Organisms adapt their metabolism and draw on reserves as a consequence of food deprivation. The central role of the liver in starvation response is to coordinate a sufficient energy supply for the entire organism, which has frequently been investigated. However, knowledge of how circadian rhythms impact on and alter this response is scarce. Therefore, we investigated the influence of different timings of starvation on global hepatic gene expression. Mice (n = 3 each) were challenged with 24-h food deprivation started in the morning or evening, coupled with refeeding for different lengths and compared with ad libitum fed control groups. Alterations in hepatocyte gene expression were quantified using microarrays and confirmed or complemented with qPCR, especially for lowly detectable transcription factors. Analysis was performed using self-organizing maps (SOMs), which bases on clustering genes with similar expression profiles. This provides an intuitive overview of expression trends and allows easier global comparisons between complex conditions. Transcriptome analysis revealed a strong circadian-driven response to fasting based on the diurnal expression of transcription factors (e.g., Ppara, Pparg). Starvation initiated in the morning produced known metabolic adaptations in the liver; e.g., switching from glucose storage to consumption and gluconeogenesis. However, starvation initiated in the evening produced a different expression signature that was controlled by yet unknown regulatory mechanisms. For example, the expression of genes involved in gluconeogenesis decreased and fatty acid and cholesterol synthesis genes were induced. The differential regulation after morning and evening starvation were also reflected at the lipidome level. The accumulation of hepatocellular storage lipids (triacylglycerides, cholesteryl esters) was significantly higher after the initiation of starvation in the morning compared to the evening. Concerning refeeding, the gene expression pattern after a 12 h refeeding period largely resembled that of the corresponding starvation state but approached the ad libitum control state.
INTRODUCTION

Organisms handle periods of food deprivation by drawing on reserves and adapting their metabolism. Humans use fasting to lose weight and for spiritual reasons. The liver is the central hub for metabolic processes, including glucose, amino acid, and lipid metabolism. Therefore, the impact of fasting and refeeding is immense, especially on hepatic parameters (Longo and Mattson, 2014). In this study we addressed the question how the circadian regulation influences the hepatic starvation response with a rarely but powerful used approach called self-organizing map (SOM).

Livers in the post-prandial state store excessive metabolites as glycogen and produce fatty acids, which are transiently stored as triacylglycerides (TAGs) or secreted as very low density lipoprotein (VLDL) (Rui, 2014). The liver synthesizes new carbohydrates and produces ketone bodies in periods of prolonged fasting after depletion of glucose stores. Hormones, such as insulin and glucagon, regulate these processes at a systemic level, and transcription factors, such as PPARs (peroxisome proliferator activated receptor), SREBP transcripts (sterol regulatory element binding transcription protein), and ChREBP (carbohydrate-responsive element-binding protein) or MLX-interacting protein-like (MLXIPL) adjust the metabolism at the molecular level.

Besides the impact of feeding state on the liver metabolism, the timing of food supply influences the metabolic state enormously (Wehrens et al., 2017). In general, the mammalian physiology is synchronized by an inner time-keeping mechanism called the circadian clock. The molecular circadian regulation is based on central clock genes expressed in almost all tissues and cells. The translated proteins generate and regulate the circadian rhythm via transcriptional and translational feedback loops. The transcriptional activators ARNTL (aryl hydrocarbon receptor nuclear translocator-like protein 1 or BMAL1) and CLOCK (circadian locomotor output cycles kaput) stimulate the expression of the negative regulators Period (Per1, Per2, and Per3) and Cryptochrome (Cry1 and Cry2), which in turn repress ARNTL/CLOCK activity. The overall circadian rhythm is coordinated by the suprachiasmatic nuclei (SCN) in the hypothalamus (Ralph et al., 1990; Welsh et al., 2010). Synchronized by an optic light/dark signal the SCN generates output signals coupling the central pacemaker with the peripheral tissues. On the basis of oscillating hormonal and endocrine signals (Yang et al., 2007) the peripheral organs, such as the liver, synchronize their own circadian oscillation. Approximately 15% of all genes are transcribed in a circadian manner whereby one big aspect of circadian regulation includes metabolic processes and energy homeostasis in peripheral tissues, especially in liver (Albrecht, 2012). The tight connection between circadian clock and metabolic processes is underlined by the fact that a vast majority of liver genes is expressed rhythmically, including those regulating, e.g., glucose or lipid metabolism (Stratmann and Schibler, 2006; Ferrell and Chiang, 2015). Interestingly, the liver clock was shown not only be entrained by SCN-synchronization, but also by external factors. One of the most prominent influencers of liver circadian rhythms is the feeding regime. The consumed food volume and the starvation intervals between the meals are able to alter the liver clock (Hirao et al., 2010) and restricted feeding can even rapidly uncouple the liver rhythm from that of SCN (Stokkan et al., 2001).

Disturbance of the normal eating patterns of mice using external food restriction alters the entire metabolism (Jensen et al., 2013), which were analyzed previously using different omics approaches (Bauer et al., 2004; Sokolović et al., 2008; Hakvoort et al., 2011). However, knowledge of specific modulations produced by circadian regulation is scarce. Therefore, we analyzed the impact of fasting and refeeding at two different time-points [zeitgeber time (ZT) 3 and ZT 12] on the physiological and metabolic states of primary hepatocytes at a global omics level. Evaluations of transcriptome data were performed using SOMs. SOMs are an alternative approach that allows the identification of global expression trends via clustering of similarly expressed genes. The relative expression of gene groups is color-coded and enables an intuitive and unbiased interpretation of the data (Wirth et al., 2011). The results demonstrated that the timing of food restriction altered the influence of starvation on hepatocytes. A 24-h starvation period produced different gene expression patterns and lipidome profiles in liver cells depending on the starting time. While starvation started in the morning led to the known adaptions like initiation of gluconeogenesis and suppression of fatty acid and cholesterol synthesis, starvation started in the evening decreased gluconeogenesis-associated gene expression and induced fatty acid synthesis genes. Refeeding mice for 12 h after a 24-h long starvation period was not sufficient to restore the gene expression pattern of ad libitum fed mice, which was revealed by persistent dysregulation of essential metabolic pathways, such as lipid metabolism and autophagy. However, an extended refeeding period of 21 h approached an expression pattern similar to that of the ad libitum state, but some differences persisted.

