(Dated: May 10, 2022)

We address the interplay between local and global symmetries in determining the continuum limit of two-dimensional lattice scalar theories characterized by $SO(N_c)$ gauge symmetry and non-Abelian $O(N_f)$ global invariance. We argue that, when a quartic interaction is present, the continuum limit of these model corresponds in some cases to the gauged non-linear $\sigma$ model field theory associated with the real Grassmannian manifold $SO(N_f)/(SO(N_c) \times SO(N_f - N_c))$, which is characterized by the invariance under the color-flavor reflection $N_c \leftrightarrow N_f - N_c$. Monte Carlo simulations and Finite-Size Scaling analyses, performed for $N_f = 7$ and several values of $N_c$, confirm the emergence of the color-flavor reflection symmetry in the scaling limit, and support the identification of the continuum limit.

I. INTRODUCTION

Global and local symmetries are cornerstones of our understanding of many different physical phenomena, ranging from high energy physics to many-body systems in condensed matter physics [1,2]. Global symmetries characterize fundamental features of a physical model, like its phase diagram and energy spectrum [3]. Gauge symmetries, instead, constraint the form of the possible interactions, responsible for the presence of Higgs phases, and are necessary to describe some emergent phenomena in condensed-matter systems [4,5].

The nature of the interplay between local and global symmetries at a phase transition is a long-standing issue [6,10], which however is still not completely clarified. Two-dimensional scalar models with local and global symmetries are perfect playgrounds to investigate this topic, since their critical properties can be studied by means of numerical simulations requiring only a moderate computational effort. In particular, recent works have considered two-dimensional scalar models with orthogonal local symmetries [11,12], and models with unitary local symmetries and scalar matter transforming in different representations of the gauge group [13,14].

According to the Mermin-Wagner theorem [15], in two dimensional systems the critical behavior associated with the breaking of a continuous global symmetry can be observed only in the zero temperature limit. This obviously remains true also for gauge models, but in this case two different classes of low-temperature behavior can a priori be expected to emerge, depending whether the gauge degrees of freedom are or are not critical at the transition.

For most of the two-dimensional gauge models studied so far (see e.g. [11,13]) gauge degrees of freedom do not develop long range correlations at the transition. In these cases gauge symmetry does not seem to play a pivotal role in determining the low-temperature universal critical behavior: the size of the gauge group (i.e. $N_c$) does not influence the critical low-temperature regime, just like the specific matter field representation. Also in this case, however, gauge symmetry plays in fact a fundamental role: that of selecting the critical degrees of freedom, preventing non-gauge invariant observables from developing critical correlations. Gauge fields are instead expected to become critical for some values of the parameters of the model studied in [13], where this fact was attributed to the presence of a quartic scalar field interactions (see [16,18] for the analogous three-dimensional case).

The aim of this paper is to extend the results of [11,14], by studying a lattice model characterized by $SO(N_c)$ local invariance, multicomponent scalar fields transforming in the fundamental representation of the color group, and non-Abelian $O(N_f)$ global symmetry together with a quartic interaction. This field content is indeed better suited than the one used in [14] to investigate a peculiar symmetry between $N_c$ and $N_f$, that we expect to emerge in the continuum limit. The origin of this symmetry is the following: we will argue the continuum limit of the model studied in this paper to be (at least in some regions of the parameter space) the Non-Linear $\sigma$ Model (NL$\sigma$M) field theory associated with the Grassmannian manifold $SO(N_f)/(SO(N_c) \times SO(N_f - N_c))$. Since this manifold is clearly invariant under the exchange $N_c \leftrightarrow N_f - N_c$, we expect this “color-flavor reflection symmetry” to characterize also the low-temperature critical behavior of the gauge model. A numerical verification of the emergence of this symmetry will strongly support the identification of the continuum limit with the Grassmann NL$\sigma$M field theory.

The paper is organized as follows: in Sec. [II] we present the lattice model. In Sec. [III] we discuss its minimum-energy configurations controlled by the quartic interaction, and identify the different continuum limits exhibited by the lattice model in the space of parameters. In Sec. [IV] we introduce the observables and the Finite-Size Scaling (FSS) theory used in actual numerical analyses. In Sec. [V] we present our numerical results, in Sec. [VI] we finally draw our conclusions and present possible outlooks of our work. Some technical details concerning the algorithms and the Monte Carlo simulations are reported in App. [X].
II. THE LATTICE MODEL

The matter field of the lattice model studied in this work is a multicomponent real scalar field $\Phi^{\alpha}_{\mathbf{x}}$, where $\alpha = 1, \ldots, N_c$ and $\mathbf{x} = (x_1, x_2)$ denotes the position on the lattice. For the sake of the simplicity we will adopt the unit-length (London limit) constraint $\text{Tr} \Phi^4_{\mathbf{x}} = 1$, which is not expected to alter the critical behavior of the model.

