ABSTRACT

The increasing precision in the determination of the Hubble parameter has reached a per cent level at which large-scale cosmic flows induced by inhomogeneities of the matter distribution become non-negligible. Here we use large-scale cosmological N-body simulations to study statistical properties of the local Hubble parameter as measured by local observers. We show that the distribution of the local Hubble parameter depends not only on the scale of inhomogeneities, but also on how one defines the positions of observers in the cosmic web and what reference frame is used. Observers located in random dark matter haloes measure on average lower expansion rates than those at random positions in space or in the centres of cosmic voids, and this effect is stronger from the halo rest frames compared to the CMB rest frame. We compare the predictions for the local Hubble parameter with observational constraints based on type Ia supernovae (SNIa) and CMB observations. Due to cosmic variance, for observers located in random haloes we show that the Hubble constant determined from nearby SNIa may differ from that measured from the CMB by $\pm0.8\%$ at $1\sigma$ statistical significance. This scatter is too small to significantly alleviate a recently claimed discrepancy between current measurements assuming a flat ΛCDM model. However, for observers located in the centres of the largest voids permitted by the standard ΛCDM model, we find that Hubble constant measurements from SNIa would be biased high by 5 per cent, rendering this tension inexistent in this extreme case.

Key words: cosmology: cosmological parameters – cosmology: large-scale structure of Universe – galaxies: haloes – methods: numerical

1 INTRODUCTION

The Hubble constant is arguably the most fundamental cosmological parameter. It is not only a measure of the expansion rate of the Universe, but it also sets the normalisation of the cosmic density parameters. Since the pioneering work by Edwin Hubble, all efforts made to determine this constant have been focused on improving the precision of distance measurements in the cosmic distance ladder as well as on reducing a number of systematic effects, related e.g. with the astrophysics of Cepheids and SNIa (for a review see Freedman & Madore 2010). These efforts have been enabled by the increasing amount and quality of the data, and resulted in measurements of the Hubble constant to an unprecedented per cent level of precision (Riess et al. 2011, Freedman et al. 2012, Tully et al. 2013).

The most competitive methods for the determination of the Hubble constant utilise combined measurements of distances to nearby Cepheids and SNIa, or CMB observations, although it is worth noting the growing relevance of constraints from time delays between gravitationally lensed multiple images of distant quasars (see e.g. Paraficz & Hjort 2014, Suyu et al. 2013). The most recent measurement based on SNIa yields $H_0 = 73.8 \pm 2.4$ km s$^{-1}$ Mpc$^{-1}$ (Riess et al. 2011). On the other hand, assuming a flat ΛCDM cosmology a recent analysis of the CMB data from the Planck mission leads to $H_0 = 67.88 \pm 0.77$ km s$^{-1}$ Mpc$^{-1}$ (Planck Collaboration et al. 2013), which differs from the previous result by $2.4\sigma$ (although both mea-
measurements seem more compatible, when using the revised determination of $H_0$ from SNIa, based on an improved distance calibration; see Efstathiou (2013). This raises the question to what degree this discrepancy is due to as yet unknown systematic uncertainties or large-scale inhomogeneities (Marra et al. 2013). A similar problem concerns the difference in the expansion rate found between low- and high-redshift supernovae. The Hubble constant determined from SNIa within $75 h^{-1}$Mpc was measured to be $6.5 \pm 1.8$ per cent higher than that at larger distances (Jha et al. 2007). This effect, referred to as the Hubble bubble, is commonly ascribed to our location in an underdense region of the cosmic web (Zehavi et al. 1998), although alternative solutions such as reddening of local SNIa were also suggested (Conley et al. 2007). Most recent analyses of SNIa data reveal that a bulk flow of nearby SNIa prevails up to redshift $z \approx 0.06$, which corresponds to a comoving distance of $180 h^{-1}$Mpc (Colin et al. 2011; Feindt et al. 2013). It is worth noting that this scale of the bulk flow appears to coincide with the size of a plausible local underdensity determined from galaxy counts in the near-infrared (Keenan et al. 2012; Whitbourn & Shanks 2013).

