ABSTRACT

In the present contribution, we use x-rays to monitor charge-induced chemical dynamics in the photoionized amino acid glycine with femtosecond time resolution. The outgoing photoelectron leaves behind the cation in a coherent superposition of quantum mechanical eigenstates. Delayed x-ray pulses track the induced coherence through resonant x-ray absorption that induces Auger decay. Temporal modulation of the Auger electron signal correlated with specific ions is observed, which is governed by the initial electronic coherence and subsequent vibronic coupling to nuclear degrees of freedom. In the time-resolved x-ray absorption measurement, we monitor the time-frequency spectra of the resulting many-body quantum wave packets for a period of 175 fs along different reaction coordinates. Our experiment proves that by measuring specific fragments associated with the glycine dication as a function of the pump-probe delay, one can selectively probe electronic coherences at early times associated with a few distinguishable components of the broad electronic wave packet created initially by the pump pulse in the cation. The corresponding coherent superpositions formed by subsets of electronic eigenstates and evolving along parallel dynamical pathways show different phases and time periods in the range of \((-0.3 \pm 0.1) \pi \leq \phi \leq (0.1 \pm 0.2) \pi\) and \(18.2^{\pm 1.4} \leq T \leq 23.9^{\pm 1.4}\) fs. Furthermore, for long delays, the data allow us to pinpoint the driving vibrational modes of chemical dynamics mediating charge-induced bond cleavage along different reaction coordinates.

I. INTRODUCTION

Since the pioneering experiments by Weinckauf and Schlag on electron mobility and dissociation in peptide cations,1 the interplay between local ionization and molecular reactivity is of considerable interest in many areas of physics, chemistry, biology, and in the materials sciences.2 Ultrafast photoionization of a molecule leads to a spatial redistribution of electronic charge, i.e., a time-dependent oscillation of its charge density.3 Quantum coherences mediating this...
process are formed and defined by the coherent superposition of several quantum mechanical eigenstates. Pure electronic quantum wave packet dynamics is usually termed “charge migration,” while dynamics involving nuclear degrees of freedom is referred to as “charge transfer.” The most stable and experimentally easily detectable coherences are formed by a pure two-state system with the oscillation period of the charge migration being defined by the energy difference between the two states lying within the spectral bandwidth of the coherent radiation pulse. Examples studied so far show timescales of 100 as to 20 fs.

The correlated motion of electrons leads to the hole localizing at a particular site, where a subsequent photoionization event may result in bond cleavage. Thus, quantum coherences increase the speed and efficiency of electron or hole migration to the reaction centers, but it is also possible for them to decohere due to coupling of electronic with nuclear degrees of freedom during the electronic wave packet propagation. If the coherences are preserved for multiple oscillation periods, the efficiency of photochemical reactions is increased even further, since it is given additional occasions for the charge-induced reaction with each full period after the initial charge formation. Therefore, it is imperative to precisely control the temporal and spectral phase of the radiation as known from photochemical control protocols using table-top lasers. A prerequisite for any control of electronic and nuclear dynamics toward specific molecular reaction pathways is a detailed analysis of structural properties, when the molecule is driven out of equilibrium and here, in particular, the analysis of the time-dependent electronic structure defining the potential energy landscape in which the nuclei move. X-ray photoelectron spectroscopy (XPS) is a well-established technique sensitive to the electronic structure. Applied in a time-resolved pump-probe scheme, it allows us to unambiguously monitor electronic coherences and vibronic coupling long before fragmentation sets in, i.e., while the electronic wave packet propagates.

