve), obtained by perturbing an elliptical isophote (e = 0.4, thin curve) with the sixth Fourier harmonic (\(B_6 = 0.1\)). The projected radial ‘length’ of the peanut, \(R_\Pi\), is defined in polar co-ordinates (see Figure 1). The angle \(\psi\) is related to the usual polar co-ordinate \(\phi\) as follows. If a point on a circle is defined in polar co-ordinates \((r, \phi)\), and the circle is ‘flattened’ in one direction such that it becomes an ellipse, then the same point has the new co-ordinates \((R, \psi)\). By using the eccentric anomaly as the angular co-ordinate, ISOFIT drastically improves on previous isophote-fitting algorithms, such as ELLIPSE.

Note that generally the harmonic coefficients \((A_n, B_n)\) can have either units of length (assumed in Equation 2), or intensity (as ISOFIT uses and outputs), or they can be dimensionless. Fortunately, it is relatively easy to alternate between units if the isophote semi-major axis and local intensity gradient are known. As usually done in the literature, we plot the dimensionless coefficients (i.e., \(B_n\) in units of intensity, re-normalised by the isophote semi-major axis \(a\) and local intensity gradient \(-\partial I/\partial a\)), as given by:

\[
B_n \rightarrow -B_n \left( a \frac{\partial I}{\partial a} \right)^{-1} ; \quad A_n \rightarrow -A_n \left( a \frac{\partial I}{\partial a} \right)^{-1} . \tag{3}
\]

In the past, quantitative studies of galactic bars have been performed on similar principles, most notably in Ohta, Hamabe & Wakamatsu (1990), Regan & Elmegreen 1997 and Aguerri, Beckman & Prieto 1998 (the latter in particular use diagnostics for bar length and strength derived from isophotal \(n = 2\) Fourier terms), but see also Schwarz (1984) and Buta, Laurikainen & Salo (2004). Out of all the Fourier coefficients of Equation 2, the sixth cosine coefficient \(B_6\) is of particular interest in our work quantifying X/Peanut-shaped features. C15 already suggested that \(B_6\) may trace the X/P feature in galaxies, and qualitatively explored this possibility (see e.g., their Fig. 4). Here we demonstrate that this is indeed the case, and we define the following peanut diagnostics, derived from the \(B_6\) profile (see Figure 2):

(i) \(\Pi_{\text{max}} (= B_{6,\text{max}})\) – the X/P peak, equal to the maximum \(B_6\) amplitude. The quantity \(B_6\), like all the \(A_n\) and \(B_n\) coefficients, is a function of radius, such that each isophote has its own value.

(ii) \(R_{\Pi,\text{max}}\) – the projected X/P length, equal to the (major-axis) radius where \(\Pi_{\text{max}}\) occurs. Note that the true length of a peanut \(l_{\text{max}}\) is only measurable from a galaxy image when the bar is viewed perfectly side-on. As the bar’s viewing angle (\(\alpha\) in our notation) is unknown, we can only calculate a lower limit of the peanut length, that is, the projected radius \(R_{\Pi,\text{max}} = l_{\text{max}} \sin(\alpha)\) (\(\alpha = 0^\circ\) for end-on and 90° for side-on orientation). This latter quantity is straightforward to compute from Equation 2:

\[
R_{\Pi,\text{max}} = R'(\psi) \cos(\psi_i) , \tag{4}
\]

calculated at the isophote with maximum \(B_6\) amplitude, and where \(\psi_i\) is the eccentric anomaly angle of the peanut, given by:

\[
\psi_i = -\arctan \left( \frac{\tan(2\pi/6)}{1 - \epsilon} \right) , \tag{5}
\]

with \(\epsilon\) being the isophote ellipticity.

(iii) \(z_{\Pi,\text{max}}\) – the X/P height, equal to the vertical extent above the disc plane computed from the isophote where \(\Pi_{\text{max}}\) occurs:

\[
z_{\Pi,\text{max}} = \frac{Z_{\Pi,\text{max}}}{\sin(i)} = \frac{R'(\psi_i) \sin(\psi_i)}{\sin(i)} , \tag{6}
\]

where \(Z_{\Pi,\text{max}}\) is the projected height and \(i\) is the inclination angle of the galaxy’s disc (such that 90° corresponds to edge-on). Since X/P structures arise from vertical oscillations (\(\perp\) to the disc plane), the observed vertical extent is diminished in proportion to the observed disc inclination. We correct for this effect for non edge-on galaxies in our
sample through the use of Equation 6, thus recovering the true vertical extent of the peanut, \( z_{R,\text{max}} \). We illustrate how \( R_{R,\text{max}} \) and \( Z_{R,\text{max}} \) are derived from an isophote in Figure 1.

(iv) \( S_R \) — the integrated strength of the X/P feature, which we define as:

\[
S_R = 100 \times \int_{R_1}^{R_2} B_0(R)dR, \tag{7}
\]

where \( R_1 \) and \( R_2 \) are the (major-axis) radii enclosing the part of the \( B_0(R) \) profile higher than the peak half-maximum\(^2 \) (\( B_{\text{max}}/2 \)).

(v) \( W_R \) — the X/P peak width, is the radial extent \( R_2-R_1 \).

Although the harmonic profiles are typically plotted as a function of the isophotal semi-major axis, i.e., ‘a’ in Figure 1, we plot \( B_0 \) as a function of \( R_R \) (see Equation 4 and Figure 1).