MATERIALS AND METHODS

Maintenance of the Mice and Feeding

Male C57BL/6N mice were maintained in a pathogen-free facility on a 12:12 h light–dark cycle (light on at 6 a.m. = ZT 0, light off at 6 p.m. = ZT 12), according to German guidelines and those of...
the world medical association declaration of Helsinki for the care and safe use of experimental animals. The animal experiments were approved by the Landesdirektion Sachsen. The mice had free access to regular chow (ssniff® R/M-H V1534; 58%, 33%, 9% calories from carbohydrates, proteins and fat, respectively; metabolisable energy: 12.8 kJ/g. ssniff® Spezialdiäten GmbH, Germany) and tap water.

Prior to the experimental procedures, animals were randomly segregated into six groups (n = 3 each). In a first experiment, starvation was started either at ZT 3 (9 a.m.) or at ZT 12 (6 p.m.) and mice were sacrificed after 24 h at the same times on the next day together with ad libitum fed groups (Figure 1A). In the refeeding experiment two groups of mice were starved for 24 h started at ZT 15 followed by refeeding for 12 or 21 h until ZT 3 and ZT 12 on the next day, respectively (Figure 1B).

Isolation of Primary Mouse Hepatocytes, RNA Isolation, and Quantitative Real-Time PCR (qPCR)

The primary hepatocytes were isolated from male C57BL/6N mice, treated like explained above. Isolation was performed by a collagenase perfusion technique as described before (Gebhardt et al., 2003). The cell suspension was cleared of non-parenchymal cells by differential centrifugation steps (Matz-Soja et al., 2014). Pure hepatocyte fraction was used for further procedures.

Total RNA from hepatocytes was extracted using RNeasy® Mini Kit (Qiagen, Hilden) and the quality was controlled by agarose gel electrophoresis. The reverse transcription was performed with the Proto Script M-MuLV First Strand cDNA Synthesis Kit (New England Biolabs). Gene expression quantification by qPCR was performed in duplicates using the Rotor-Gene SYBR® Green PCR Kit and a Rotor-Gene Q (Qiagen). Gene specific intron-spanning primers were designed with Primer 3 software and are listed in Supplementary Table 1. The specific qPCR products were quantified using internal amplification standards; 18S was used as reference gene. Values are plotted as average of biological replicates (n = 3) ± standard deviation. The statistical evaluation was performed with the unpaired Student’s t-test (GraphPad Prism 7). The null hypothesis was rejected at *p < 0.05, **p < 0.01, and ***p < 0.001 levels.

Illumina Microarray Processing and Data Analysis Using SOM

For each condition, the RNA from three mice was pooled and used as one sample in the microarrays (BeadChip Array MouseRef-8 v2, Illumina). The analysis was performed by the Interdisciplinary Centre for Clinical Research, Leipzig (Faculty of Medicine, Leipzig University). The following link provides the raw data of the microarray¹.

All computational analyses were performed using R software (Ihaka and Gentleman, 1996). Microarrays were annotated using the annotation provided by Illumina and raw expression data were pre-processed using the lumi package (Du et al., 2008). Pre-processing included background correction using the bgAdjust method, variance stabilization transformation, and quantile normalization. Detection calls were performed with default parameters to remove absent beads. Furthermore, the expression values for single beads were mapped to a gene symbol identifier. For each array, multiple bead IDs mapping to the same gene symbol were averaged.

General expression trends in each sample were identified using SOMs as implemented in the oposSOM package (Löffler-Wirth et al., 2015). SOMs are artificial neural networks trained by unsupervised learning (Kohonen, 1982). This machine learning approach allows dimension reduction of high-dimensional data by clustering similarly regulated genes to so-called “metagenes”. For each treatment, it can be defined if the expression of a certain metagene is over or under the mean expression of this metagene in the analyzed pool (termed as over- and underexpression), and all groups are compared equivalently. The metagenes, here 20 × 20, can be visualized in a map where adjacent metagenes have similar expression profiles and more distant ones are expressed differently, with the invariant genes located in the center of the map. Furthermore, a color gradient codes the expression level of the metagenes, maroon indicating the highest expression, blue the lowest expression, and yellow and green intermediate levels (Wirth et al., 2011). This image-based analysis allows an intuitive interpretation and provides an overview of the overall regulation patterns. Apart from the creation of SOMs, the oposSOM package also provided additional analytical methods including the identification of over- or underexpressed spots in the SOMs, clustering of metagenes using k-means (Hartigan and Wong, 1979), and enrichment testing for metagene-cluster and over- or underexpressed spots using Gene Ontology (GO) terms (Ashburner et al., 2000) as provided by the Ensembl database (Aken et al., 2016).

Based on the k-means clustering as performed automatically by the oposSOM package, we performed a gene enrichment analysis (GEA) for all genes with an absolute expression change ≥ 1.5-fold and the genes from each cluster using the web-based tool DAVID (Database for Annotation, Visualization and Integrated Discovery Bioinformatics Resources 6.8², RRID:SCR_001881). We selected Mus musculus as the background and filtered the GO terms with a Benjamini–Hochberg corrected p-value < 0.05.

Visualization of single genes for the identified significant GO terms was performed using heatmaps. The expression levels of single genes were displayed as relative expression values compared to the mean expression in all six samples analogous to the metagenes (termed as over- and underexpression). All genes with an absolute expression change ≥ 1.5-fold [log2(1.5)] between at least two of the six groups were considered for further analysis.

The STRING database version 10.5³ was used to explore the interactions between the studied genes/proteins related to hepatic starvation response (Szklarczyk et al., 2015). The networks were

FIGURE 1 | Timeline of feeding/starving cycles and sacrifice. (A) Mice were fed ad libitum or starved for 24 h prior to sacrifice at ZT 3 (9 a.m.) or ZT 12 (6 p.m.). (B) Mice were starved for 24 h from ZT 15 (9 p.m.) to ZT 15 and refed for 12 or 21 h prior sacrifice. The arrows indicate the times of sacrifice.

constructed in the “confidence” mode with a high confidence score (0.7).