Linking the electronic quantum wave packet motion to charge-induced chemical dynamics in photoionized glycine (Gly) molecules is the goal of the present study. The amino acid is an abundant basic neurotransmitter in the central nervous system. Due to its compact nature and tendencies to form hydrogen bonds, it facilitates the coiling of proteins and is, therefore, incorporated frequently in hydrophobic protein helices, which results in a partial gas pressure on the order of 10−2 mbar at the nozzle. Under these conditions, only two conformers commonly referred to as Gly I and Gly III are expected to be present in the beam at a ratio of ~2:1. An electrostatic potential is applied to the capillary in order to minimize field inhomogeneities affecting the electron and ion spectrometer performance. The capillary is guarded by a ceramic sheath from electrical contact with the proximal spectrometer electrodes. The charged-particle detection axis is oriented perpendicular to the FEL and to the molecular beam direction. The molecular beam oven is mounted on an XYZ-manipulator, so that the orifice can be steered as close as possible (~1 mm) to the FEL focus resulting in a target density in the interaction zone of about 900 molecules per mm2. Exchangeable noble gas atom beams can be fed into the interaction zone with the FEL beam perpendicularly, was produced using a resistively heated oven design. The crystalline powder was acquired from Sigma-Aldrich with >98.5% purity. The sample reservoir has a 150 mm long stainless steel capillary with a 1 mm outer and 0.5 mm inner diameter attached to the capillary in order to minimize field inhomogeneities affecting the electron and ion spectrometer performance. The temperature-controlled molecular beam source was operated at around 160 °C, which results in a partial gas pressure on the order of 10−2 mbar at the nozzle. Under these conditions, only two conformers commonly referred to as Gly I and Gly III are expected to be present in the beam at a ratio of ~2:1. An electrostatic potential is applied to the capillary in order to minimize field inhomogeneities affecting the electron and ion spectrometer performance. The capillary is guarded by a ceramic sheath from electrical contact with the proximal spectrometer electrodes. The charged-particle detection axis is oriented perpendicular to the FEL and to the molecular beam direction. The molecular beam oven is mounted on an XYZ-manipulator, so that the orifice can be steered as close as possible (~1 mm) to the FEL focus resulting in a target density in the interaction zone of about 900 molecules per mm2.

II. EXPERIMENTAL SETUP

An effusive molecular beam of glycine molecules, crossing the FEL beam perpendicularly, was produced using a resistively heated oven design. The crystalline powder was acquired from Sigma-Aldrich with >98.5% purity. The sample reservoir has a 150 mm long stainless steel capillary with a 1 mm outer and 0.5 mm inner diameter attached to deliver the sublimated molecules to the interaction zone. Both the crucible and the capillary have respective thermocouples and heating elements. In this way, the capillary can be prevented from clogging. The experimental setup, focusing on the molecular beam source operation, the FEL beam propagation, the x-ray FEL pulse characteristics and optics as well as on the performance parameters of the applied electron and ion spectrometers. Section III reports the experimental results, beginning with time-resolved Auger electron spectroscopy in Subsection III A. Here, orbital-selective information at early times of the charge-induced chemical dynamics is derived from the coincidence and correlation analysis of the simultaneously recorded electrons and ions generated by the FEL pulses. The x-ray interaction with glycine molecules results in both intact Gly2+ parent ions and characteristic fragments. The corresponding photoion–photoion coincidence map is discussed in Subsection III B. A detailed wavelet analysis of the recorded time-dependent electron and ion data is presented in Subsection III C.

This final subsection on the experimental results highlights the key observations of the present study, which are time-frequency spectra of different coherent superpositions of electronic states dressed by vibrational excitations along different charge-induced reaction pathways. We conclude with a brief summary and outlook. In the Appendix, useful background information on the continuous wavelet transform is given, which will be used extensively in the analysis of time dependent signals with multiple frequency components and variable amplitudes in Sec. III and Subsection III C, respectively.
The Free-Electron Laser in Hamburg (FLASH) at Deutsches Elektronen-Synchrotron DESY is capable of producing single-spike, self-amplified spontaneous emission (SASE) radiation pulses with a high degree of longitudinal coherence and a spectral bandwidth of $\Gamma = 0.37\%$ at a central wavelength of $\lambda_{\text{FEL}} = 4.55$ nm corresponding to an FEL photon energy of $E_{\text{FEL}} = 272.7$ eV. The small spectral bandwidth of the fs pulses allows for resonant excitation of a particular core-shell transition in the glycine cation with high specificity while tracking the molecular dynamics with fs resolution. The single-spike operation at the FLASH facility is achieved by using a photoinjector laser with reduced pulse duration and by limiting the bunch charge compared to the typical SASE operation in order to facilitate the electron bunch compression.22,23 Running the electron gun with a pulse duration of 1 ps instead of 6.5 ps and bunch charges of 35 pC instead of 1 nC leads on average to 1.5 FEL spikes per photon pulse with Fourier-limited rms pulse duration of only $24 \pm 0.2$ fs, albeit at reduced x-ray pulse energies below 2 $\mu$J. The pulse energies are measured with noninvasive gas monitoring detectors, which count the number of electrons generated in a low-density gas target on a pulse-to-pulse basis with an accuracy of 10%.24 Single-spike lasing at FLASH has been fully characterized for a central wavelength of 7 nm25 and has been used successfully for time-resolved FEL experiments at wavelengths down to 4.5 nm.26,27 Up to 500 photon pulses with 1 $\mu$s spacing are grouped in a pulse train of around 0.5 ms total length. The nearly collimated FEL beam is focused by a nickel-coated toroidal mirror with a mirror surface of $25 \times 25$ mm$^2$ and 5.7 m focal length onto the molecular glycine beam. Assuming a TEM$_{00}$ mode, the Rayleigh length and beam waist radius are 291 mm and 20 $\mu$m, respectively. The toroidal mirror is mounted on a hexapod that allows it to move the toroid with mm and $\mu$Rad precision. This facilitates exact steering of the FEL beam through the detection chamber despite the 5.7 m long lever arm as well as matching the nominal 8° incidence angle of the toroidal mirror to prevent any astigmatism. A schematic overview of the experimental setup is shown in Fig. 1.