In our analysis, an X/P feature can be ‘strong’ in two ways: when it displays a high \( B_0 \) amplitude, or if the peak in the \( B_0 \) profile is extended over a large radial range (i.e., a large \( W_R \)). This will be more clear when we present actual \( B_0 \) profiles in the following sections, and is illustrated here schematically in Figure 2. Both of these cases are accounted for in our definition of the peanut strength diagnostic, \( S_R \). We chose to perform the integral in Equation 7 within the half-maximum limits so that the X/P feature is well separated from other potential components or the noise in the \( B_0 \) profile, as \( B_0 \) approaches zero. Throughout this work, we provide the X/P length, height, strength and peak width from other potential components or the noise in the diffuse galaxy light (i.e., the peanut, bulge, disc) and thus introduces noise/bias in the true shape of these components. To diminish this effect, shorter wavelengths are preferable, particularly since determining the shape of the peanut accurately makes it possible to detect weak or nested peanuts, which would otherwise be lost in the noise.

We compiled a sample of 11 nearly edge-on galaxies with known X/P structures from the literature (Sandage 1961; Tsikoudi 1980; Jarvis 1986; de Souza & Dos Anjos 1987; Shaw 1987; Shaw, Dettmar & Barteldrees 1990). We sourced the imaging for our sample from three archives, namely i) the Hubble Legacy Archive\(^3 \) for visible and NIR imaging taken with the Hubble Space Telescope (HST) ii) Data Release 9 (DR9, Ahn et al. 2012) of the Sloan Digital Sky Survey\(^4 \) (SDSS), where we generally opted for the redder bands (\( r, i, z \)) and iii) the Spitzer Survey of Stellar Structure in Galaxies\(^5 \) (S\(^4\)G, Sheth et al. 2010, Buta et al. 2015) for NIR imaging (3.6\( \mu \) and 4.5\( \mu \)). We decided on the optimal source on a case-by-case basis, depending on the image availability, level of dust obscuration and field of view size. For NGC 128 and NGC 2549, we made use of more than one image.

Table 1 lists the full sample, together with the source archive and bandpass (filter), as well as the morphological classification from the Third Reference Catalogue of Bright Galaxies\(^6 \) (de Vaucouleurs et al. 1991), hereafter RC3. The inclination angle \( i \) of each galaxy is also listed, and was calculated from the axis ratio reported in Salo et al. (2015) for the S\(^4\)G galaxies, and in RC3 for the remainder, while assuming an intrinsic thickness of an edge-on disc of 0.22 (Unterborn & Ryden 2008). The intrinsic thickness is degenerate with the inclination: when a disc approaches an edge-on viewing angle, its axis ratio is dominated by its natural thickness. For this reason, all our galaxies with an RC3 value of \( b/a < 0.22 \) are assumed to be exactly edge-on (\( i = 90^\circ \)). Additionally, Table 1 lists the physical scale (pc arcsec\(^{-1} \)) of each image, corrected for infall into the Virgo Cluster and the Great Attractor, as provided by the NASA/IPAC Extragalactic Database\(^7 \) (NED), plus the 2MASS\(^8 \) \( K \)-band magnitude (\( M_K \)) of each galaxy, as listed in NED. Finally the gas rotational velocity (\( v_{\text{rot}} \)) and the stellar velocity dispersion (\( \sigma_v \)) were retrieved from the HyperLeda\(^9 \) (Makarov et al. 2014) database and are also listed in Table 1 for each galaxy. We used the \( v_{\text{rot}} \) of the gas reported by Giovanelli et al. (1986), Giovanelli et al. (2007), Haynes et al. (2011) and Braun, Thilker & Walterbos (2003) for NGC 678, NGC 4710, NGC 4469 and NGC 7332, respectively; the stellar rotational velocity reported by Bertola & Capaccioli (1977) and Simien & Prugniel (1997) for NGC 128 and NGC2549; and

---

\(^2\) Variations of this can readily be envisaged, and we tested a few but preferred \( R_{R,\text{max}} \).

4 ANALYSIS

4.1 Methodology: Modelling a Strong Peanut – NGC 128

Here we demonstrate our analysis of X/P bulges on the interesting, well-known peanut galaxy NGC 128. This peculiar lenticular galaxy displays a very pronounced X/P structure (Figure 3) and is in fact the first galaxy where such a feature was noted (Burbidge & Burbidge 1959).

The first image that we modelled was the SDSS r-band image. Using ISOFIT, nested isophotes were fit at increasing major-axis steps, each having full freedom in varying their geometric parameters, such as centre position, ellipticity (ε) and position angle (PA). ISOFIT distorts the purely elliptical shapes at each radial location through Fourier terms (Equation 2) whose number (1 to n) are chosen at the start of the run. The modes chosen for our analysis were n = 2, 3, 4, 6, 8, and 10. Briefly, n = 2, 3, and 4 are the standard harmonics used in the literature (n = 2 fits the ϵ and PA, n = 3 fits for asymmetry and n = 4 for boxyness/discyness), whereas n = 6, 8, 10 are higher order terms which in general are negligible but for peanut galaxies are relevant (n = 6 is in fact crucial since this is the harmonic which describes the X/P feature, as we will show). Because odd-numbered harmonics capture even more complicated asymmetries, we did not include n > 3 odd terms.