Shotgun Lipidomics

Lipids from primary hepatocytes were extracted by a modified protocol of Folch (Folch et al., 1957) and analyzed by shotgun mass spectrometry as described previously (Schuhmann et al., 2012). Briefly, hepatocytes (an amount equivalent to 10 µg of total protein) were dissolved in 200 µl ammonium bicarbonate solution (150 mM). For the subsequent quantification 10 µl internal standard mixture were added (20 pmol TAG 12:0-12:0-12:0, 20 pmol DAG 17:0-17:0, 40 pmol diethyl PC 18:0-18:0, 50 pmol diethyl PE 20:0-20:0, 10 pmol PG 17:0-17:0, 40 pmol PS 12:0-12:0, 50 pmol PI 16:0-16:0, 40 pmol LPC 12:0, 40 pmol LPE 14:0, 30 pmol SM d18:1-12:0, 90 pmol CE 12:0, 20 pmol Cer d18:1-12:0, 50 pmol cholesterol d7; Avanti Polar Lipids, Inc., Alabaster, AL, United States). Then, 265 µl of methanol and 730 µl of chloroform were added and the mixture was vortexed for 1 h at 4°C. The lower organic phase was collected, dried in a vacuum centrifuge and the lipid extracts were re-dissolved in 120 µl chloroform:methanol [1:2 (v/v)] mixture. The analysis was performed in both, negative, and positive ion mode. For negative mode analyses, 10 µl extract were mixed with 90 µl of 6.5 mM ammonium acetate in propanol before infusion and analyzed in positive ion mode. The following lipid classes were identified and quantified using the LipidXplorer software (Herzog et al., 2011): tri- and diacylglycerides (TAG/DAG), cholesteryl esters (CE), sphingomyelins (SM), phosphatidylethanolamines (PEs), phosphatidylcholines (PCs), and cholesterol. The concentrations are plotted in pmol lipid per µg total protein as average of the biological replicates (n = 3) ± standard deviation.

RESULTS

Feeding procedures immensely affect an organism’s metabolism. The present study examined alterations in the physiology and the metabolism of murine hepatocytes following a 24-h starvation
period initiated at ZT 3 (morning) or ZT 12 (evening) compared to hepatocytes from mice fed ad libitum (Figure 1A). Our data indicated that the effects strongly depended on the timing of starvation. We also compared hepatocytes in refeed state to the corresponding starvation group and ad libitum fed mice to evaluate whether 12 or 21 h of refeeding were sufficient to restore the ad libitum expression profile (Figure 1B).

Global Hepatic Gene Expression Is Influenced by Feeding and Timing

Illumina microarrays, analyzed, and visualized using SOMs, delivered an overview of the hepatic alterations induced by different feeding regimes. A GEA of all regulated genes (Supplementary Table 2A) produced an impression of the involved GO terms. Further we performed a separate analysis for each cluster to distinguish between them. Based on the SOMs of the ad libitum samples from ZT 3 and ZT 12 it strikes that a large amount of the genes in the liver were expressed in a circadian manner (Figure 2A), since the expression of almost all metagenes differed. ZT 3 showed two overexpression spots at the left margin, annotated as clusters A and B by a k-means clustering of the SOMs (Figure 2D and Supplementary Table 2B). Cluster A is associated with immune system processes (complement activation,' classical pathway', 'innate immune response') and many GO terms in regard to extracellular space and membrane ('extracellular region', 'plasma membrane'; 'cell surface'), while cluster B contains many lipid metabolism associated GO terms ('fatty acid metabolic process', 'acyl-CoA metabolic process') and the GO term 'autophagy'. The large underexpression spot in the upper right corner partly covered by cluster J contains many cholesterol and steroid associated GO terms ('cholesterol metabolic process', 'steroid metabolic process'; 'fatty acid metabolic process'). In comparison to ZT 3, ZT 12 exhibited a mean expression in the area of clusters B and J (Figures 2A,D). But ZT 12 had a small overexpression area in the upper left corner (cluster H) related to the GO term 'metabolic process' and an underexpression spot in the lower right corner (cluster F) containing GO terms associated with protein binding and degradation ('chaperone binding', 'endoplasmic reticulum', 'proteasome accessory complex').

Starvation started at both ZT 3 and ZT 12 immensely changed the expression profiles of the metagenes in the SOMs compared to the related ad libitum state (Figure 2B). Additionally, comparing ZT 3 and ZT 12 starvation no congruence is visible, which implies a diurnal-driven response to fasting. The 24-h starvation period at ZT 3 began during the day followed by a whole night of fasting (Figure 1A), which changed the size and shape of the overexpression spot in the lower left corner and the underexpression spot in the upper right corner (clusters B and J), regions associated with lipid and steroid metabolism (Figures 2B,D). In contrast, the ZT 12 starvation period started in the night followed by a whole day of fasting (Figure 1A) and resulted in a totally changed metagene expression, where the whole left margin is underexpressed, while the right margin shows an overexpression (Figure 2B). The regions (clusters B and J) where GO terms related to autophagy, lipid and steroid metabolism are localized have an opposed expression comparing ZT 3 and ZT 12 starvation.

The refeeding experiment (Figure 1B) revealed disparate SOMs after refeeding mice for 12 h and the ZT 3 ad libitum group (Figure 2C). However, the SOM of 12 h refeed (Figure 2C, upper panel) showed high similarity with the corresponding ZT 12 starvation group (Figure 2B, lower panel). The mice sampled at ZT 12 were starved for the same 24-h period, but were refeed for 21 h prior sacrifice. This prolonged refeed period produced a somehow mixture of expression profiles from ZT 12 ad libitum and starvation state (Figure 2C). While clusters F and H resemble that of ZT 12 ad libitum (Figure 2A, lower panel), the regions where lipid and steroid metabolism are localized (clusters B and J) still showed the starvation pattern (Figure 2B, lower panel).

Altersations in Relevant Metabolic Features Following Starvation and Refeeding

SOM analysis identified differently regulated metabolic alterations produced by the various feeding regimes. A list of all regulated genes detected by the microarrays is compiled in Supplementary Table 3. The present study focused on the expression of genes related to intermediary metabolism (glucose and lipid metabolism), steroid metabolism, insulin signaling, and autophagy. We also analyzed central clock gene expression because the circadian aspect of the feeding regimes was particularly interesting. The interactions of the involved genes/proteins were visualized within a protein interaction network, illustrating the mutual connections (Supplementary Figure 1).

Circadian Regulation

Diurnal influence

Being the first order clock genes, Arntl and Clock gene products activate the expression of different target genes, including Per1/2/3 homolog and Cry. PER and CRY, in turn, repress their own expression by interacting with ARNTL and CLOCK (Partch et al., 2014). Consequently to these regulations the expression of Arntl/Clock and Per occurs in antiphase, which is seen in Figure 3 (ad libitum). In the ad libitum state Arntl and Clock were overexpressed at ZT 3 and underexpressed at ZT 12, Per1 and Per2 were regulated vice versa. Nr1d2 (Rev-erb beta), another gene of the negative feedback loop, exhibited a typical rhythmic regulation with a higher expression at ZT 12 than at ZT 3. These results were verified by qPCR and used to validate the microarray (data not shown).