The electrons and ions generated in the interaction of the ultra-short FEL pulses with glycine molecules are detected simultaneously in opposite directions. In total, 13 electrostatic potentials at the ion TOF and the electron MBES can be applied to guide the particles as indicated in Fig. 1. Retardation voltages (Ret 1–4) can be used to discard low energy electrons and fine-tune the energy resolution of the remaining electrons. The ion drift tube needs to be quite short to allow for collection of the heavy and slow ions before the arrival of the next FEL pulse, i.e., keeping their time-of-flight below 1 $\mu$s. This, however, reduces the mass-to-charge resolution. The magnetic field of the permanent magnet in the interaction zone is 400 mT, and the electron drift tubes are wrapped in a solenoid to form a homogeneous magnetic field of 8 mT, which yields a kinetic energy resolution of $\Delta E / E = 2\%$. Both the electron and the ion side use double multichannel plates (MCPs) in a chevron arrangement. The initial MCP signals are fed into conventional pre- and output amplifiers before being further analyzed by a time-to-digital converter and recorded. The positions of the detector and electrodes of the MBES are fixed, whereas the positions of the interaction volume given by the FEL focus and the capillary and delay unit (SDU) based on interleaved reflective gratings.28–30 This device is located in front of the focusing mirror and has been described in detail elsewhere.31 Briefly, given the absence of transmissive beam splitters in the soft x-ray spectral range, splitting one FEL pulse into two time-delayed pulse replicas (pump and probe) can be achieved by two split half-mirrors with a relative longitudinal displacement and illuminated at grazing incidence. However, the two beams then need to be re-overlapped under an angle in the focus, which

**FIG. 1.** (Left) Top-view of the experimental setup scheme. The FEL pulses are split into two pulse replicas with adjustable time delay by the “Split-and-Delay Unit” (SDU) and focused toward the interaction zone, where the glycine sample is evaporated by a molecular beam source. Absolute calibration of the FEL pump—FEL probe delays is achieved by means of optical laser and white-light interferometry (WLI) tracking the SDU optics displacement. (Right) Cross section of the magnetic bottle electron spectrometer (MBES) and ion time-of-flight (TOF) spectrometer. (Inset) Structural formula of glycine.
results in tilted wavefronts, thus averaging of their relative phase in the focal volume. Furthermore, large Mach–Zehnder SDUs that are usually used at FELs require several x-ray optics compromising stability and overall transmission of the device. Alternatively, using two interleaved reflective gratings in the present setup naturally produces two collinear pulses in a single reflection of each beam path. The generated pulse pair exhibits a constant phase difference across the beam profile with equal 1:1 intensity sharing and robust spatial overlap. One of these nickel-coated grating mirrors is fixed, while the second one can be vertically and horizontally pivoted in order to planarly align the two mirrors with nanometer precision under a fixed grazing incidence angle of 8°. The movable grating mirror can also be linearly displaced in the direction of the surface normal to enable the delay of one of the two pulse replicas. The 3D position of the movable mirror is monitored by means of optical laser and white-light interferometry (WLI) for absolute calibration of the FEL pump–FEL probe delays. Furthermore, the recorded data are used in an active feedback stabilization loop based on a field-programmable gate array while the delay is scanned. Thereby, the compact instrument minimizes temporal jitter and allows for time-resolved soft x-ray pump-probe electron and ion spectroscopy with a single-digit attosecond precision and a maximum useful scan length of about 1 ps time delay.32

III. RESULTS AND DISCUSSION
A. Time-resolved Auger electron spectroscopy upon resonant x-ray absorption

Important insight about the charge-induced chemical dynamics in glycine is gained from electron spectra taken as a function of x-ray-pump–x-ray-probe delay. Nonetheless, one has to keep in mind that high-energy FEL pump photons open-up various energy absorption and energy redistribution channels by generating electronically excited many-body states in the glycine cation.33 Thus, the main challenge of the present study is to discriminate those in order to observe the subsequent chemical dynamics upon photoionization of a particular inner-valence orbital. Glycine has 40 valence electrons occupying 20 closed-shell molecular orbitals (MOs) for which the first 17 binding energies are listed in Table I. The notations a′ and a″ denote in- and out-of-plane orbitals. The a′ orbitals can comprise of σ and/or π symmetry MOs, whereas a″ only comprises of π symmetry MOs. The discrimination between different valence ionization and subsequent relaxation channels is achieved by detecting the generated electrons and ions simultaneously shot-by-shot and by looking at electron–electron coincidences and electron-ion correlations. In the following, we discuss the overall coherent dynamics probed by time-resolved Auger electron and ion spectroscopy.