The determination of the Hubble constant from measurements of distances and recessional velocities in the local Universe is inevitably affected by large-scale flows resulting from fluctuations in the matter distribution (Courtois et al. 2013). It is crucial then to theoretically predict these effects at the level of precision required by upcoming observations. Current theoretical works rely on analytical calculations based on either linear perturbation theory or its modifications that include some non-linear effects (Wang et al. 1998; Cooray & Caldwell 2000; Li & Schwarz 2008; Wiegand & Schwarz 2013; Kahlhoefer et al. 2013; Marra et al. 2013). Although this approach can give valid initial insights, it is insufficient for taking into account all non-linear effects and therefore to provide accurate predictions for the next generation measurements. Non-linear effects not only modify peculiar velocities at small scales, but they also implicitly define locations of reference observers in the most evolved structures of the cosmic web, i.e. dark matter (DM) haloes. The only way to include all these effects in a theoretical calculation of the variance of the perturbed Hubble flow is to use cosmological N-body simulations (Turner et al. 1992; Martinez-Vaquero et al. 2002; Aragon-Calvo et al. 2011). In this paper, we utilise large-scale cosmological N-body simulations to study the effects of large-scale inhomogeneities and the distribution of DM haloes on the local measurements of the Hubble constant. The simulations were run in volumes comparable to the Hubble volume and thus they are suitable for a statistical study on the local Hubble flow. The goal of the paper is not only to quantify deviations of the local Hubble parameter from the global expansion rate, but also to consider a number of assumptions, such as the location of reference observers in the cosmic web or the reference frame for the measurement, which considerably modify these predictions.

The manuscript is organised as follows. In section 2, we describe the simulations and methods used to find DM haloes and cosmic voids. In the next section, we introduce the notion of the local Hubble parameter and its connection to large-scale inhomogeneities. We also describe here the technical details of calculating predictions for the local Hubble constant parameter based on cosmological simulations. Section 4 presents the main results of the paper and is divided into several detailed subsections in which the effects of different sets of assumptions to calculate the local Hubble parameter are discussed. In section 5, we calculate the theoretical predictions for a few different measurements of the Hubble parameter based on SNIa or CMB data and compare them to observational constraints. We conclude and summarise in section 6.

## 2 SIMULATIONS

We use two large-scale cosmological N-body simulations, the JUropa HuBbLE volume (Jubilee, Watson et al. 2013) with a volume of $(6h^{-1}$Gpc$^3$ and a part of the Big MultiDark (Big MD, Heß et al., in prep.) which is a suite of simulations with volumes of $(2.5h^{-1}$Gpc$^3$. The two simulations are based on the results of the of 5-year CMB data from the Wilkinson Microwave Anisotropy Probe (WMAP) satellite (Dunkley et al. 2009; Komatsu et al. 2009). The assumed cosmological parameters, $(\Omega_m = 0.27, \Omega_b = 0.73, \Omega_k = 0.044, h = 0.70, \sigma_8 = 0.80, n_s = 0.96)$ for the Jubilee and $(\Omega_m = 0.29, \Omega_b = 0.71, \Omega_k = 0.047, h = 0.70, \sigma_8 = 0.82, n_s = 0.95)$ for the MultiDark, are consistent with recent results from Planck (Planck Collaboration et al. 2013). For more details of each simulation see Watson et al. 2013 and Heß et al. (in preparation).

The two simulations have $6000^3$ (Jubilee) and $3840^3$ (Big MD) particles. The corresponding particles masses are $7.49 \times 10^9 h^{-1}M_{\odot}$ and $2.2 \times 10^9 h^{-1}M_{\odot}$, yielding minimum resolved halo masses (with 50 particles) of $4 \times 10^{12} h^{-1}M_{\odot}$ and $1 \times 10^{12} h^{-1}M_{\odot}$, respectively. Combining the two simulations, we resolve DM haloes spanning the mass range from Milky-Way-size galaxies with $10^{12} h^{-1}M_{\odot}$ to massive galaxy clusters with $10^{15} h^{-1}M_{\odot}$.