Starvation

Expression of central clock genes were primarily regulated in a diurnal manner (Figure 3). However, fasting also influenced central circadian genes. A 24-h starvation period initiated at ZT 3 or ZT 12 increased Arntl and Clock expression levels, but the typical diurnal regulation of these genes remained. The opponent Per2 was down-regulated after starvation initiated at ZT 3 and up-regulated in the ZT 12 starvation mice compared to the corresponding ad libitum samples. The Per1 expression was only
FIGURE 2 | Global hepatic gene expression dependent on feeding patterns and timing. (A–C) Self organizing maps (SOMs) illustrating the expression of metagenes (20 × 20); maroon indicates an overexpression, blue an underexpression. Mice were sacrificed at ZT 3 and ZT 12 after (A) fed ad libitum, (B) starved for 24 h or (C) starved for 24 h and refed for 12 h until ZT 3 or 21 h until ZT 12. (D) Annotation of the SOMs using k-means clustering and following gene-enrichment analysis. Selected GO terms are shown. A full list is available in Supplementary Table 2B.
marginally changed by 24-h starvation in the morning and the evening, while Nr1d2 was decreased after both starvation periods.

**Refeed**
When mice were fasted for 24 h and refed for 12 h until ZT 3, the Arntl expression was highly increased, while a prolonged refeed period of 21 h abolished the effect of starvation (Figure 3). The Clock expression was no longer altered after both refeed periods. Per1 expression was decreased after a 12 h refeed, but the 21 h refeed already restored the ad libitum expression. Per2 expression was higher after both refeed periods in comparison to ad libitum. The expression of Nr1d2 showed big changes after both refeed periods, the expression was further decreased after 12 h and increased after 21 h refeed.

All in all, a 21 h refeeding seemed to be sufficient to abolish the alterations in the expression of the genes of the primary negative-feedback loop (Arntl, Clock, Per1, and Per2) caused by starving the mice. But after 12 h refeed the expression of Arntl, Per1, and Per2 still showed major changes compared to the ad libitum sample.

**Insulin Signaling**

**Diurnal influence**
Insulin is one of the master regulators of the metabolism and its effects are partially mediated by insulin receptor signaling (Boucher et al., 2014). The microarray analyses revealed diurnal regulation of several genes of this pathway (Figure 4). For example, Pik3r1 (phosphatidylinositol 3-kinase, regulatory subunit, polypeptide 1), part of the inositol phosphorylation complex, showed a lower expression in the morning (ZT 3) compared to the evening (ZT 12). The same regulation occurs for Mup4 (major urinary protein 4) whose influence on energy metabolism is not well understood yet. However, Pdk4 (pyruvate dehydrogenase kinase, isoenzyme 4), regulator of glucose metabolism, was higher expressed in the morning than in the evening.

**Starvation**
The 24-h starvation period initiated in the morning produced strong overexpression of central hepatic insulin signaling genes [e.g., Pdk4, Mup4, Irs2 (insulin receptor substrate 2) and Igfbp1 (insulin like growth factor binding protein 1)]. Notably, all of these genes, except Pdk4, were strongly down-regulated after starvation initiated at ZT 12. The expression of Pik3r1 and Eif4ebp2 (eukaryotic translation initiation factor 4E binding protein 2), which is a regulator of translation, was lowered in both starvation periods (Figure 4). The transcription factor Srebf1c was down-regulated only due to starvation started at ZT 3, and it was unaffected by evening starvation (Figure 6).

Socs2 and Socs3 (suppressor of cytokine signaling), which were not regulated diurnally in ad libitum fed mice, are associated to the negative regulation of insulin signaling. The data for Socs2 and Socs3 revealed a change from an overexpression in ZT 12 ad libitum sample to a strong underexpression due to starvation started at ZT 12. Socs3 expression also slightly decreased when starvation was initiated at ZT 3, but Socs2 expression slightly increased (Figure 4).

**Refeed**
The expression of nearly all detected genes of insulin receptor signaling did not recover during the 12 h refeeding and resembled the expression of the ZT 12 starvation mice (Figure 4). Exceptions included Pdk4, which almost reached ad libitum levels, and Srebf1c, which was highly induced during refeeding. The gene expression levels of Pdk4, Eif4ebp2, Pik3r1, and Irs2 after a refeeding period of 21 h were similar to the corresponding ad libitum levels. The Socs2 and Socs3 genes were considerably underexpressed after both refeeding periods.

**Autophagy**

**Diurnal influence**
In ad libitum fed mice, central genes of the mammalian autophagy pathway, such as Ulk2 (unc-51 like kinase 2) and Uvrag (UV radiation resistance associated gene), were lower expressed in the morning compared to evening. However, Sgstm1
down-regulated in the evening (was up-regulated after food deprivation started at ZT 3 and ad libitum). A regulator of autophagy, Cebpb (CCAAT/enhancer binding protein beta) was higher expressed in the evening than in the morning (Figure 5).

Starvation
When starvation was started at ZT 3 expression of many of the autophagy-associated genes [e.g., Ulk2, Uvrag, Sqstm1, Pik3c3 (phosphatidylinositol 3-kinase catalytic subunit type 3), Trp53inp1 (transformation related protein 53 inducible nuclear protein 1), Gabarapl1 (gamma-aminobutyric acid A receptor-associated protein-like 1), Map1lc3b (microtubule-associated protein 1 light chain 3 beta)] was not altered (Figure 5). Only Trp53inp2, which is essential for autophagosome formation, was markedly up-regulated during the ZT 3 starvation period.

This observation dramatically changed when the starvation period of 24 h was started at ZT 12. The above-mentioned central autophagy genes, with the exception of Sqstm1, were dramatically down-regulated during this fasting period, which was especially prominent for Ulk2 expression. The transcription factor Cebpb was up-regulated after food deprivation started at ZT 3 and down-regulated in the evening (Figure 5).

Refeed
Our study revealed that the dramatic down-regulation of central autophagy genes due to the initiation of starvation in the evening remained during a refeeding period of 12 h (Figure 5). The expression of Uvrag, Trp53inp1, Stbd1 (starch binding domain 1) and Arsa (arylsulfatase A) was further reduced. However, Sqstm1 and Irgm1 (immunity-related GTPase family M member 1), which are involved in autophagic protein degradation (Traver et al., 2011), were up-regulated during the 12 h refeeding period. After a prolonged refeeding of 21 h, most autophagy-related genes approached the ZT 12 ad libitum expression levels, but did not reach it. Cebpb was expressed at the ad libitum level after the 12 h refeed, but its expression was lowered after the 21 h refeed (Figure 5).