The pulse pump with a central photon energy of 273 eV ionizes the glycine molecule, marking Δt = 0. The kinetic energy of the outgoing photoelectron provides information about the involved MOs. In the applied experimental scheme depicted in Figs. 2(a)–2(d), events featuring electrons with Ekin = (253 ± 1.0) eV, where ΓFEL = 1.0 eV is the FEL’s bandwidth, from the 10a′ orbital are of interest. The 10a′ orbital spans nearly the full molecular backbone, and in consequence, the transient local electron–hole density moves to the same extent, thus making this orbital an excellent candidate for the study of charge-induced chemical dynamics involving geometric changes. The prepared electron–hole state undergoes oscillatory charge migration according to its effective and conformer-dependent level splitting of $E \approx 0.2$ eV mediated by electron correlations.36,37 The two distinct levels indicated in Fig. 2(c) for simplicity are both comprised of $\approx 50\%$ of a pure inner valence hole state (1h) character and $\approx 50\%$ of a series of two-holes-one-particle (2h1p) configurations.35 The superposition of these cationic eigenstates possesses a high degree of electronic coherence on the order of 95% according to theory. If the electronic wave packet survives until after the variable time delay $\Delta t$, and the pure 1h state is localized in the vicinity of the C$_\text{Gly}$ nucleus again, the 273 eV probe pulse will resonantly excite a C$_\text{Gly}$ 1s electron into the 10a′ vacancy, allowing for subsequent Auger decay and emission of an Auger electron. The resonance of the probe-induced Auger decay as a function of photon energy was observed by counting the 10a′ photoelectron–Auger electron coincidences falling into the characteristic energy detection windows as shown in Fig. 2(e). This detection scheme selectively addresses coherent dynamics involving the 10a′ orbital. Other processes, which are certainly possible, do not contribute to the electron–electron coincidence data and, therefore, do not affect the interpretation of the data. In these measurements, the FEL photon energy was tuned in the range between 269 and 281 eV,38 which is specifically chosen to stay beneath the carbon K-edge (284.2 eV) as well as the nitrogen and oxygen K-edge (410 eV, 543 eV).39,40 Note that the molecule has two C1s orbitals, 4a′ and 5a′ with an energy difference of 2.9 eV, which is somewhat larger than the spectral bandwidth of the FEL. A coherent superposition of these states in the resonant absorption process is not possible with the limited x-ray pulse bandwidth. Also note that the corresponding time period of 1.4 fs for the 2.9 eV energy difference lies beyond the present time resolution of the pump-probe experiment.

Table I. Experimental binding energies (BE) of glycine orbitals (conformer Gly I) in eV. a′ and a″ denote different orbital orientations (in-plane and out-of-plane). O$_\text{C}$ belongs to the carbonyl group (C = O), while O$_\text{H}$ belongs to the carboxyl group (C–OH).
The measured yield of Auger electrons vs pulse delay represents the oscillatory positive charge density with time period $T = 19.6^{\pm 1.4}$ fs, since the $5a' \rightarrow 10a'$ transition will more likely occur, the closer the transient hole is to the corresponding $C_a$ atom. With this scheme, we could characterize the birth, propagation, and fate of the electronic coherences in a kinematically complete recent experiment. In brief, we counted the multi-particle events and plotted the relative change of the detected electron yield correlated with the generation of a Gly$^{2+}$ parent ion and recorded together with an electron at the kinetic energy corresponding to valence ionization of $10a'$ as a function of pump-probe delay. The time-resolved Auger electron spectroscopy result is shown in Fig. 2(f). Advanced ab initio many-electron simulations using the time-dependent B-spline restricted correlation space–algebraic diagrammatic construction (ADC) simulation method allowed us to explain the detected coherent quantum evolution in terms of the electronic coherence at early times. Its dynamics is monitored for a period of 175 fs. An important observation for the present study on charge-induced chemical dynamics mediated by nuclear motion is an evolving modulation that implicate the coupling of electronic to vibronic coherence at longer time scales. The glycine cation comprises $N = 10$ atoms resulting in $3N - 6 = 24$ normal modes for nuclear motion. As we will see in the following, if the probe-induced Auger electron yield is...
The authors observed that the most common fragmentation pathway probed in our time-resolved study, we plot the time-resolved X-ray-induced photoion–photoion coincidence (PIPICO) map. Very similar to the synchrotron work discussed above, the major fragmentation pathways include C–C bond breakage resulting in fragments with \( \frac{m}{q} \) of (30, 45) and further splitting into (16, 45), (27–30, 28–29), (16, 28–29), and (16, 16–17) or minor variations as can be seen in Fig. 3(b). The decreasingly smaller fragment pairings exhibit exponentially increased yields. The second pathway of water elimination sketched in Fig. 3(c) produces the combinations (18, 57), (28, 29), (12–14, 28), (16, 29), or (12–14, 16). The doubly charged [NH–CH₂–CO]²⁻ cannot be present in the PIPICO map albeit as false coincidences. We note in passing that near-diagonal elements may also appear due to false coincidences. Furthermore, a coincidence of two cations with a combined mass larger than one glycine mass leads to false ion and thereby false electron coincidences. Similarly, any coincidence events including a dication and another charged ion result in false coincidences. The indicated region of false coincidences including Gly²⁺ is experimentally larger due to the limited ion TOF spectrometer resolution. For other dications, the false coincidences are more difficult to isolate because of overlap with singly charged cations.