To define the lattice Hamiltonian, we start from the most general quartic interaction for the field $\Phi^{\alpha}$. The Hamiltonian can be written in the form

$$
H = H_K(\Phi_{\mathbf{x}}, U_{\mathbf{x},\mu}) + V(\Phi_{\mathbf{x}}) + H_G(U_{\mathbf{x},\mu}).
$$

In this expression $H_K(\Phi, U)$ and $V(\Phi)$ represent the scalar field kinetic energy and the quartic interaction respectively, which are defined as follows

$$
H_K(\Phi_{\mathbf{x}}, U_{\mathbf{x},\mu}) = -\frac{N_f}{N_c} \sum_{\mathbf{x},\mu > 0} \text{Tr} \Phi^4_{\mathbf{x}} U_{\mathbf{x},\mu} \Phi_{\mathbf{x}+\hat{\mu}},
$$

$$
V(\Phi_{\mathbf{x}}) = w \sum_{\mathbf{x}} \text{Tr} \Phi^{\beta}_{\mathbf{x}} \Phi^{\gamma}_{\mathbf{x}} \Phi^{\gamma}_{\mathbf{x}} \Phi^{\beta}_{\mathbf{x}}.
$$

The last term $H_G(U_{\mathbf{x},\mu})$ in Eq. (2) represents instead the kinetic term of the gauge field, and it is written by means of the plaquette operator $\Pi_{\mathbf{x}}$ in the usual Wilson form:

$$
H_G(U_{\mathbf{x}}) = -\frac{\gamma}{N_c} \sum_{\mathbf{x}} \text{Tr} \Pi_{\mathbf{x}},
$$

$$
\Pi_{\mathbf{x}} = U_{\mathbf{x},1} U_{\mathbf{x}+1,2} U_{\mathbf{x}+2,1} U_{\mathbf{x},2}.
$$

The model is characterized by a gauge $SO(N_c)$ invariance under the local transformation

$$
\Phi_{\mathbf{x}} \rightarrow W_{\mathbf{x}} \Phi_{\mathbf{x}}, \quad U_{\mathbf{x},\mu} \rightarrow W_{\mathbf{x}} U_{\mathbf{x},\mu} W^\dagger_{\mathbf{x}+\hat{\mu}},
$$

where $W_{\mathbf{x}} \in SO(N_c)$, and by a global $O(N_f)$ invariance under $\Phi_{\mathbf{x}} \rightarrow \Phi_{\mathbf{x}} M$, with $M \in O(N_f)$. The partition function of the statistical model is finally defined by

$$
Z = \sum_{\{\Phi, U\}} e^{-\beta H},
$$

where $\beta$ plays the role of the inverse temperature.

The Hamiltonian in Eq. (2) has several limiting cases which correspond to known and already studied models. For $w = 0$ and $\gamma = \infty$ it trivially reduces to the standard $O(N_c) \times O(N_f)$ model, while for $w = 0$ and finite $\gamma$ it reduces to the model studied in [11]. The case $N_c = 2$ for $w = 0$ is quite peculiar, since the global symmetry is not $O(N_f)$ but $U(N_f)$, see [24]. Finally, as will be clear from the analysis of the minimum-energy configurations carried out in the next section, when $N_f > N_c$ the Hamiltonian reduces in the limit $w = \infty$ and $\gamma = \infty$ to that of the so called Stiefel models, which are the NL$\sigma$Ms defined on the homogeneous spaces $SO(N_f)/SO(N_f-N_c)$ [21, 23].

In this work we will mainly focus on the case $\gamma = 0$, as we do not expect the gauge coupling to play a relevant role at criticality in two dimensions (apart from crossover effects in the limit $\gamma \rightarrow \infty$), just as in all previously studied cases [11, 14].

III. MINIMUM-ENERGY CONFIGURATIONS AND CONTINUUM LIMITS

In this section we identify the minimum-energy configurations of the gauge model in Eq. (2), which are expected to be the ones characterizing the low-temperature ($\beta \rightarrow +\infty$) critical behavior of the model. The minimum-energy configurations are selected by the quartic interaction, and their determination uses arguments that partially retrace those used in Refs. [11, 18].