Intermediary Metabolism

Diurnal influence
Many genes associated with intermediary metabolism (lipid and glucose metabolism) showed a time-dependent expression. The transcription factors that mainly regulate intermediary metabolism, such as Ppara, Pparg, and Hnf4a (hepatocyte nuclear factor 4 alpha), were higher expressed at ZT 12 than at ZT 3. Mlxipl (ChREBP) exhibits a vice versa regulation (Figures 6, 7). Srebfl transcripts showed no diurnal changes (Figure 6). The members of the Elovl (elongation of very long chain fatty acids protein) family (Elov12, Elov13, and Elov15), which are involved in lipid metabolism, were higher expressed at ZT 3 compared to ZT 12, but Elov16 exhibited an inverse regulation (Figure 7).

Starvation
The regulation of hepatic lipid and glucose metabolisms is based on different transcription factors. The expression of Ppara, Pparg, and Hnf4a was elevated after starvation initiation at ZT 3 compared to the ad libitum group (Figures 6, 7).

Notably, starvation initiated at ZT 12 decreased the expression of Ppara by significantly more than 40% and Pparg and Hnf4a were only marginally regulated. Hes6, which is an interaction partner of HNF4a, exhibited diminished expression during starvation started at ZT 3 and increased expression under ZT 12 starvation. Fg21 (fibroblast growth factor 21), which is another regulatory element that is closely connected to the PPAR family and the starvation response, exhibited an expression increase by approximately 20-fold after starvation initiated at ZT 3, but this increase was much lower in the ZT 12 group (Figure 6). Mlxipl was strongly down-regulated after starvation in the morning and was not altered in the evening group. The Srebflc mRNA levels decreased by more than threefold after food deprivation started ZT 3 but were not affected in the ZT 12 group.

The liver ensures the synthesis of sufficient amounts of acetyl coenzyme A (CoA), especially during starvation. Therefore, beta-oxidation is increased due to starvation by the up-regulated expression of many of the involved enzymes, including Cpt2 ( carnitine palmitoyltransferase 2), Hadhb (hydroxyacyl-CoA dehydrogenase/3-ketoacyl-CoA thiolase/enoyl-CoA hydratase), Ehhadh, Aca1ab (acytetyl-CoA acyltransferase 1B), Acs1l (acyl-CoA synthetase long-chain family member 1) and Decr1 (2,4-dienoyl CoA reductase 1) (Figure 7). However, this increase was much greater when starvation was initiated at ZT 3 rather than at ZT 12. Members of the Acs1 family are responsible for the activation of long fatty acids and exhibited different regulation. While Acs1 strongly increased by starvation started at ZT 3, Acs1β and Acs1δ strongly decreased. In contrast, starting starvation of mice at ZT 12, Acs1l and Acs15 expression was not altered and Acs1β increased.
Ketogenesis is an essential metabolic pathway to generate ketone bodies during starvation. Genes for the two essential enzymes of ketone body formation, *Hmgcs2* (3-hydroxy-3-methylglutaryl-CoA synthase 2) and *Hmgcl* (3-hydroxymethyl-3-methylglutaryl-CoA lyase), were highly increased after 24-h starvation started at ZT 3, but regulation was only marginal at ZT 12. *Hmgcs2, Hmgcl, Ehadh, Hadhb,* and *Aca1lb* are also involved in the degradation of the amino acids valine, isoleucine, and leucine. The up-regulation of all enzymes after starvation initiated at ZT 3 ensured an efficient supply of acetyl-CoA (*Figure 7*).

The key enzyme of fatty acid synthesis, *Fasn* (fatty acid synthase), was decreased by 24-h starvation started at ZT 3 and, surprisingly, increased in the ZT 12 group. The gene expression of enzymes involved in elongation and formation of unsaturated fatty acids [e.g., *Scd1* (stearoyl-CoA desaturase 1), *Fads1* (fatty acid desaturase 1), *Hsd17b12* (hydroxysteroid-17-beta dehydrogenase 12), *Thrsp* (thyroid hormone responsive), and

**FIGURE 6** | Response of regulatory factors to starvation and refeeding in a diurnal manner. Expression of *Ppara, Pparg, Srebf1a, Srebf1c,* and *Fgf21* in primary hepatocytes of mice fed *ad libitum* (white bars), starved 24 h (black bars) or starved 24 h and refeed 12 h (until ZT 3) and 21 h (until ZT 12) (gray bars) quantified using qPCR (*n* = 3). Data are plotted as mean ± standard deviation relative to ZT 3 *ad libitum*, *p* < 0.05, **p** < 0.01, and ***p*** < 0.001.
Mid1ip1 (Mid1 interacting protein 1)) were predominantly down-regulated after starvation initiated at ZT 3 (Figure 7). In contrast, starvation initiated at ZT 12 elevated Scd1 and Mid1ip1 expression and did not change Fads1, Hsd17b12, and Thrsp. The members of the Elovl family showed only a regulation underexpression. The members of the Elovl family showed only a regulation underexpression.

By gluconeogenesis the liver can synthesize glucose, which is an essential pathway during starvation. As expected, Pck1 (phosphoenolpyruvate carboxykinase 1), the enzyme for the rate-limiting step of gluconeogenesis, and G6pc (glucose-6-phosphatase catalytic subunit), essential to release glucose in the last step of gluconeogenesis, were both increased due to starvation started at ZT 3, but decreased at ZT 12. Gck (glucokinase), catalyzing the opposite reaction, shows an inverse regulation (Figure 7).

Taken together, the expression patterns at ZT 3 predominantly corresponded to the known starvation responses of the liver. However, the initiation of fasting at ZT 12 revealed unknown regulatory events that produced more subtle and inversely regulated expression levels.

Refeeding
Refeeding mice after a 24 h starvation challenges the liver. The depleted stores must be refilled, and the metabolism should return to a normal feeding state. The transcription factors Ppara and Pparg remained elevated after the 12 h refeeding compared to the ad libitum group, but ad libitum expression was nearly restored after refeeding for 21 h. Fgf21 expression remained increased after both refeeding periods (Figure 6). By contrast, Hnf4a expression after the 12 h refeeding was comparable to that after starvation started at ZT 12 and decreased after 21 h refeeding compared to ad libitum. Mlxipl expression was restored after the 12 h refeeding (Figure 7). The expression of Srebf1c increased significantly after both refeeding periods (Figure 6).