From the time-integrated PIPICO-map shown in Fig. 3(a), one can conclude that the probe-induced core–shell transition, i.e., the resonant C₄s electron excitation into the 10a' vacancy, mainly leads to fragmentation processes governed by the rupture of the C–C₄ bond. It seems to involve the localization of the positive charges to the opposite sides of the C–C₄ bond, which is reasonable from the viewpoint of Coulomb repulsion. However, it is important to note that the 10a' inner-valence orbital (also in the dicaticon state of glycine) is delocalized over the entire molecule as can be seen from the inset in Fig. 2(b). Therefore, the probe-induced ion fragment distribution is quantum mechanically determined by the Auger final states of Gly²⁺, not by classical Coulomb forces as pointed out already by Ità et al. Furthermore, the resonant 5a' → 10a' transition between the electronic states as a function of pump-probe delay is accompanied by a transition of vibrational states. Note the vibronic coupling, which results in a change of the internuclear distance, is greatly enhanced in the vicinity of conical intersections or avoided crossings. In this case, the Born–Oppenheimer approximation fails, and the nuclear and electronic wave functions can no longer be separated. Indeed, energy spacings in the energy region of partial breakdown of the molecular orbital picture to which the 10a' states of the glycine cation belong are of the same order of magnitude as some of the vibrational quanta, and the two degrees of freedom are expected to strongly couple, resulting in quantum eigenstates represented by linear superpositions of electronic states dressed by vibrational excitations. Thus, the full electronic coherence initially brought to life by the few-fs ionization of glycine in the inner valence region discussed in Subsection III A is very likely of mixed electronic and vibrational character and a few oscillations are reflected in the spectrum.
Structural Dynamics

C. Wavelet analysis of multi-particle correlations between electrons and fragment ions

The remaining question is whether the subsequent electron-nuclear dynamics mediating the dissociation of the dication—after the second ionization produced by the probe pulse—still allows one to disentangle the coherent dynamics observed in the cation. In particular, it is interesting to ask the question whether it is possible to extract different characteristics of the electronic coherence at early times depicted in Fig. 4(a) by correlating the recorded time-resolved electron spectra with the occurrence of specific fragments in the TOF mass spectra. Apart from the photoelectron–Auger electron–Gly2+ (three-particle) correlation, two further species of correlated cationic fragments show fingerprints of x-ray pump-induced coherent dynamics in the recorded three-particle correlation. These are H⁺ and H₂O⁺, respectively, as well as the group of NH₃⁺, COOH, and H₂O⁺ that could not be resolved because of the limited mass-resolution of the short TOF spectrometer. Figure 4(b) shows the change of the time-dependent electron yield up to pump-probe delays of 35 fs for the two groups including the data related to the Gly2+ parent ion for comparison. All pump-probe traces use the same electron kinetic energy selection as before, i.e., the analysis is focused on glycine Auger electron emission and subsequent chemical dynamics following 10a’ photoionization.

It can be seen that the different fragmentation channels still monitor the charge (hole) migration in the spatially extended 10a’ molecular orbital with a time period of ~20 fs albeit showing slightly different relative phases. This experimental result supports the assumption that by measuring specific fragments associated with the dication as a function of the pump-probe delay, one can selectively probe electronic coherences associated with a few components of the electronic wave packet created initially by the pump pulse in the cation as predicted theoretically by Delgado et al.52 It seems that the energy gaps between the coherently coupled electronic states do not vary too much along the reaction coordinate during the first few tens of fs, allowing the electronic coherences to survive long enough to leave their signature in the time-resolved fragmentation spectra.