By means of the singular value decomposition, the scalar field matrix $\Phi^{\alpha}_{\mathbf{x}}$ can be rewritten as follows

$$
\Phi^{\alpha}_{\mathbf{x}} = \sum_{j=1}^{N_c} \sum_{\delta=1}^{N_f} C^{ij}_{\mathbf{x}} D_{\mathbf{x}}^\delta F_\alpha^{i\delta},
$$

where $C$ and $F$ are two square matrices in $O(N_c)$ and $O(N_f)$ respectively, $D = \text{diag}\{s_1, \ldots, s_q\}$ is a $N_c \times N_f$ matrix with non-negative diagonal entries and $q \equiv \min[N_c, N_f]$. The fixed-length constraint becomes

$$
\text{Tr} \Phi^4_{\mathbf{x}} = \sum_{i=1}^{q} s_i^2 = 1,
$$

and the the quartic potential term is equal to

$$
\text{Tr} \Phi^4_{\mathbf{x}} \Phi_{\mathbf{x}} \Phi_{\mathbf{x}} \Phi_{\mathbf{x}} = \sum_{i=1}^{q} s_i^4.
$$

The explicit form of the minimum-energy configurations is fixed by the sign of the quartic coupling $w$:

(I) $s_1 = 1$, $s_2 = s_3 = \ldots = s_q = 0$ if $w < 0$

(II) $s_1 = \ldots = s_q = 1/\sqrt{q}$ if $w > 0$. 
The residual symmetry of these minima determines the low-temperature critical behavior of the model, which is thus expected to be different for positive or negative values of the coupling \( w \). The case \( w = 0 \) requires special attention and, apart from a few cases in which analytical results can be obtained (see [14][18]), we have to rely on numerical simulations for the identification of the critical behavior when \( w = 0 \).

When configurations of type (I) dominate the partition function (i.e. for \( w < 0 \)), the continuum limit is expected to be the same as the \( \mathbb{R}P^{N_f-1} \) model [11][14]. The simplest way to understand this fact is to note that, by using configurations of type (I) it is possible to construct the gauge invariant composite field \( B_x = \Phi_x^t \Phi_x \), which behaves as a rank-1 real space projector (i.e. \( B_x = B_x^t = B_x^t \) and \( \text{Tr} B_x = 1 \)). Indeed the \( \mathbb{R}P^{N_f-1} \) model describes the dynamics of a rank-1 projector \( P_x \) in an \( N_f \) dimensional space. By introducing the unit-length vector \( S_x \), using the definition \( P_x^{\alpha \beta} = S_x^\alpha S_x^\beta \), the action of the \( \mathbb{R}P^{N_f-1} \) model can be written as [24][27]

\[
H_{RP} = -\sum_{x,\mu} \text{Tr} P_x P_{x+\mu} - \sum_{x,\mu} \left( S_x \cdot S_{x+\mu} \right)^2,
\]

which displays the two main features of the \( \mathbb{R}P^{N_f-1} \) universality class: \( O(N_f) \) global invariance and \( Z_2 \) local invariance. We thus expect the \( SO(N_c) \) symmetry not to play any significant role in the continuum limit of the model for \( w < 0 \). Moreover in [11] it was numerically shown that the same is also true for the case \( w = 0 \), and for all the values of \( \gamma \) investigated.

We can now discuss the case in which the dominant configurations are those of type (II). Using an argument analogous to that used for the unitary groups in [18], it is possible to show that if \( N_f \leq N_c \) there is no residual global symmetry for the field \( \Phi_x \) in this case, hence no critical behavior at all is expected in the low-temperature limit when \( w > 0 \) (see [14] for a numerical check). For this reason, in the following, we will assume \( N_f > N_c \), hence \( q = N_c \). As for the case of type (I) minima, it is convenient to introduce a gauge invariant composite field, which is now \( B_x = N_c \Phi_x^t \Phi_x \). It is indeed simple to show, using the explicit form of the type (II) minima, that \( B_x = B_x^t = B_x^t \) and \( \text{Tr} B_x = N_c \), hence \( B_x \) is a rank-\( N_c \) real space projector. The lattice NL\( \sigma \)M written by using \( B_x \), whose Hamiltonian is

\[
H_G = -\sum_{x,\mu} \text{Tr} B_x B_{x+\mu},
\]

is a possible discretization of the NL\( \sigma \)M field theory associated with the real Grassmannian manifolds

\[
SO(N_f)/(SO(N_c) \times SO(N_f - N_c)),
\]

where we have neglected discrete subgroups that, as usual, are not expected to play any role in the zero temperature limit.