The first aspect analysed from our isophotal study was the major axis surface brightness profile $μ(R_{maj})$, which we subsequently decomposed into galaxy components. There is a long history of using analytical functions to describe the radial surface brightness profiles of galaxies and their components (see Graham 2013 for a review), with multi-component (≥2) decompositions routinely fit these days (e.g., Laurikainen et al. 2014; Savorgnan & Graham 2016). The decomposition was performed with the software PROFILER (Ciambur in prep.). PROFILER constructs a model $μ(R_{maj})$ from user-defined analytical functions (such as Sérsic, exponential, Gaussian, etc.) each of which is intended to describe a particular photometric component (e.g., the disc, the bulge). The model is built by adding together all the components and then convolving the resulting profile with the instrumental point spread function (PSF). This process is iterated until the best-fitting solution is found. PROFILER employs the Levenberg-Marquardt (Marquardt 1963) minimisation algorithm, as well as a hybrid (fast Fourier transform-based + direct) convolution scheme. PROFILER has many desirable features, such as a fast minimisation process (chiefly due to its efficient convolution scheme), an intuitive graphical user interface, and several options for the choice of PSF profile, specifically Gaussian or Moffat (Moffat 1969) functions, or any user-provided profile in the form of a table of values. For NGC 128, the PSF was characterised by

| Galaxy (peanut) | Telescope (filter) | Type | Scale $[\text{pc arcsec}^{-1}]$ | Inclination $i [\text{°}]$ | $v_{rot} [\text{km s}^{-1}]$ | $σ_ν [\text{km s}^{-1}]$ | $M_K [\text{mag}]$ |

* $v_{rot}$ of stars

Figure 3. NGC 128 in the SDSS r-band. This galaxy has a peculiar disc morphology, particularly at $R \gtrsim 40''$, which is likely related to its interaction with the companion galaxy NGC 127, also displayed here (to the West).

Gas rotational velocities values reported by Courtois et al. (2009) for the rest of the sample.

In Table 1, those galaxies where an inner, nested peanut was found, are henceforth labelled with (a) for the inner peanut and (b) for the outer.
fitting Gaussian profiles to bright unsaturated stars in the image, with the IRAF task IMEXAMINE.

The decomposition of NGC 128’s surface brightness profile is shown in the top panel of Figure 4. In addition to the spheroid component (red curve) and inclined disc component (blue curve), the profile also displays the signatures of two bar components, plotted in cyan. While multiple, nested, bars are known to occur in some galaxies (Friedli et al. 1996, Erwin et al. 2001, Erwin 2011), this instance is particularly interesting as the bulge of NGC 128 is peanut-shaped, and X/P structures are known to be associated with bars. Martinez-Valpuesta, Shlosman & Heller (2006) show how, in their simulations, bars can undergo recurrent buckling events, each giving rise to a progressively longer peanut-shaped structure, but the X/P structures themselves do not co-exist (they occur as single structures at different times, not a nested structure). For NGC 128 though, as we will show below, each of the two co-existing bars has its own corresponding peanut.

The second image that we investigated was a higher-resolution image of NGC 128, taken with the NICMOS – 3 (NIC3) instrument on board the HST. While the field-of-view is small, the better spatial resolution at smaller radii is ideal to showcase the X/P feature of this galaxy, and measure it more accurately than from the SDSS r-band. Again, the modelling was performed with ISOFIT, and additionally, a two-dimensional reconstruction of the image was generated with the IRAF task CMODEL (also introduced in C15). NGC 128 and the reconstructed image are displayed in Figure 5. The residual image (data minus reconstruction) is shown in Figure 6.

If we were to generate a perfect model of the galaxy, then subtracting it from the image would produce a residual map in which the distribution of pixel values is centred on zero, and has some inevitable dispersion due to the noise in the data. However, failing to adequately capture a given photometric component leads to systematics in the residual, which broaden the pixel distribution and cause it to depart from a (narrow) Gaussian shape. We can discern which is the harmonic that captures the X-shape/peanut-shape from Figure 6. The figure shows the distribution of pixel values in the residual image (left-hand panels) and the residual image itself (right-hand panels), for five values of the maximum harmonic order chosen in ISOFIT. The first (top) case corresponds to purely elliptical isophotes (n = 0)10, for which the residual image displays obvious (and essentially expected) X-shaped systematics. The latter are reflected in the relatively broad dispersion of the pixel distribution (the red curve), which also appears to be bi-modal: the bright features are compensated by dark features, each giving rise to its own peak. It is notable that upgrading the model’s

---

10 Strictly speaking, ISOFIT does use the n = 2 harmonic to adjust the ellipticity (ε) and position angle (PA) of ellipses as they are fitted. However, once adjusted, the old ellipses distorted by n = 2 become new ellipses with no distortions (n = 0) but updated ε and PA.
Figure 6. Finding the harmonic order which captures the X/P feature in NGC 128, based on the NIC3 image. Left panels – the red curves represent the pixel distribution in the residual image for five upper limits in the number of harmonic terms, from top to bottom: \( n = 0 \), i.e., no harmonic terms, purely elliptical isophotes (top), \( n \leq 4 \) (middle), \( n \leq 6 \), \( n \leq 8 \) and our preferred model, \( n \leq 10 \) (bottom). The black curve is the same in all five panels, and represents the pixel distribution corresponding to the residual image from the highest-quality model (i.e., the bottom panel), which corresponds to the reconstruction in Figure 5 and is adopted throughout our work. Right panels – residual profiles associated with the five cases considered on the left-hand side.