DM haloes in both simulations are found using the AMIGA halo finder, AHF (Gill et al. 2004; Knollmann & Knebe 2009). The finder identifies the halo centres as the overdensity peaks located on a recursively refined grid. Every centre is then used to find gravitationally bound particles and, on the basis of these particles, to calculate various properties of the haloes, including the halo mass $M_{\text{halo}}$ which is defined as the mass of a spherical overdensity region with the mean density equal to $178\rho_b$, where $\rho_b$ is the background density. The final set of all distinct haloes identified in the Jubilee and the Big MD simulations (both at redshift $z = 0$) contain $9.1 \times 10^7$ haloes with masses $M_{\text{halo}} > 10^{13} h^{-1}M_{\odot}$ and $5.8 \times 10^7$ haloes with masses $M_{\text{halo}} > 10^{12} h^{-1}M_{\odot}$, respectively. For the latter, there are $5 \times 10^7$ haloes with masses $10^{12} h^{-1}M_{\odot} < M_{\text{halo}} < 10^{13} h^{-1}M_{\odot}$.

In addition to DM haloes, we also identify voids formed in the Jubilee simulation. Voids are found as regions in the simulation box which do not contain DM haloes above a certain mass (Watson et al. 2013). We adopt $10^{14} h^{-1}M_{\odot}$ as the mass threshold of the void finder. With this mass limit, we identify the most extended voids which have the strongest effect on the local Hubble parameter. Every void is defined

\footnote{http://jubilee-project.org}
as a sphere that maximally fills a volume devoid of haloes (Gottlöber et al. 2002). The centre of this sphere is used as the void centre. The total number of voids found at redshift $z = 0$ in the $6h^{-1}$Gpc simulation is $2.6 \times 10^5$.

### 3 LOCAL HUBBLE PARAMETER FROM SIMULATIONS

The observed velocities of galaxies in the local Universe combine a recessional velocity component due to the global expansion of the Universe and a peculiar velocity component resulting from the local density fluctuations. Without prior information on the distances to galaxies, these two velocity components cannot be disentangled, and therefore local measurements of the Hubble constant may differ from the actual global rate of expansion. The local Hubble parameter depends not only on the cosmological model, but also on the location of the observer in the cosmic web and on the selection of the objects used for the measurement. A deviation from the global expansion rate is expected on distances which are comparable in size or smaller than cosmic voids, which set a natural scale of transition to homogeneity (Scrimgeour et al. 2012). To study the effects of inhomogeneities on the local Hubble parameter, cosmological simulations should be run in boxes much larger than the box size of the simulations. Therefore, the side length of the simulation box should be at least of a few $h^{-1}$Gpc.

The local Hubble parameter $H_{\text{loc}}$ is the slope of a linear relation between the observed velocities of galaxies or groups of galaxies and the distances from the observer to these objects

$$v_{\text{pec}} \cdot \hat{r} + H_{\text{loc}} r = H_{\text{loc}} r,$$

where $v_{\text{pec}}$ is the peculiar velocity vector, $\hat{r}$ is the normalised position vector and $r$ is the distance. In a homogeneous universe, peculiar velocities vanish and one recovers the Hubble law, i.e. $H_{\text{loc}} = H_0$. In a non-homogeneous universe, observers located in voids or overdense regions measure expansion rates that are larger or smaller than $H_0$, respectively.

The calculation of the local Hubble flow from theory can be expressed in Bayesian terms. For a fixed cosmological model, the probability distribution of the local Hubble parameter is given by

$$p(H_{\text{loc}}) = p(H_{\text{loc}}|\text{observer}) p(\text{observer}),$$

where $p(\text{observer})$ describes the probability distribution of the locations of observers in the cosmic web. For simplicity, this formula neglects a number of factors related to how $H_{\text{loc}}$ is actually measured in different kinds of observations. Among these factors, the most important are the selection function of objects used for the measurement (both along the line of sight and on the sky) and the errors on distances. In section 4, we assume an idealised measurement for which all errors are negligible and the observations are complete at all radii $r < r_{\text{max}}$. This means that the probability $p(H_{\text{loc}})$ is fully determined by the large-scale structures formed in the simulations and the location of the observers in the cosmic web. The effect of adopting a selection function for the redshift distribution is considered in section 5, where we calculate probability distributions for the differences in $H_{\text{loc}}$ measured at different scales.