The same conclusion about the global symmetry breaking pattern for \( w > 0 \) can be reached also in another way, by using as effective model the Hamiltonian \( H_K(\Phi_x, U_{x,\mu}) \), with the field \( \Phi_x \) restricted to be of the form (11). Introducing the rescaled field \( \tilde{\Phi}_x = \sqrt{N_c} \Phi_x \), the effective model Hamiltonian is written as

\[
H_{K \to \infty} = -\frac{N_f}{N_c} \sum_{x,\mu} \text{Tr} \tilde{\Phi}_x^t U_{x,\mu} \tilde{\Phi}_{x+\mu}.
\]

By using essentially the same arguments discussed in [18] for the unitary group case, one obtains again for the global invariance group of \( H_{K \to \infty} \) the expression in Eq. (14) (again up to discrete groups).

Two-dimensional Grassmannian NL\( \sigma \)M field theories have been introduced in Refs. [28][29], are known to be asymptotically free [3][29] and their \( \beta \)-functions are known up to 4-loops in dimensional regularization [30]. Since Grassmann manifolds are invariant under the color-flavor reflection \( N_c \leftrightarrow N_f - N_c \), our study of the minimum-energy configurations leads us to expect this symmetry to emerge in the critical low-temperature behavior of the lattice model in Eq. (2) when \( w > 0 \). We explicitly note that this symmetry is present also when \( w < 0 \), however in that case it is realized in a somehow trivial way: the critical behavior is expected to always be that of the \( \mathbb{R}P^{N_f-1} \) model, for all \( N_c \) values. In Sec. V we will provide numerical evidence that, for \( w > 0 \), the universal FSS curves of the lattice model considered in this paper do depend on \( N_c \), and that the color-flavor reflection symmetry is realized.

We close this discussion by noting that the second approach used above to identify the invariance group when \( w > 0 \), and in particular the effective Hamiltonian in Eq. (15), is especially convenient to clarify the relation of the model we are studying with the Stiefel models. In the limit \( \gamma \to \infty \) we have \( U_{x,\mu} \to 1 \) up to gauge transformations (at least in the thermodynamic limit). Moreover it is immediate to verify that for type (II) minima the following relation holds true

\[
\tilde{\Phi}_x \tilde{\Phi}_x^t = 1_{N_c \times N_c},
\]

where \( 1_{N_c \times N_c} \) denotes the \( N_c \times N_c \) identity matrix (note that this relation is gauge invariant although color indices are not contracted). For \( \gamma \to \infty \) the Hamiltonian \( H_{K \to \infty} \) in Eq. (15) thus reduces, up to an irrelevant multiplicative factor that can be reabsorbed in the normalization of \( \beta \), to that of the Stiefel model \( V_{(N_f,N_c)} \), which is usually written as [21][23]

\[
H_S = -\sum_{x,\mu} \text{Tr} \pi_x \pi_{x+\mu},
\]

where \( \pi_x \) are \( N_c \times N_f \) real matrices (with \( N_f > N_c \)) satisfying the constraints

\[
\pi_x \pi_x^t = 1_{N_c \times N_c}.
\]

The continuum limit of this model is described by the NL\( \sigma \)M field theory having the manifold
FIG. 1: Graphical representation of the different low-temperature continuum limits expected from the study of the minimum-energy configurations when $N_f > N_c$. Minima of type [I] ($w < 0$) and [III] ($w > 0$) are associated to the $\mathbb{R}P^{N_f-1}$ and Grassmanian models respectively. The case $w = 0$ is numerically found to have the same asymptotic behavior of the $w < 0$ case (see [III]). For $\gamma \to +\infty$ we recover the $O(N_f)$ vector model when $w < 0$, the $O(N_fN_f)$ vector model when $w = 0$ and the Stiefel model $V_{N_f,N_c}$ when $w > 0$. It $N_f \leq N_c$ no critical behavior is expected for $w > 0$.

$SO(N_f)/SO(N_f - N_c)$ as target space, and which is associated to the symmetry breaking pattern $SO(N_f) \to SO(N_f - N_c)$ (see e.g. [21] for more details).

A summary graph of the different low-temperature behaviors expected on the basis of the residual symmetry of the minimum-energy configurations is shown in Fig. 1.