In order to fully unravel the impact of vibrational modes on the energetics and dynamics of the populated cationic states, further theoretical work is necessary. Recently, interesting results have been reported by Delgado et al.52 The fragmentation study evaluated the full-electron wave function including non-adiabatic effects and revealed early electron dynamics induced by attosecond pulses. A
direct comparison is somewhat difficult, since in the present experiments, small-bandwidth, soft x-ray FEL pulses at 273 eV have been applied, whereas the theoretical work focused on broadband XUV photon pulse excitation typical for high-harmonic generation (HHG) sources. The calculations were performed for pulses centered at three different photon energy, 12, 16, and 20 eV, which result in much broader wave packets and, thus, shorter time periods of the induced chemical dynamics.

The complete ion-correlated XPS dataset spanning a 175-fs time-scale for the two groups of fragments is shown in Figs. 4(c) and 4(d). At first glance, the data show pronounced oscillations also for long delays. In order to better understand the dynamic oscillation period and its amplitude evolution, a time-frequency distribution was produced using the continuous wavelet transform with Airy wavelets (see the Appendix and Ref. 53). The oscillation frequencies in the corresponding false color plots presented in Figs. 4(e) and 4(f) were converted to periods for better comparability. The so-called "cone of influence," where part of the wavelet in time domain extends past the finite recorded experimental signal trace, is removed from each plot. Here, artificial edge effects disturb the frequency analysis at early times and, therefore, are not taken into account in the present analysis of vibrational timescales for small molecules such as glycine are generally in the range of 10–100 fs for particular bonds and partial groups and up to 1 ps for intramolecular vibrations. Rotations of small moieties around bonds are significantly slower and carried out on timescales of 100–350 ps, which is far too slow to affect the present results. What follows is a brief discussion of potentially involved vibrational modes mediating charge-induced bond cleavage along different reaction coordinates albeit not yet substantiated by theoretical simulations of the induced chemical dynamics.

1. H+ and H2 PEPEPICOV yield

We assume that the relative change of the electron yield correlated with H+ and H2 ion detection monitors part of the initial electronic coherence that couples to CH2 bending (δ) and wagging (ω) vibrational modes with time periods in the range of 22.8 and 23.1 fs, respectively. The detected protons and H2 ions together with the Auger electron signal, which is particularly sensitive to the local C–H moiety, likely originate from the –C–H2–moiety of glycine. Here, the hole state localizes, and the resonant core-inner valence absorption can take place before any other fragmentation of the molecule sets in. In other words, the local soft x-ray probe pulse absorption into the 10a state at the –C–H2– moiety populates dissociative reaction channels of vibrationally excited glycine molecules. We are aware of the fact that the picture of hydrogen fragmentation from hot related vibrational modes, although physically reasonable, remains incomplete and ultimately requires a more detailed formulation. Basically, the many body wave packet dynamics shown in Fig. 4 is of mixed electronic and vibrational character. The full time-dependent characterization of its time-frequency spectrum
theoretically within the highly computationally demanding inner-valence energy region is currently beyond reach and should be the subject of future theoretical studies.

2. \( \text{NH}_2^+ \) and \( \text{H}_2\text{O}^+ \) PEPEICOV yield

The same holds true for the observed chemical dynamics, which involves the generation of \( \text{NH}_2^+ \), \( \text{O}^- \), \( \text{OH}^- \), and \( \text{H}_2\text{O}^+ \) ionic fragments being even more complex. According to the wavelet analysis of the recorded data, it contains both a 20.6 fs and strong 39.4 fs vibrionic component covering the first ~130 fs. These fragments are products from both discussed fragmentation pathways (C–C bond breaking or water elimination, see Fig. 3), making the interpretation of the vibrational modes difficult. Slower, delayed oscillations can be generally attributed with intramolecular degrees of freedom for nuclear motion. According to experimental work by Rosado et al.,\(^{56}\) there exists a prevalent vibrational mode with a period of 41.7 fs mainly consisting of \( \nu \text{C}–\text{C} \) stretching (45% contribution) and \( \nu \text{NH}_2 \) rotation (13%). Another vibrational mode with intermediate intensity consisting of \( \nu \text{NH}_2 \) (46%), \( \nu \text{C}–\text{C} \) (17%), and \( \delta \text{NH}_2 \) (16%) has a period of 37.8 fs.\(^{55}\) The 20.6 fs oscillation shown in Fig. 4(f) likely does not relate to electronic coherences as it is present for over 130 fs but instead might relate to NH\(_2\) bending (\( \delta \text{NH}_2 \) (71%), \( \nu \text{NH}_2 \) (24%)) with a period of 20.5 fs.\(^{56}\) The \( \nu \text{C} = \text{O} \) stretch vibration has a similar period of 18.7 fs\(^{55}\) and might be enabled in this selective ion channel after the electronic decoherence time, requiring coherent vibrionic coupling. Additional characteristic modes such as C–O stretching with 30.3 fs, C–N stretching plus C–C vibrations corresponding to 32.2 fs,\(^{55}\) and further C–C stretching modes with periods of 24.1\(^{55}\) and 26.4 fs\(^{55}\) might also play a role in the recorded time-dependent fragmentation pattern. However, their relative contribution cannot be extracted from the present dataset.