level of sophistication to the use of \( n \leq 4 \), i.e., the standard boxyness/discyness terms, does little to nothing to improve the fit. The dispersion is just as broad, still bi-modal, and the X-shape just as pronounced (Figure 6, middle panels). This clearly shows that, for edge-on galaxies, the X/P feature cannot be quantified with the \( B_4 \) harmonic term. It is only when the sixth harmonic is included that the pixel distribution suddenly approaches a Gaussian shape, with a dispersion 2.3 times narrower than the \( n \leq 4 \) case (2.5 times narrower than for the pure ellipse model), and the X-shaped feature is adequately captured. The pixel distribution resulting from our highest-quality model (corresponding to \( n \leq 10 \)) is overplotted in black in all panels of Figure 6.

In passing, we note how ISOFT/CMODEL enable the easy visual identification of a background spiral galaxy in the image of NGC 128.

The role played by \( B_6 \) is even more apparent when we plot the radial profiles of the harmonic coefficients. We show the even-\( n \) cosine coefficients output by ISOFT in Figure 7, for the range of harmonic orders \( 4 \leq n \leq 10 \).

In Figure 7, \( B_4 \) (which models boxyness/discyness, as usual) contributes significantly to the isophote shape. The \( B_4 \) profile indicates a transition from discy (\( B_4 > 0 \)) to boxy (\( B_4 < 0 \)) to discy again with increasing \( R_{maj} \). However, it
is not this harmonic which captures the X/P feature, but in fact the \(B_6\) harmonic (Figure 6). It is clear that \(B_6\) dominates over all other coefficients at \(R_{\text{maj}} \gtrsim 20''\). This is in fact the locus where the peanut is most prominent, as we show in Figure 5 through the outer thick contour (which corresponds to \(I_{\text{max}}\)) overlayed on the data and the reconstructed image. As \(R_{\text{maj}}\) decreases, so does the \(B_6\) amplitude, mirroring the isophotes becoming more elliptical (slightly boxy) and the peanut shape less and less apparent. The higher-order harmonics are comparatively low-level, and most likely only serve to refine the final isophote shape, as we shall discuss below.

It is worth noting that at \(R_{\text{maj}} \sim 5''\) there is another peak in the \(B_6\) profile. While this is a radius where the isophote has contributions from other harmonic orders, it is likely that there is in fact a second, nested X/P structure in these inner regions. The use of ISOFIT, therefore, is essential in identifying and measuring very faint X/P structures that would otherwise not be detected.

Curiously, a faint 8-prong pattern is evident in the central \(\sim 6''\) of the residual image, when employing the \(n \leq 6\) model (Figure 6, third panel down). As the \(n = 6\) harmonic describes the X/P shape, the \(n = 8\) term then captures this fainter 8-spoked feature (see Figure 7, third panel down). One can speculate that the latter pattern may reflect that in the central \(\sim 6''\), the spheroid component contributes to the isophote shapes along the minor-axis, and thus the spheroid, disc an peanut together induce a total of eight ‘bumps’ in the shapes of the inner isophotes: two from the disc (along the major-axis), two from the bulge (along the minor-axis) and four from the peanut’s X-like ‘arms’. This pattern might also be caused by the fact that the two nested X shapes are slightly offset from each other, i.e. they do not necessarily have the same point of origin and certainly do not have the same opening angle \(\psi\) of the X ‘arm’ relative to the major-axis (see Table 2). This offset may therefore cause these low-level, leftover systematics, which are corrected by the higher order harmonics.

The five X/P diagnostics of NGC 128 were computed from both the HST- and SDSS- derived \(B_6\) profiles (Figures 7 and 8). This was necessary because, due to the small field of view of the HST image, the integrated strength of the main (outer) peanut could not be measured reliably (\(R_2\) from Equation 7 corresponds to an isophote semi-major axis of \(\sim 38''\), outside of the NIC3 CCD). It also provided a consistency check for \(I_{\text{max}}, R_{\Pi, \text{max}}\) and \(z_{\Pi, \text{max}}\) from two different images of the same galaxy. In addition to the main outer peanut, we also measured the five quantities for the inner peanut. The results are tabulated in Tables 2 and 3.

Figures 4 and 7 nicely show how the two X/P structures of NGC 128 are associated with its two bars. This is indicated through the major-axis radii of the isophotes corresponding to the two peanuts of this galaxy, namely \(R_{\text{maj},a}\) for the inner peanut and \(R_{\text{maj},b}\) for the outer. We draw the reader’s attention to the fact that, for a given isophote, the projected peanut radius \(R_{\Pi}\) is different to the isophote’s major-axis radius \(R_{\text{maj}}\), the latter being always longer than the former (see Figure 1). In Figures 4 and 9 we follow the standard practice of plotting the surface brightness profile as a function of isophote semi-major axis, i.e., \(R_{\text{maj}}\). For consistency, we indicate in these two plots the \(R_{\text{maj}}\) of the isophotes having the maximum \(B_6\) value, corresponding to the two peanuts. These two radii clearly correspond visually to approximately the ends of the inner and outer bars (i.e., the radii where the bar profiles cease to be flat and start to drop off in surface brightness), respectively, though we
recognise that the actual peanut *lengths* are shorter than the bars, which is in agreement with simulations (see the review article by Athanassoula 2016, and also Athanassoula & Misiriotis 2002, Martínez-Valpuesta, Shlosman & Heller 2006).