IV. OBSERVABLES AND FINITE-SIZE SCALING

To characterize the critical behavior of the lattice models we use Monte Carlo simulations and Finite-Size Scaling (FSS) techniques [31,33]. We focus on the bilinear local operator $Q_x$

$$B_{x}^{\alpha\beta} = \sum_{i=1}^{N_c} \Phi_{x}^{i\alpha} \Phi_{x}^{i\beta}, \quad G_x^{\alpha\beta} = B_x^{\alpha\beta} - \frac{\delta^{\alpha\beta}}{N_f},$$

and, more specifically, on some Renormalization Group (RG) invariant quantities associated to this operator. Starting from the two point correlation function

$$G(x - y) = \langle \text{Tr} Q_x Q_y \rangle,$$

we can define the second-moment correlation length

$$\xi^2 = \frac{1}{4 \sin^2(\pi / L)} \frac{\tilde{G}(0) - \tilde{G}(p_m)}{\tilde{G}(p_m)},$$

where $\tilde{G}(p) = \sum_{\mathbf{x}} e^{i p \cdot \mathbf{x}} G(\mathbf{x})$ is the Fourier transform of $G(\mathbf{x})$ and $p_m = (2\pi / L, 0)$ is the minimum momentum on the lattice. The first RG invariant quantity we consider is the ratio between the second-moment correlation length and the lattice size

$$R_\xi \equiv \xi / L,$$

and lattices with equal extent along the two directions will always be adopted. The second RG invariant quantity we use is the quartic Binder cumulant $U$, defined by

$$U = \frac{\langle \mu_2^2 \rangle}{\langle \mu_2 \rangle^2}, \quad \mu_2 = \frac{1}{4} \sum_{x,y} \text{Tr} Q_x Q_y.$$

Since $R_\xi$ is found to be a monotonic function of the temperature, it is convenient to use $R_\xi$ instead of $\beta$ to parametrize the Binder cumulant $U$, writing $U(\beta, \xi, L) = U(R_\xi, L)$. Indeed, since both $R_\xi$ and $U$ are RG-invariant quantities, the curve $U(R_\xi, L)$ is expected to approach in the FSS limit (i.e. for $L \to \infty$ at fixed $R_\xi$) a universal scaling curve

$$U(R_\xi, L) \xrightarrow{\text{FSS}} U(R_\xi),$$

where $U(R_\xi)$ depends on the universality class of the transition, the lattice boundary conditions and aspect ratio. Scaling corrections of the form $L^{-2} \ln^p L$ are expected, as for all asymptotically free theories (see e.g. [34] for a detailed analysis of the $O(N)$ models).

In the next section we will use Eq. (24) to investigate whether two different lattice systems share the same universality class. We will also present some numerical results obtained for the Stiefel models in Eq. (17). The observables used for the Stiefel models can be obtained from the ones defined in this section by the replacement $\Phi_x \to \pi_x / \sqrt{N_c}$.

V. NUMERICAL RESULTS

In this section we discuss the numerical results obtained by simulating the model defined in Eq. (2). We carried out Monte Carlo simulations and FSS analyses for fixed $N_f = 7$ and several values of $N_c$, to check the emergence of the color-flavor reflection symmetry $N_c \leftrightarrow N_f - N_c$ in the asymptotic low-temperature critical behavior when $w > 0$. Technical details concerning Monte Carlo simulations are postponed to the App. A.

In Fig. 2 we present our results for $U(R_\xi, L)$ in the models with $N_c = 2$ and $N_c = 5$, with quartic coupling fixed to $w = 10$ and $\gamma = 0$. For $N_c = 2$ we observe that FSS corrections are quite small, and results coming from lattice sizes $L = 64$ and $L = 128$ are consistent with each other. We thus used a polynomial interpolation of $L = 64$ and 128 data to estimate the universal scaling curve $U(R_\xi)$ of this model. This universal curve is then compared, in the bottom panel of Fig. 2, with the results obtained for the $N_c = 5$ model. In this case we observe scaling corrections larger than the ones obtained for $N_c = 2$, however data for the model with $N_c = 5$ are...
FIG. 2: Top: Binder cumulant $U$ versus $R_\xi$ for the case $N_c = 2, N_f = 7$ and quartic coupling $w = 10$ ($\gamma = 0$). The solid line is a polynomial interpolation of the $L = 64$ and $L = 128$ data, and it is our estimate of the asymptotic curve $U(R_\xi)$ for the Grassmannian $SO(7)/(SO(2) \times SO(5))$ (note that $L = 64$ and $L = 128$ data are consistent with each other). Bottom: Binder cumulant $U$ versus $R_\xi$ for the case $N_c = 5, N_f = 7$ and quartic coupling $w = 10$ ($\gamma = 0$). The solid line is the estimate of $U(R_\xi)$ obtained from $N_c = 2$ data.