Hepatocytes exhibited a strong up-regulation of Fasn expression, especially after the 21 h refeed; while after 12 h refeed the increase was comparable with starvation started at ZT 12. The genes Scd1, Acsl5, Elovl6, Hsd17b12, Fads1, and Thrsp showed a similar regulation pattern as Fasn. However, the expression of other enzymes, such Acs1, Acsl3, Elovl2, and Elovl3 resembled the corresponding ad libitum sample after 12 and 21 h refeed (Figure 7). Expression of the enzymes of beta-oxidation and mitochondrial fatty acid synthesis were restored (Cpt2, Ehhadh, Hadhb, Decc1) or remained decreased (Acaa1b) after both refeeding periods (Figure 7).

The synthesis of ketone bodies and degradation of amino acids are no longer a necessary energy source when sufficient amounts of nutrients are available. Accordingly, the expression of Hmgcs2 was slightly decreased after 12 and 21 h of refeeding compared to the corresponding ad libitum samples, and Hmgcl exhibited the same expression as the ad libitum state. The level of Pck1 strongly decreased after the 12 h refeeding compared to ad libitum and was slightly reduced after refeeding for 21 h. Both refeeding times restored G6pc expression to ad libitum levels (Figure 7).

Steroid Metabolism
Diurnal influence
Steroid metabolism, especially cholesterol synthesis, is another important function of the liver, and it is partially regulated diurnally (Figure 8A). Comparing ZT 3 and ZT 12 ad libitum Pmvk (phosphomevalonate kinase), Mvd (malonate decarboxylase), Ebp (phenylalkylamine Ca2+ antagonist binding protein), Sc5d (sterol-C5-desaturase), and Cyp17a1 (cytochrome P450, family 17, subfamily a, polypeptide 1) exhibited a higher expression in the morning than in the evening. The regulators of SREBP1, Scap (SREBP cleavage-activating protein) and Insig1/2 (insulin induced gene), were also expressed higher at ZT 3 than at ZT 12. In accordance with enhanced synthesis over the day, the amount of hepatic cholesterol is 1.3-fold higher in the evening.
The expression of many enzymes [Cyp7a1, Cyp7b1, Akr1d1, Akr1c6 (aldo-keto reductase family 1, member D1/C6)] involved in steroid degradation by formation of bile acids were also higher expressed in the evening than in the morning (Figure 8B). Concerning steroidogenesis and cholesterol conversion, the hydroxysteroid dehydrogenases Hsd3b5 and Hsd17b2 showed a higher expression in the evening.

Starch

Already in the early fifties it was shown that the synthesis rate of cholesterol is markedly decreased by starch. This metabolic profile was true in mice starved from ZT 3, in which most genes encoding cholesterol synthesizing enzymes [Pmvk, Mvd, Fdps (farnesyl diphosphate synthetase), Sqle (squalene epoxidase), Lss (lanosterol synthase), Dhcr24 (24-dehydrocholesterol reductase), Cyp51, Nsdhl (NAD(P) dependent steroid dehydrogenase-like), Hsd17b7, Ebp, Sc5d, and Dhcr7] exhibited reduced expression compared to ad libitum mice (Figure 8A). By contrast, the shift of starchion time to the evening produced a reverse regulation and a primarily elevated expression of these genes. Notably, 24 h starchion did not significantly alter the cholesterol content (Figure 8B). The regulatory transcription factor of cholesterol synthesis, Srebf1a, was not significantly altered following starchion (Figure 6). Due to starchion initiated at ZT 3, Insig1 and Insig2 exhibited a reciprocal expression, reflecting published data (Ye and DeBose-Boyd, 2011), while the evening starchion period resulted in an equal increase in Insig1 and Insig2 expression. Scap expression was slightly lower after starchion in both periods (Figure 8A).

Cytochrome P450 enzymes (CYPs) and hydroxysteroid dehydrogenases (HSDs) synthesize steroid hormones with cholesterol as starting compound. The expression of Cyp17a1 (steroid 17α-monooxygenase), which is a key enzyme of steroidogenesis, was highly induced after starchion started at ZT 12 and not altered in ZT 12 mice. By contrast, Hsd expression (Hsd3b5, Hsd17b2, and Hsd17b6) was more or less down-regulated after both starchion periods (Figure 8A).

The breakdown of cholesterol is performed by the synthesis of bile acids in the liver. Cyp7a1, which is the rate-limiting enzyme, was dramatically down-regulated following starchion initiated at ZT 3 and unchanged in ZT 12 mice compared to ad libitum. Cyp7b1 was almost unaffected after starchion started at ZT 3 and highly decreased in ZT 12 mice. Akr1c6 is another enzyme of bile acid synthesis and was down-regulated after both starchion periods. Akr1d1 was marginally altered. Acox2 was unchanged after starchion initiated at ZT 3, but it was increased in ZT 12 mice (Figure 8A).

Cholesterol metabolism exhibits a similar regulation in response to fasting like the lipid metabolism: cholesterol synthesis was regulated in the known manner in ZT 3 mice, but its synthesis exhibited unknown regulation in ZT 12 mice.

Refeeding

The genes of cholesterol synthesis (Pmvk, Mvd, Sqle, Lss, Dhcr24, Hsd17b7, and Sc5d) remained elevated after the 21 h refeeding period compared to ZT 12 ad libitum (Figure 8A). Fdps, Cyp51, Nsdhl, and Ebp were even higher expressed after 21 h refeeding compared to the corresponding starchion period at ZT 12. The expression of almost all above-mentioned genes was elevated after the 12 h refeed compared to ZT 3 ad libitum and was
very similar to that under ZT 12 starvation. Only Ebp and Scd5 exhibited restored expression after 12 h refeeding (Figure 8A). Expression of the regulator Srebf1a was highly induced after the 12 h refeeding compared to ZT 3 ad libitum, and it was restored after refeeding for 21 h (Figure 6). Scap and Insig2 exhibited a similar expression after 21 h refeed and at ZT 12 ad libitum. After 12 h refeed the expression of Insig1 was slightly increased and Insig2 was elevated much more, whereas Scap was decreased (Figure 8A).

Cyp17a1 expression remained increased after the 21 h refeeding and decreased after 12 h compared to the corresponding ad libitum samples. Hsd17b6 expression was lower after 12 and 21 h refeed than in the ad libitum samples. Hsd3b5 remained down-regulated after 21 h refeeding. Hsd17b2 expression increased after 12 h refeed (Figure 8A).