We would like to emphasize that all values taken from Ref. 56 are reported for the neutral glycine molecule. Therefore, the data interpretation striving to pinpoint the driving vibrational modes in the cation that mediate bond cleavage along different reaction coordinates can only be regarded as a first attempt to shine light on the charged-induced chemical dynamics at work in this many-body quantum system. Furthermore, the involvement of \( \text{NH}_2 \) to a lesser degree \( \text{O}^- \), \( \text{OH}^- \), and \( \text{H}_2\text{O}^+ \) in both the recorded ion yield and the related vibrational modes implies that the oscillatory yield pattern is a result of protonation likelihood based on the oscillatory intramolecular –H · · · O– proximity. It has yet to be resolved whether each of the two main oscillations (20.6 and 39.4 fs) can be attributed to a particular fragment. It is so far also unclear what role the resonant \( \text{C}_2 \) is to inner valence excitation (5a' → 10a'), for which the Auger electron channel is sensitive, plays in the protonation process. In any case, we are convinced that the presented experimental findings will prove beneficial for the development of theoretical treatments of the complex interplay between electronic states and nuclear degrees of freedom.

IV. SUMMARY AND OUTLOOK

Time-resolved Auger electron spectroscopy in a single-color, x-ray pump-probe scheme was applied to study charge-induced chemical dynamics in the cation of the amino acid glycine (Gly\(^+\)). The breaking of covalent bonds in the molecule is triggered by inner-valence photoionization with few-fs pulses at a photon energy of 273 eV. This pump photon energy was chosen because it opens an orbital-selective and element-specific detection window to probe charge dynamics exclusively in the 10a' molecular orbital. The discrimination is based on the probe-induced, resonant core-shell electron transition (5a' → 10a') followed by Auger decay. Coincidence detection and covariance mapping of electrons and ions generated in the interaction of Gly\(^+\) with the time delayed fs FEL probe pulses allowed to trace the life cycle of the electronic wave packet including its birth, propagation, and fate. By correlating the recorded x-ray photoelectron spectroscopic data to specific fragment ions as a function of time delay, we monitored how the initially prepared pure electronic wave packet of the spatially extended 10a'molecular orbital couples to specific vibrational modes propagating along selected dissociation pathways, while the charge-induced chemical dynamics proceeds in the parent ion.

The key result is that different fragmentation channels still monitor the initial charge migration in the 10a' molecular orbital at early times with a time period of \( \approx 20 \) fs albeit showing slightly different relative phases. This observation indicates that by measuring specific fragments associated with the dication as a function of the pump-probe delay, one can selectively probe electronic coherences at early times associated with a few components of the broad electronic wave packet induced by the pump pulse in the cation. After a few oscillations, strong vibrionic coupling sets in because the energy spacings in the energy region of partial breakdown of the molecular orbital picture to which the 10a' states belong are of similar magnitude as some of the vibrational quanta. It results in a complex interplay between electronic states and nuclear degrees of freedom. Even at short timescales vibronic coherence can play a role, and further theoretical work is necessary to disentangle (if possible) the impact of electron and vibronic coherence.

Obviously, the initial ionization starts multiple dynamical pathways, which are driven by the electronic 10a' superposition state dressed by multiple vibrational modes. From the experimental data, we conclude that the transient electronic signature corresponding to specific channels (H\(^+\), H\(^2\)\(^+\)) and (NH\(_2\)\(^+\), H\(_2\)O\(^+\)) is already subtly different, and, for instance, if we could fully resolve the Auger spectrum (down to vibrational substructure) or could measure the XPS at high resolution, we assume that we would be able to identify these two distinct channels emerging after \( \approx 35 \) fs also spectroscopically. Nonetheless, this subtle difference is seen in the small phase and time period differences of the electronic coherences observed in Fig. 4(b). Taking together the electronic and nuclear system, these parallel dynamical pathways evolve into the propensity for different fragment patterns following the probe step. In other words, the selected fragment ion changes the contributions of the vibrational modes to the specific observed pathway.