FIG. 3: Top: Binder cumulant $U$ versus $R_\xi$ for the case $N_c = 3, N_f = 7$ and quartic coupling $w = 10$ ($\gamma = 0$). The solid line is polynomial interpolation of the $L = 64$ and $L = 128$ data. The dashed line is our estimate of $U(R_\xi)$ for the $N_c = 2, N_f = 7$ model. Bottom: Binder cumulant $U$ versus $R_\xi$ for the case $N_c = 4, N_f = 7$ and quartic coupling $w = 10$ ($\gamma = 0$). The solid line is our estimates of $U(R_\xi)$ for the $N_c = 3, N_f = 7$ model.

clearly converging to the same asymptotic curve as the $N_c = 2$ model. The different approaches to the asymptotic curve observed for $N_c = 2$ and $N_c = 5$ show that color-reflection symmetry is not a generic symmetry of the model, but an emerging symmetry in the critical domain.

In Fig. 3, we report data for $U(R_\xi, L)$ in the models with $N_c = 3$ and $N_c = 4$, still with quartic coupling $w = 10$ and $\gamma = 0$. We can immediately note that the critical behavior found in this case is different from the one observed when $N_c = 2$ (and $N_c = 5$), whose universal curve $U(R_\xi)$ is represented in Fig. 3 by the blue dashed curve. This fact provides an indication that color degrees of freedom actively participate to the critical behavior when $w > 0$. We remind the reader that a completely different behavior was found in Ref. [11] for $w = 0$. In that case the low-temperature critical behavior was the same as the $\mathbb{R}P^{N_f-1}$ model for all the values $N_c > 2$ studied. As discussed in Sec. [11] the same is expected to happen for negative values of the quartic coupling for any $N_c$.

We have thus seen that color-reflection symmetry is realized for $N_c = 2$ and 5, and that this symmetry is not trivially realized in the low temperature phase (i.e. there is a dependence of the critical behavior on $N_c$). The same procedure adopted to compare the results obtained for $N_c = 2$ and $N_c = 5$ can now be applied to analyze also the cases $N_c = 3$ and $N_c = 4$. The red solid curves in Fig. 3 are obtained by polynomially interpolating data corresponding to $L = 64$ and 128 with $N_c = 3$ (residual corrections to scaling are visible between $L = 64$ and 128, but they are smaller than two standard deviations). The same curve is seen to consistently describe the critical behavior of the model also for $N_c = 4$, as expected on
the basis of the emergent color-reflection symmetry.

Finally, in Fig. 4, we discuss the extreme cases $N_c = 1$ and $N_c = 6$, once again for $w = 10$ and $\gamma = 0$. For $N_c = 1$ the model studied reduces to the standard $O(7)$ model (although we use spin-2 observables instead of the usual vector ones), and again an emergent color-flavor reflection symmetry is observed: despite the presence of large scaling corrections, the critical behavior of $U(R_\xi, L)$ for the model with $N_c = 6$ is compatible with the one observed in the $O(7)$ model. As often happens for $O(N)$ models, corrections to scaling are roughly compatible with a $L^{-1}$ scaling [35]. The peak value of the Binder cumulant ($U_{\text{max}} \approx 1.15$) is already sufficient to show that this critical behavior is different from the one seen for $N_c = 2$ ($U_{\text{max}} \approx 1.125$) and $N_c = 3$ ($U_{\text{max}} \approx 1.10$).