The key enzyme of bile acid synthesis Cyp7a1 was up-regulated after both refeeding times. Akr1d1 and Akr1c6 were also up-regulated, especially after the 21 h refeed. Acox2

**FIGURE 9** | Lipidome profile of primary hepatocytes. Mice were fed ad libitum (white bars) or starved 24 h (black bars). Concentration of tri- and diacylglycerides (TAG/DAG), cholesteryl esters (CE), sphingomyelins (SM), phosphatidylethanolamines (PE), and phosphatidylcholines (PC) (n = 3). Data are plotted as mean ± standard deviation, *p < 0.05 and **p < 0.01.
expression was restored after refeeding (12 and 21 h), but Cyp7b1 remained down-regulated after 21 h of refeeding (Figure 8A).

**Lipidome Analysis of Hepatocytes**

Beside the evaluation of the gene expression, we analyzed the lipidome profile of the hepatocytes via mass spectrometry (Figure 9). The amount of lipids in mice fed *ad libitum* exhibited a basal level and no diurnal changes, with the exception of sphingomyelin (SM), where the content was 1.4-fold higher in ZT 12 than in ZT 3 mice. However, hepatic lipids used for storage, such as TAGs and cholesteryl esters (CEs), were strongly elevated in starving mice, and this regulation is highly time-dependent. Starvation started at ZT 3 produced a greater than fourfold increase in TAGs and CEs compared to *ad libitum* mice. By contrast, 24 h starvation initiated at ZT 12 produced only an approximately twofold increase. Polyunsaturated TAG species primarily reflected these differences in TAG levels (Supplementary Figure 2). However, TAGs with a high saturation level (50:1 and 52:2) were equally increased after both starvation periods because these TAGs are less reactive and remain longer in the cells. Diacylglycerides (DAGs) are transient precursor of TAG, and these molecules are produced at a much lower level. Both starvation periods slightly altered DAG levels. The membrane components SM and phosphatidylethanolamines (PE) were significantly reduced when starvation was initiated at ZT 12. The PC content did not change (Figure 9). Hepatic TAG exhibited still a 2.5-fold increase after the 12 h refeeding compared to *ad libitum* mice. However, the 21 h refeeding normalized the TAG concentration. Refeeding did not significantly alter the other lipid classes (Supplementary Figure 3).

**DISCUSSION**

The results of our study revealed a strong circadian-driven response to fasting in the liver (Figure 10). Twenty-four hour starvation initiated and terminated in the morning (ZT 3 to ZT 3) induced the expression of genes involved in metabolic pathways that produce energy-rich substrates for the organism. The gene expression of energy-consuming and temporary expendable processes diminished. However, starvation started in the evening (ZT 12 to ZT 12) produced a totally different hepatic expression signature, with partially opposing regulations, e.g., genes involved in gluconeogenesis decreased, while genes of fatty acid and cholesterol synthesis were induced. These novel findings were unraveled by the analysis of transcriptome data using SOMs.

For energy-consuming and temporary expendable metabolic processes, we discovered similar diurnal regulation differences by starvation. The synthesis of fatty acids, mainly carried out by fatty acid synthase, seems to be increased based on the elevated expression of *Fasn* after food deprivation in the evening. This observation was contrary to the decreased *Fasn* expression detected after starvation started in the morning and the published knowledge of diminished lipogenesis upon fasting (Horton et al., 1998). The hypothesis of the opposing lipogenesis regulation after different starvation periods was strengthened by the expression of *Gck*, forming the carbon source (pyruvate) for lipogenesis, which was also induced after starvation started in the evening and decreased in the known way after morning starvation (Iynedjian et al., 1987). Cholesterol synthesis is another process known to be diminished while starving. However, enzymes of cholesterol synthesis exhibited elevated gene expression following starvation initiated at ZT 12. Food deprivation initiated at ZT 3 reduced the expression levels of most down-stream genes encoding cholesterol synthesizing enzymes, which indicates diminished cholesterol synthesis, as previously shown (Tomkins and Chaikoff, 1952), even if expression of the rate-limiting enzyme of cholesterol synthesis,
Hmgcr (3-hydroxy-3-methyl-glutaryl-coenzyme A reductase), was not found in our microarray. Bile acids are secreted into the intestine to increase the solubility of hydrophobic molecules and allow their absorption (Hofmann and Borgström, 1964) and have a poorly understood function as potent signaling compounds (Chiang, 2017). Our study revealed a higher expression of genes involved in bile acid synthesis in the evening than in the morning in ad libitum fed mice. This result was consistent with the known diurnal expression of the rate-limiting enzyme CYP7A1, which is highest when the greatest amount of food is consumed (Gooley, 2016). Mice are nocturnal and consume approximately three times more food during scotophase than during photophase (Kurokawa et al., 2000). Bile acid production is a redundant process during starvation, and our analysis revealed a lower expression of Cyp7a1 after food deprivation at ZT 3. However, starvation in the evening did not alter Cyp7a1 expression. Several groups reported a similar pattern of Cyp7a1 expression after starvation (Noshiro et al., 1990; Li et al., 2012), but other studies demonstrated an induction (De Fabiani et al., 2003; Shin et al., 2003). The timing and length of the starvation period used by different groups may explain these diverse results and illustrate the importance of our study. Steroid hormone synthesis is generally localized in the gonads and adrenal glands, but the adult liver also performs steroidogenesis under specific conditions (Grasfeder et al., 2009; Rennert et al., 2017). Cyp17a1 expression, which is a central steroidogenic enzyme, was induced following evening starvation. This result confirms previous work and strengthens the idea of steroids as mediators of starvation responses (Bauer et al., 2004; Grasfeder et al., 2009). Our data show a novel regulation
of energy-consuming processes after starvation started in the evening, contrary to the established down-regulation frequently published as the hepatic starvation response after fasting initiated in the morning.

The accumulation of lipids in the liver (steatosis) often accompanies starvation (Kok et al., 2003; van Ginneken et al., 2007). Adipose tissues secrete fatty acids, which are taken up by hepatocytes and esterified to the storage lipids TAG and CE or secreted as VLDL. Lipidomics analysis revealed significantly elevated TAG and CE contents due to starvation, but this increase was twice as great after food deprivation initiated in the morning than when it was initiated in the evening. This may be based on the diurnal regulation of adipose triglyceride lipase (ATGL) and hormone-sensitive lipase (HSL), which are the lipolysis pacemaker enzymes in adipose tissue and direct targets of CLOCK/ARNTL (Shostak et al., 2013). The lower level of TAG and CE after starvation started in the evening appears inconsistent with the increased expression of Fasn. Two possible explanations are (i) since Fasn was only detected at the mRNA level, the synthesis of enough enzyme protein and the accumulation of a measurable increase of TAG may be delayed for several hours and/or (ii) the synthesized fatty acids were not stored in the liver but secreted, and the analysis could not capture them. To unravel this uncertainty, additional studies have to be performed.