The time-frequency spectra of the many-body quantum mechanical wave packets represented by coherent superpositions of electronic states dressed by vibrational excitations have been measured for the first time along different reaction coordinates in the cation. We could show that the observed coherences reveal rich information on the many-body quantum system including ultrafast decay and site-specific couplings that differ in phase. The presented experimental results provide a strong incentive for further development of theoretical tools to approach these important aspects of many-body quantum dynamics.

In order to retrieve absolute phase information of the excited coherences from the experimental data, more sophisticated ultrafast methods are necessary, which rely on nonlinear interferometric measurements.\(^{59}\) Wavepacket interferometry and coherent...
multidimensional spectroscopy are well-established methods to probe the structure and dynamics of quantum systems with high time resolution and wavelengths ranging from the ultraviolet to the far infrared and beyond. The transfer of these methods toward XUV and soft x-ray photon energies is, of course, highly desirable. However, it imposes quite some challenges to the experimentalists due to the required ultra-high timing and phase stability of the instrumentation, and only a few examples have been reported so far. In any case, it can be safely concluded that the pioneering experimental and theoretical works in the field of ultrafast x-ray atomic and molecular physics in the past decade open up new exciting possibilities to study many-body quantum effects in electron and nuclear dynamics. 

**ACKNOWLEDGMENTS**

We acknowledge DESY (Hamburg, Germany), a member of the Helmholtz Association HGF, for the provision of experimental facilities. The experimental part of this research was carried out at FLASH, beamline FL24. Beamtime was allocated for Proposal No. F-20191551. This work was funded by the Deutsche Forschungsgemeinschaft (DFG; German Research Foundation) through the Cluster of Excellence “Advanced Imaging of Matter” (EXC 2056, project ID 390715994), the Collaborative Research Center “Light-induced Dynamics and Control of Correlated Quantum Systems” (SFB-925, Project No. 170620586), Project Nos. KI 482/20-1 and LA 1431/5-1, and the Federal Ministry of Education and Research of Germany under Contract No. 05K10C1H. M.R. and V.A. acknowledge financial support from the UK Engineering and Physical Sciences Research Council through Grant No. EP/V009192/1. J.P.M. acknowledges financial support from the UK Science and Technology Facilities Council and the UK Engineering and Physical Sciences Research Council through Grant No. EP/R019509/1. We also acknowledge the scientific exchange and support of the Center for Molecular Water Science (CMWS) and support of the Innovation Pool of the Research Field Matter of the Helmholtz Association (ECRAPS). We acknowledge the use of the Maxwell computational resources operated at Deutsches Elektronen-Synchrotron DESY, Hamburg, Germany.

**APPENDIX: WAVELET ANALYSIS**

In general, a wavelet analysis allows to study the amplitude evolution of a non-stationary signal at scaling frequencies. A wavelet \( \psi(t) = g(t) e^{i \omega t} \) is a modulated signal with frequency \( \omega \) convoluted with an envelope \( g(t) \). The classification and naming of wavelets refer to the shape of the envelope. The generalized Morse wavelets encompass a wide selection of wavelets by introducing the shaping parameters \( \beta \) and \( \gamma \) describing the width of the envelope in frequency and time domain. With \( \gamma = 3 \), so-called Airy wavelets, the most Gaussian-like envelope shape can be achieved as well as the symmetry in frequency domain maximized. The generalized Morse wavelets \( \Psi_{\beta,\gamma}(\omega) \) in frequency domain are given by Lilly and Olhede as

\[
\Psi_{\beta,\gamma}(\omega) = \int_{-\infty}^{\infty} \psi_{\beta,\gamma}(t) e^{-i \omega t} dt = H(\omega) \psi_{\beta,\gamma}(\omega) e^{-\gamma \omega^2}, \tag{A1}
\]

where \( \psi_{\beta,\gamma} \) is a normalization constant and the Heaviside function \( H(\omega) \) ensures that \( \Psi_{\beta,\gamma}(\omega) = 0 \) for \( \omega < 0 \). We use a time-bandwidth product of \( \beta \gamma = 60 \) and 48 voices per octave. The boundary where part of the wavelet in time domain extends past the finite signal is called "cone of influence" (COI). The COI is chosen as the points where the autocorrelation magnitude of the respective wavelet decays by \( \frac{1}{2} \).