We finally want to provide some indication that, for large values of $\gamma$, data can be significantly affected by the crossover between the Stiefel and the Grassmanian critical behaviors, with color-flavor reflection symmetry that is absent in the Stiefel case. For this purpose we have first of all determined the scaling curves $U(R_\xi)$ for the Stiefel models $V_{(7,2)}$ and $V_{(7,5)}$, shown in Fig. 5. These curves make evident the fact that the color-reflection symmetry characterizing the critical behavior of the gauge models is not present in the Stiefel case. Data for the gauge model with $N_c = 2$, $N_f = 7$, quartic coupling $w = 20$ and gauge coupling $\gamma = 15$, are reported in Fig. 6 and clearly display a crossover behavior between two different regimes. Results slowly converge to the expected Grassmanian asymptotic curve when increasing the lattice size, but on small lattices they are far from it and quite close to the results of the Stiefel model $V_{(7,2)}$. Note however that on a finite lattice the $\gamma \to \infty$ limit of the gauge model does not coincide with the Stiefel model with periodic boundary conditions, due to the presence of nontrivial holonomies (Polyakov loops) that can not be gauged away. To obtain an exact matching one should generalize to the non-Abelian case the fluctuating boundary conditions used in [24] for the Abelian case.

VI. CONCLUSIONS

In this paper we have addressed the interplay of local and global symmetries in determining the universal low-temperature critical behavior of 2D scalar models. In particular, we have considered multilayer lattice models with $SO(N_c)$ gauge symmetry and non-Abelian $O(N_f)$ global symmetry, in the presence of a quartic interaction...
between the scalar fields, thus extending the results already presented in [11].

By studying the minimum-energy configurations we identified two different low-temperature regimes. If the coefficient of the quartic coupling is negative (w < 0), the SO(N_c)-gauge models share the same low-temperature critical behavior of the RP^{N_f-1} models, and color degrees of freedom do not play any active role in the critical domain. In particular the low-temperature effective theory is independent of the number of colors N_c. If instead w > 0, the nature of the low-temperature regime crucially depends on the number of colors and flavors. If N_f ≤ N_c no global symmetry remains, and no diverging correlation length and critical behavior are present. If instead N_f > N_c, the low-temperature behavior is expected to be described by the gauged non-linear σ model field theory associated with the real Grassmannian manifold SO(N_f)/(SO(N_c) × SO(N_f − N_c)).

To support the identification with the Grassmannian NLσM field theory of the critical behavior when N_f > N_c and w > 0, we investigated the N_c-dependence of the asymptotic scaling curve U(R_ξ) and, in particular, the presence of the color-flavor reflection symmetry N_c ↔ N_f − N_c in the critical region. For this purpose we focused on the case N_f = 7, studied for several values of N_c with w = 10 and γ = 0. We numerically verified that gauge degrees of freedom do play a role in the critical behavior, since the asymptotic scaling curves obtained in the cases N_c = 1, 2 and 3 are different from each other. Moreover, we provided robust evidence of the emergence of color-reflection symmetry in the critical domain, with the results obtained using N_c and N_f − N_c colors that approach the same asymptotic curve in the FSS limit.

It is interesting to note that for some values of N_c and N_f the Grassmanian models can have peculiar properties that will be worth investigating. For example, the N_c = 2 model admits instanton solutions analogous to that of the CP^{N-1} models, a fact already noted in the seminal work [38]. However to our knowledge the θ dependence of this model has never been systematically investigated.

Another aspect that deserves to be further explored is the stability of the results presented in this paper against an explicit breaking of the gauge symmetry. It is tempting to guess a gauge breaking term to be relevant for w > 0 and irrelevant for w < 0, based on the analogy with the case of 3D Abelian models with critical [35] or non-critical [37] gauge modes. It is however not clear a priori how far this analogy can be trusted, also because in a non-Abelian theory we have much more freedom on the form of the gauge symmetry breaking term, that could for example leave a residual continuous subgroup exact.

Finally, in this work we focused on real scalar models with orthogonal gauge symmetry, but an extension to the case of complex scalar models with unitary symmetry can be immediately carried out. In this latter case we can have, depending on the sign of the quartic interaction, a CP^{N_f-1} critical behavior (for w < 0) or a complex Grassmannian SU(N_f)/(SU(N_c) × SU(N_f − N_c)) critical behavior (for w > 0).

Acknowledgement. Numerical simulations have been carried out on the CSN4 cluster of the Scientific Computing Center at INFN-PISA.

Appendix A: Monte Carlo simulations

In this appendix we present some technical details regarding our Monte Carlo simulations, the algorithms adopted, and the statistics accumulated.

For the gauge models the typical statistics used is of the order of 10^7 “complete lattice sweeps” (defined in the following subsection), while for the Stiefel models it is of the order of 10^6 “complete lattice sweeps” [39]. To analyze data and estimate error bars we used standard blocking and jackknife techniques, and the maximum blocking size adopted was of the order of 10^5 and 10^4 data, for gauge and Stiefel models respectively.