### 4.2 The Full Galaxy Sample

Having now detailed the analysis and quantification of X/P structures in our case-study of NGC 128, we now present the remaining galaxies. While NGC 128 hosts a remarkably strong and obvious peanut structure, this is not necessarily the case for all such galaxies (moreover, its inner peanut was hidden under the luminosity of the bulge and disc). Peanut bulges come in a wide range of shapes and sizes: some puffing up strongly outside the disc plane and showing a clear X-shape (e.g., NGC 3628, ESO 443-042), others (e.g., NGC 2654, NGC 2683) displaying so-called *spurs* (Erwin & Debattista 2013), some barely perturbing the discy/lenticular shape of their host (e.g. NGC 2549) while others showing peanut-like isophotes ‘pinched’ along the minor axis (e.g., NGC 128, NGC 4469). Nevertheless, our method of isophotal analysis proved robust for all of these cases, as the peanut invariably left its imprint on the radial $B_0$ profiles of these galaxies.

The results of the isophotal analysis (image, reconstruction, residual and $B_0$ profile) for each individual galaxy are shown in Appendix A (Figure A1), while we report the peanut diagnostics in Table 2. Before proceeding, provide some additional remarks concerning some of the galaxies in our sample.

(i) NGC 2549 – This is the second galaxy where we detect both an inner and an outer X/P structure. As for NGC 128, we denote the inner peanut with $(a)$ and the outer with $(b)$. Also similarly to NGC 128, we measured the diagnostics for $(a)$ from an *HST* image, this time taken with the Wide Field (WF) + Planetary Camera (PC), WFPC 2. We refer the reader to Fig. 8 in C15 to see the image, reconstruction and residual, and their Fig. 10 to see the $B_0$ profile. However, because the peak in the outer peanut coincided spatially with the gap between the WF and PC chips, we again opted to model peanut $(b)$ using the SDSS $r$-band image. We show the latter in Figure A1 with an increased number of contours overplotted, to aid the eye in making out the inner peanut. Although we also see the signature of peanut $(a)$ in the SDSS $B_0$ profile, we prefer the higher spatial resolution (and lower seeing) of the *HST* image for measuring it, since poorer seeing smears out and systematically underestimates the X/P peak (we see this in Table 2, where the $B_0$ profile of NGC 128 has lower amplitude for both peanuts in the SDSS data compared to the *HST* data). Again, we indicate the major-axis radii of peanuts $(a)$ and $(b)$ on the surface brightness profile decomposition (Figure 9), and again we see that both radii match approximately the ends of the two bars: $\sim 0.07''$ for bar $(a)$ (in good agreement with the range $8 - 10''$ reported in Laurikainen et al. 2011) and $\sim 0.0168''$ for bar $(b)$.

(ii) NGC 2654 and NGC 2683 – Both of these galaxies display regions of comparatively low brightness, bordered by ‘spurs’, along the major axis on either side of the ‘bulge’, suggesting that they are boxy/peanut (Erwin & Debattista 2013) or barlens galaxies (Laurikainen et al. 2014, Athanassoula et al. 2015) viewed close to, but not exactly, edge-on, with a thin bar aligned such that its viewing angle $\alpha < 90^\circ$ (i.e., not exactly side-on).

(iii) NGC 4111 – This galaxy appears to host an inner peanut as well, at $\sim 2''$, in the SDSS $i$-band image. However, a closer inspection reveals an edge-on dust torus perpendicular to the disc plane at precisely this spatial scale. The obscuration which this induces causes the isophotes to appear ‘pinched’, just as they would if an inner peanut were there. Therefore, we chose to not classify this as an inner peanut, at least not until higher-resolution NIR imaging is available (NB: The ‘inner peanut’ does not show at all in the $B_0$ profile extracted from the *Spitzer* imaging, both $3.6\mu$ and $4.5\mu$).

(iv) NGC 4469 – The major axis of this galaxy is heavily obscured by dust. As there is no NIR image available, we used the reddest SDSS passband $(z)$ image, which has relatively poor S/N, and still shows the dust slightly, in the inner regions (see residual map). Nevertheless, the $B_0$ profile, though noisy, is robust and very nicely shows the peanut signature.

(v) NGC 4710 – The image of this galaxy (and, much more obviously, the residual image) shows two pronounced stripes, which were attributed to dark stripes on the CCDs caused by a bright star (there are two because the image is a mosaic of different individual exposures).

For each galaxy in the sample, we extracted the major-axis surface brightness profile, $\mu(R_{maj})$, and decomposed it...
with PROFILER to obtain the disc scale length. As we have discussed above, X/P structures are closely associated with the galactic discs in which they are embedded. If a disc buckles and gives rise to a bar, which also buckles and gives rise to a peanut, the peanut may reflect the disc’s fundamental properties. A pertinent question, therefore, is: are the peanut’s metrics (size, shape) random, or do they depend on their host disc’s properties? We address this question by measuring the disc’s scale length, $h$, and expressing the peanut height, projected length, peak width and integrated strength in units of $h$, as well as in kiloparsecs. Because our test-case galaxy, NGC 128, displays very unusual (warped) morphology, and the surface brightness profile of its disc is not exponential, but Sérsic ($n \sim 0.4$; see Figure 4), it is not meaningful to assign it a scale length. As such, we only report values of $h$ for the rest of the galaxies in our sample.