Regulation of the Hepatic Starvation Response

Additionally, for the transcription factors regulating the observed starvation-induced transcriptional alterations, our study exhibited novel diurnal expression profiles. A main activator of the energy-supplying processes is the PPAR family. Elevated expression of Ppara and Pparg in the liver upon fasting induces beta-oxidation, stimulating lipid uptake and fatty acid storage (Kersten et al., 1999; Gavrilova et al., 2003; Tanaka et al., 2005). However, we detected this up-regulated expression only when starvation was initiated at ZT 3 and not at ZT 12, which explains the weak induction of beta-oxidation, the decreased gluconeogenesis and ketogenesis and the lower amount of TAG accumulation in the liver after evening starvation. Furthermore, HNF4A contributes to this regulation due to additional activation of Ppara and diminishment of the repressor Hes6 (Martinez-Jimenez et al., 2010). Our data nicely reflected this mechanism after starvation started in the morning. However, after evening starvation, Hnf4a was unchanged and the Hes6 level increased.

The SREBP1 family and ChREBP (Mlxipl) are transcription factors more responsible for the post-prandial state and are supposed to be down-regulated during starvation to not activate energy-consuming pathways. For Mlxipl, we detected a transcriptional response with a strong down-regulation after starvation in the morning, but no changes were observed when starvation was initiated in the evening. This was contrary to the published regulation carried out only at the post-translational level via phosphorylation (Iizuka and Horikawa, 2008) and requires a more focused study. Srebf1c expression was reduced only after food deprivation initiation in the morning, and its expression was unchanged following starvation in the evening, which may explain the induced expression of the target Fasn when starvation was started at ZT 12. SREBP-1a is known to regulate cholesterol synthesis, but even if its expression was not relevantly altered, neither after starvation initiated in the morning nor in the evening, the genes encoding cholesterol synthesizing enzymes responded with a down- or up-regulation, respectively. Additionally, the influence of the SREBP1 inhibitors, INSIG1/2, seemed to depend on diurnality, since Insig1/2 expression was elevated after both starvation periods, but the regulatory output differed. Therefore, the known regulatory mechanisms of Srebf1 expression did not seem applicable when starvation was initiated in the evening, and further investigations are needed to delineate these mechanisms. All in all, the diurnally regulated expression of the transcription factors Ppara, Pparg, Mlxipl, Srebf1a, and Srebf1c following starvation likely underlie many of the observed metabolic alterations.

Concerning the regulation of the fed and starved state, two hormones are omnipresent: insulin and glucagon. Since the hormones were not determined in our study, we can only speculate about their levels and influence. Shi et al. (2013) demonstrated diurnal differences in mice with enhanced insulin activity during the night and a metabolism that was characterized by insulin resistance during the day. However, 24 h starvation started in the morning changed the diurnal insulin regulation, and serum insulin levels dropped by approximately two-thirds, resulting in the known starvation responses (Ahrén and Havel, 1999), but no data were available for evening starvation. Glucagon, on the other hand, regulates metabolism in the fasted state. It was shown that glucagon induces the expression of the hormone Fgf21 (Berglund et al., 2010), which in turn activates gluconeogenesis and ketogenesis. The expression of Fgf21 was much more induced when starvation was started in the morning than in the evening, which explains the diurnal differences in gluconeogenic and ketogenic gene expression and suggests that the glucagon response also depends on the timing of starvation.

The overall regulators of circadian rhythm are the core clock genes Arntl, Clock and Per, which were elevated after both starvation periods but maintained their typical diurnal expression pattern. This result was consistent with a previous study that demonstrated induced Arntl expression due to raised glucagon levels (Sun et al., 2015). Since the transcriptional analysis was performed in hepatocytes, a screen of other organs would help to fully understand the regulatory differences following starvation started in the morning and in the evening.

Metabolic Adaptations and Regulations Upon Refeed

Peripheral tissues first refill their glucose stores when an organism switches from a starved to a refeed state, and the liver subsequently synthesizes and stores glycogen, fatty acids, and cholesterol (Berg et al., 2002). Our experimental setting investigated the effects of two refeeding durations (12 and 21 h) after the same starvation period (Figure 11). The already mentioned clusters B and J in the SOMs, where most genes of intermediary and steroid metabolism were localized, exhibited similar expression profiles
Effects of Diurnal Timed Starvation

FIGURE 11 | Summary of expression changes following 12 and 21 h refeeding after 24 h starvation. Arrows indicate higher (↑) or lower (↓) expression after refeeding for 12 h until ZT 3 (yellow) and 21 h until ZT 12 (brown) compared to the corresponding ad libitum samples. Equality signs (=) indicate a restored ad libitum expression levels.

after both refeeding periods, which were totally different from the ad libitum groups. The expression levels in other regions of the SOM after 21 h refeeding partially resembled the ad libitum group, which indicated a return to the untreated state.

Since food intake delivers all essential metabolites, the liver (i) activates the energy-consuming metabolism and (ii) the production of energy-rich substrates returns to normal. The liver no longer synthesizes ketone bodies and glucose after refeeding, and the expression of the relevant genes reached ad libitum or decreased levels. The genes of beta-oxidation were expressed at ad libitum levels as well. Early findings demonstrated that refeeding suppressed autophagy (Mortimore et al., 1983), which was confirmed since most of the autophagic genes exhibited a much lower expression after 12 h refeeding compared to starvation, and these genes returned to an approximately ad libitum level after 21 h. In contrast, the synthesis of fatty acids and steroids is induced by refeeding. Our study demonstrated that the expression of Fasn was highly increased to a maximum after the 21 h refeed. The genes encoding cholesterol synthesizing enzymes were elevated after 12 and 21 h of refeeding as well. This led to an induced synthesis of fatty acids and cholesterol to refill the emptied stores. Bile acid synthesis is associated with the food consumption, and it increased due to elevated expression levels of Cyp7a1, as reported previously (Li et al., 2012). The lipidome profile revealed that TAG content remained increased after 12 h refeeding but reached ad libitum levels after 21 h. Previous studies demonstrated a normalization of liver lipid content after 48 h of refeeding (Kok et al., 2003).

Since SREBF1 stimulates lipogenesis and cholesterol synthesis, the expression of the transcription factors Srebf1a and Srebf1c...