For lattice models with local gauge symmetry, we observed that the value of the inverse temperature β has to be increased to keep R_ξ constant while increasing the value of N_c (at fixed N_f = 7). Specifically, for the lattice size L = 128, we used for the model with N_c = 2 inverse temperatures in the range β ∈ [1.7, 2.1], for N_c = 3 we used β ∈ [3.0, 3.5], for N_c = 4 we used β ∈ [4.5, 5.0], while for the case N_c = 6 the range β ∈ [7.5, 8.3] was adopted. For the case N_c = 5 our largest lattice was L = 64, and in this case we used β ∈ [5.8, 6.3]. Using these inverse temperature intervals we got values of R_ξ in the range [0.05, 0.3] in all the cases.

1. Algorithms: gauge models

To update the field Φ_x of the gauge models we use both a Metropolis [39] and a pseudo-overrelaxation algorithm [40, 41]. In the Metropolis update, the trial field Φ_x′ is generated from Φ_x by rotating two random matrix elements by an angle drawn from an uniform distribution in [−α, α]. The value of α is chosen in such a way to have an average acceptance rate of about 30%. The pseudo-overrelaxation step is performed by using as trial field the reflection of Φ_x with respect to the force F_x defined by

\[ F_x \equiv \sum_\mu \left( U_{x,\mu} \Phi_{x+\mu} + U_{x-\mu,\mu} \Phi_{x-\mu} \right), \]  

(A1)

thus

\[ \Phi_x' = \frac{2 \text{Tr} \left( \Phi_x F_x \right)}{\text{Tr} \left( F_x F_x \right)} F_x - \Phi_x. \]  

(A2)

This trial field is then accepted or rejected by a Metropolis test, which is unnecessary when w = 0 since in that case the update is energy preserving.

The gauge field U_{x,\mu} is updated using the Metropolis algorithm, with the trial link U_{x,\mu}' generated by applying
to $U_{x,y}$, a random $SO(2)$ matrix randomly embedded in $SO(N_c)$. Also in this case the parameters of the rotation are tuned in order to maintain an average acceptance of approximately $30\%$.

A “complete lattice sweep” is defined to be a series of 10 update sweeps on the whole lattice for both scalar and gauge fields. For the gauge field the Metropolis update is always adopted, while for the scalar field a single Metropolis update is followed by 9 pseudo-overrelaxation steps.

2. Algorithms: Stiefel models

The Stiefel Hamiltonian is defined in Eq. (17) by using the field $\pi_x$, which is a $N_c \times N_f$ matrix subject to the constraint $\pi_x \pi_x^T = 1_{N_c \times N_c}$. Assuming for the sake of the simplicity that $N_f > N_c$, we represent $\pi_x$ by the first $N_c$ rows of the $N_f \times N_f$ orthogonal matrix $\tilde{\pi}_x$, that will be our fundamental field in the following. The update of $\tilde{\pi}_x$ is performed by using the Metropolis algorithm [39] and the single cluster algorithm [42].

The Metropolis update of the field $\pi_x$ is performed by using the trial state $\tilde{\pi}_x' = \tilde{\pi}_x O$, where $O$ is an $O(2)$ random rotation embedded in a random way in $O(N_f)$. The rotation angle is drawn from a uniform distribution in $[-\delta, \delta]$, and the value of $\delta$ is chosen to obtain an average acceptance of about $30\%$.

In the cluster update we start by generating the random unit-length $N_f$-vector $v^a$ and selecting a random lattice site. The cluster construction is performed by activating the link $x \rightarrow y$ with probability $p_{x,y}$ given by

$$p_{x,y} = 1 - \exp \left( \min(0, 2\beta N_f X) \right),$$

(A3)

where

$$X = \sum_{i=1}^{N_c} \left[ \left( \sum_{\alpha=1}^{N_f} \pi_{i\alpha}^x v^\alpha \right)^2 \left( \sum_{\beta=1}^{N_f} \pi_{i\beta}^y v^\beta \right) \right].$$

(A4)

The whole cluster is then “flipped” using

$$(\tilde{\pi}_x)^{\alpha\beta} \rightarrow (\tilde{\pi}_x)^{\alpha\beta} - 2v^\beta \sum_{\lambda=1}^{N_f} (\tilde{\pi}_x^{\lambda\alpha} v^\lambda),$$

(A5)

which is easily seen to be an $O(N_f)$ matrix.

A “complete lattice sweep” is a series of 10 Metropolis updates on the whole lattice, each one followed by a cluster update.