The PSF profiles used to convolve the model $\mu(R_{\text{max}})$ were always characterised from bright stars in the image of each galaxy. A second example of a PROFILER decomposition is shown for NGC 2549 in the top panel of Figure 9, where the model consisted of a bulge (Sérsic function, red curve), a disc (exponential, blue curve) and a bar associated with each of the two peanuts (Ferrers functions – Ferrers 1877, cyan curves), once again nicely confirming the bar-peanut connection in this second galaxy with a nested peanut structure.

4.3 Scaling Relations

The data shows a remarkably tight correlation between $R_{\text{H,max}}$ and the integrated peanut strength $S_H$ (i.e., the area under the $B_0$ curve). We display this relationship in the upper panels of Figure 10. As $B_0$ is dimensionless, with any radial dependence normalised out through Equation 3, it is independent of $R_{\text{H,max}}$, and therefore so is $S_H$, which is

| Galaxy | $h$ [arcsec, kpc] | $R_{\text{H,max}}$ [kpc] | $z_{\text{H,max}}$ [kpc] | $S_H$ [kpc] | $W_H$ [kpc] | $\psi$ [°] | shape |

†from HST image, ‡from SDSS image

Note: Due to the non-exponential disc in NGC 128, we do not have an (exponential) scale length $h$ value.
derived from the profile. This relation implies that stronger peanuts are located further out in a galaxy, and it is further surprising that, while reasonably tight in units of kpc, it also holds when expressing both quantities in units of the disc scale length $h$ (Figure 10, top-left panel). This suggests that when a disc defined by a scale length $h$ buckles and forms a bar, which in turn gives rise to a peanut, the resulting peanut still retains the information about its parent disc’s scale length. This is consistent with the scenario proposed by Bureau et al. (2006), who suggest that the different components of galaxies with X/P features (including the peanut component itself) are dynamically coupled, and most likely all originated from the disc material.

We performed basic linear fits to all the trends plotted in Figure 10, which we show as Equations 8, 9, 10 and 11. As NGC 128 ($b$) appears to be an outlier from all the trends, we excluded it from the fits. The fact that this galaxy is an outlier is not entirely surprising considering its peculiarity. More specifically, in addition to its visibly distorted morphology, there is also evidence that it hosts a counter-rotating gas disc, tilted at $\sim 26^\circ$ from its major axis (Emsellem & Arsenault 1997). Perhaps NGC 128 is an example of the scenario proposed by Binney & Petrou (1985), who argue that galaxy interactions (slow accretion: galactic cannibalism) may if not generate, then at least enhance the peanut shape. NGC 128 is just such a galaxy, and we deliberately show its companion NGC 127 in Figure 3, which visibly exchanges material with it. In fact, several of our galaxies display somewhat distorted ($S$-shaped) disc planes, possibly indicating instability due to tidal interaction (e.g., NGC 7332). Note that we expect non-symmetric harmonics (both $A_{n}$ and $B_{n}$ coefficients) in galaxies observed in the process of bar-buckling. For such cases, the dominant shape of the instability would be a strong banana shape, which would likely be described by, e.g., $n = 3$ or, if the disc is comparatively bright at those radial scales, by $n = 5$ (in edge-on disc projection, side-on bar projection).

All the linear regressions were performed with the bisector method. The fit uncertainties were computed through bootstrap re-sampling (10 000 samples), which is best suited for such sparse data.

\[
\frac{R_{\Pi,\text{max}}}{\text{kpc}} = (0.03 \pm 0.08) + (0.53 \pm 0.07) \frac{S_{n}}{\text{kpc}} \quad (8)
\]

\[
\frac{R_{\Pi,\text{max}}}{h} = (0.08 \pm 0.07) + (0.46 \pm 0.05) \frac{S_{n}}{h} \quad (9)
\]

\[
\frac{z_{\Pi,\text{max}}}{\text{kpc}} = (0.15 \pm 0.17) + (0.25 \pm 0.09) \frac{S_{n}}{\text{kpc}} \quad (10)
\]

\[
\frac{z_{\Pi,\text{max}}}{h} = (0.09 \pm 0.06) + (0.21 \pm 0.05) \frac{S_{n}}{h} \quad (11)
\]

That the peanut strength correlates with both its height and its length is not surprising given that the latter two appear to be correlated to each other. As shown in Figure 11, the shorter ($R_{\Pi,\text{max}} \lesssim 2.5 \text{kpc}$) X/P structures follow a characteristic height-to-length ratio of $\sim 0.5 - 0.6$, which breaks down for the longer X/P structures. While the bar orientation (the $\sin(\alpha)$ term mentioned prior to Equation 4) may impact this trend, driving down the observed projected length if not viewed perfectly side-on, the discrepancies can be perhaps also understood from the point of view of the peanut’s age or additional, non-secular processes, as we will speculate in Section 5.

In terms of the peanut height above the disc ($z_{\Pi,\text{max}}$), we found that for all galaxies in our sample this lies in the range $0.1h \leq z_{\Pi} \leq 0.5h$, or equivalently, within $\sim 2.6$ kpc. The stronger peanuts also seem to reach greater heights above the disc plane, though this trend is not as tight as the location–strength relation.

### 4.3.1 Peanut–Disc ScalingRelations

Just as ‘bar strength’ has been tested for correlations with properties of the host disc, such as star formation (e.g., Martinet & Friedli 1997; Aguerri 1999), nuclear activity (e.g., Laurikainen, Salo & Rautiainen 2002; Laurikainen, Salo & Buta 2004; Cisternas et al. 2013), central velocity dispersion (Das et al. 2008), various gaseous features (e.g., Peeples & Martini 2006; Kim, Seo & Kim 2012; see also Athanassoula, Machado & Rodionov 2013), etc., we can now test for correlations between peanut strength and the physical characteristics of the host disc. It is hoped that this will provide a further quantitative setting for testing the different mechanisms proposed for peanut formation, and thus a deeper understanding of their evolutionary path.

We observed a positive, though weak, correlation of the galaxy’s $v_{\text{rot}}/\sigma_{*}$ (Figure 12). This trend shows, in essence, that peanuts are more pronounced in faster rotating galaxies, once more pointing towards their link with the host disc. As before, we performed linear (bisector method) fits to the relations in Figure 12, and estimated the uncertainties via bootstrap re-sampling. We show the relations as Equations 12 and 13. We note, however, the exclusion of 5 data points...
from these fits, namely NGC 2654 and ESO 443-042, as we lacked values for their velocity dispersion, $\sigma_*$; NGC 128(a) and (b), because of ambiguities arising from this galaxy’s complicated morphology (see Section 5); and NGC 4469, as we find that its reported value of $v_{\text{rot}} = 18 \pm 9 \, \text{km s}^{-1}$ is implausibly low for a rotation-supported, edge-on disc galaxy.

\[
\frac{v_{\text{rot, gas}}}{\sigma_*} = (0.21 \pm 0.30) + (0.75 \pm 0.16) \frac{R_{\Pi, \max}}{h} \quad (12)
\]

\[
= (0.32 \pm 0.48) + (2.17 \pm 0.82) \frac{R_{\Pi, \max}}{h}
\]

\[
\frac{v_{\text{rot, gas}}}{\sigma_*} = (0.39 \pm 0.25) + (0.34 \pm 0.06) \frac{S_\Pi}{h} \quad (13)
\]

\[
= (0.47 \pm 0.28) + (0.98 \pm 0.18) \frac{S_\Pi}{h}
\]

We did not find any correlation between any of our X/P diagnostics and the galaxy global, $K_s$-band magnitude.

5 DISCUSSION

Having diagnosed and quantified the X/P features in our galaxy sample, we now shift the focus of the paper to discussing the information encoded in our peanut diagnostics.

Most studies in the literature invoke either the buckling of bars (Raha et al. 1991) or vertical Lindblad Resonances (Combes et al. 1990) to describe essentially the same class of objects. While numerical simulations have been resoundingly successful at reproducing, visually, X/P-like structures, direct comparisons between observations and simulations have seldom been performed. As such, it remains an open question which physical mechanism is responsible for which type of X/P structure. Our study aims, among other things, to provide a set of useful measurements from real X/P galaxies which can act as constraints for $N$-body simulations of galactic dynamics (e.g., Saha & Gerhard 2013).

The first point to note is that our sample galaxies are remarkably heterogeneous in terms of their radial $B\ell$ profile shape. While all show an unambiguous peak in $B\ell$, which is the mark of the peanut, the peak can be shaped like a hump (e.g., NGC 128a, NGC 2549a and b, NGC 4111), hump-on-plateau (NGC 128b, NGC 2654, NGC 4710, ESO 443-042), top-hat (NGC 3628), saw-tooth (steady rise followed by sharp decline; NGC 2683, NGC 4469) or even pyramid (NGC 678). This is not very surprising since bars (and triaxial ellipsoids in general) can host a large variety of orbit families (Patsis, Skokos & Athanassoula 2002, Patsis & Katsanikas 2014a, Patsis & Katsanikas 2014b, Valluri et al. 2015), each of which potentially leaving its characteristic imprint on the photometric morphology of the host galaxy.

If a bar buckles, it forms a peanut in the inner regions (Raha et al. 1991, Athanassoula & Martinez-Valpuesta 2009), and one would expect a relatively flat $B\ell$ profile (e.g., top-hat) along the entire peanut length. On the other hand, a resonance mechanism usually occurs in a narrow radial range, thus corresponding to a comparatively sharper peanut peak (e.g., hump or pyramid). It would be interesting to see from simulations i) whether there is a characteristic $B\ell$ shape for each of the two phenomenologies and ii) how the shape evolves with time.

We might be observing peanuts at different stages of
Figure 12. Top: The $v/\sigma$ ratio as a function of peanut strength. The colour scheme is analogous to Figures 10 and 11. Data points enclosed in squares were excluded from the linear fits (see Section 4.3), which are given by Equations 12 and 13. The data point corresponding to the outer peanut of NGC 128 is a significant outlier of this trend, and is outside (to the right of) the plot area (it was excluded from the fits, where applicable). Bottom: The $v/\sigma$ ratio as a function of peanut length.

their lifetime, i.e., newly-formed or old. As these features have been shown to drift outwards with time (Quillen et al. 2014), the radial length $R_{\Pi,\text{max}}$, coupled with the peak width, $W_{\Pi}$, of the $B_6$ profile, might be an indicator of their age. The latter point is supported by noticing that for the two galaxies which host nested peanuts (NGC 128 and NGC 2549), the inner peanut (which is presumably the younger) has a narrower span than the outer, presumably older X/P structure. For this work, however, we are limited by projection effects and can only measure the projected peanut length, $R_{\Pi,\text{max}} = l_{\Pi,\text{max}} \sin(\alpha)$. This aspect is a strong restriction to any conclusions we may draw from Figures 10 to 12. For now we speculate that we may see tentative evidence of radial drift (starting from the ‘characteristic ratio’ and moving out in radius while keeping the same height) or length/height enhancements due to external, non-secular processes, such as tidal interactions), though we require additional information on the bar’s orientation in the disc plane to draw any conclusions. The key to constraining $\alpha$ may lie in applying our method to edge-on (disc) projections of simulated galaxies viewed at different bar angles $\alpha$, ranging from side-on to end-on. The $B_6$ profiles, which may contain information about $\alpha$, could easily be recovered from isodensity contours of the simulation projections (rather than isophotes). Such a study exceeds the scope of this paper, however, and we defer it for future works.

6 CONCLUSIONS

In this work we define five quantitative diagnostics of X/P structures in edge-on galaxies, based of the sixth Fourier mode ($B_6$) of their isophotes: i) the peak amplitude of the $B_6$ radial profile, $I_{\Pi,\text{max}}$, ii) its projected length along the major-axis, $R_{\Pi,\text{max}}$, iii) its height above the disc plane, $z_{\Pi,\text{max}}$, iv) the integrated strength, $S_{\Pi}$ (Equation 7) and v) the width of the $B_6$ peak, $W_{\Pi}$. Additionally, we introduce a qualitative classification of X/P galaxies, based on the shape of the $B_6$ profile.

We demonstrate our methodology on NGC 128, a galaxy with a very strong peanut, and extend our analysis to a sample of eleven other galaxies known to host such structures. This technique is accurate, easy to implement and automate, and it performs best when using imaging with low dust obscuration (dust-free galaxies or NIR wavelengths).

Our main findings can be summarised as follows:

- The $n = 4$ Fourier harmonic of isophotes ($B_4$) does not describe the X/peanut–shaped structure. Out of all the
Fourier harmonics tested ($0 \leq n \leq 10$), it is the $n = 6$ order ($B_6$ term) which captures the peanut.

- We detect, for the first time, nested peanuts (one inner and one outer) in two of the eleven galaxies of our sample, namely NGC 128 and NGC 2549.
- The galaxies in our sample are quite heterogeneous in terms of their $B_6$ profile shapes (which range from hump-shaped, hump-on-plateau, top-hat, saw-tooth and pyramid, in our classification scheme). We speculate that these may provide insight into disentangling between the various peanut formation scenarios in the literature.
- We identified trends between peanut projected length and strength, and between peanut height and strength. The stronger peanuts are located at larger radii and reach greater heights above the disc plane. These trends hold when expressed in units of kpc and disc scale length, indicating that peanuts ‘know’ about the disc in which they live. Together with an apparently characteristic height-to-length ratio for small peanuts, this constitutes valuable constraints for simulations.
- We additionally identified a positive, though weak, correlation between peanut parameters (length and strength) and the galaxy’s $v_\text{rot}/\sigma_*$, such that faster-rotating galaxies tend to host larger and more pronounced X/P structures. This provides yet more support for the peanut–host disc relation between peanut parameters (length and strength) and between peanut height and strength. The $v_\text{rot}$ expresses warm thanks to Françoise Combes for a very

7 ACKNOWLEDGEMENTS

BCC expresses warm thanks to Françoise Combes for a very stimulating discussion on the topic of X/P galaxies. This research has made use of the NASA/IPAC Extragalactic Database (NED), and the NASA/IPAC Infrared Science Archive (IRSA), which are operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. Funding for SDSS-III has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, and the U.S. Department of Energy Office of Science. Part of this work is based on observations made with the NASA/ESA Hubble Space Telescope, and obtained from the Hubble Legacy Archive, which is a collaboration between the Space Telescope Science Institute (STScI/NASA), the Space Telescope European Coordinating Facility (ST-ECF/ESA) and the Canadian Astronomy Data Centre (CADC/NRC/CSA). We acknowledge the usage of the HyperLeda database.

APPENDIX A: MODELLING THE GALAXIES

In this section we show the results of our ISOFIT/CMODEL analysis for each of the galaxies in our sample. Specifically, in each panel of Figure A1, we show the galaxy image and its orientation, the image reconstruction made with Cmodel in each panel of Figure A1, we show the galaxy image and its analysis for each of the galaxies in our sample. Specifically, in each panel of Figure A1, we show the galaxy image and its orientation, the image reconstruction made with Cmodel in each panel of Figure A1, we show the galaxy image and its analysis for each of the galaxies in our sample.

...
the residual image obtained by subtracting the reconstruction from the original image and, at the bottom, the $B_6$ profile as a function of peanut radius (see Figure 1). The image and its reconstruction both have their respective isophote contours overlayed (at identical levels), and the thicker contour corresponds to the maximum $B_6$ amplitude ($I_{max}$).
Figure A1. Each quadrant, from top to bottom panel: image, model, residual and $B_6$ profile. Thick contours correspond to $\Pi_{\text{max}}$ (the isophote with maximal $B_6$ amplitude).