The probability $p(\text{observer})$ should encompass a priori information about our own location in the cosmic web, such as that we live in a galaxy group within a DM halo of a certain mass. This kind of information can significantly modify the final predictions for $H_{\text{loc}}$. The probability distribution $p(\text{observer})$ may also be interpreted as a mathematical representation of the Copernican principle or any deviation from it. It is a way of quantifying the meaning of the term ‘typical observers’. From a technical point of view, we shall not deal with any explicit form of $p(\text{observer})$, but instead we shall consider different schemes for placing random observers in the cosmic web. Every scheme, however, corresponds to a unique form of $p(\text{observer})$.

In order to calculate $p(H_{\text{loc}})$ from the simulations, we define a set of observers and haloes hosting observable objects in the Universe, i.e. galaxies and groups of galaxies. In all cases, we use $10^5$ observers which are randomly distributed in the cosmic web according to different choices for $p(\text{observer})$. We checked that the number of observers is sufficient to precisely calculate $p(H_{\text{loc}})$. For every observer, we find all haloes at distances $r < r_{\text{max}}$ and fit the linear model of eq. (1) to the line-of-sight velocities and distances. The resulting $10^5$ best-fit values of $H_{\text{loc}}$ are then treated as a random sample drawn from the probability distribution $p(H_{\text{loc}})$. We use these values to compute the mean and the confidence intervals of the probability distribution $p(H_{\text{loc}})$. We repeat the calculations for the maximum radius $r_{\text{max}}$ spanning the range from $20h^{-1}$Mpc to $300h^{-1}$Mpc. The linear fit is carried out assuming equal weights for all the haloes within $r_{\text{max}}$ so that the final probability distribution of the local Hubble parameter is fully determined by the large-scale structures that emerged from the evolution of the assumed cosmological model. Unless it is explicitly stated (as in subsection 4.5), the peculiar velocities in eq. (1) are given by the bulk velocities of the haloes in the comoving rest frame. This choice of the reference frame corresponds to measuring the Hubble parameter in the CMB rest frame (Turner et al. 1992). In observations of nearby Cepheids or SNIa, the transformation to this reference frame relies on correcting the observed redshifts for the motion of the Milky Way as determined from the CMB dipole.

When we fit for the local Hubble parameter, we use the peculiar velocities of the haloes in the $z = 0$ snapshots of the simulations. However, the assumed maximum value of $r_{\text{max}}$, $300h^{-1}$Mpc, corresponds to redshift $z = 0.1$. This means that our calculation neglects the evolution of peculiar velocities at $z < 0.1$. Using linear perturbation theory (see more details in subsection 4.1), we estimate the impact of the evolution between $z = 0$ and $z = 0.1$, and find that the resulting relative corrections to the variance of the local Hubble parameter are smaller than 5 per cent. We also check that the corrections needed to account for the differences in cosmological parameters of the two simulations are of the same order of magnitude. To prevent our results from being
affected by these two effects, we provide all our results within a 10 per cent precision.

4 RESULTS

Here we consider several choices for \(p\) (observer) and calculate the corresponding distribution of \(H_{\text{loc}}\). We explore the following distributions of observers within the simulation box: random in space; random in DM haloes of different masses; in the centres of voids; and in the local rest frames of DM haloes.

4.1 Random observers in space

The first simple way of selecting observers is to draw random positions in the simulation box (Turner et al. 1992). In this case, observers are not assigned to the haloes and the resulting distribution of the local Hubble parameter represents a volume weighted statistic, i.e. one assigns equal probabilities to all positions in the simulation box rather than to all distinct haloes. This scheme of distributing observers is less natural than selecting random DM haloes as the locations for observers. However, the main motivation for considering this approach is that the same distribution of observers is implied when using analytical calculations based on perturbation theory (for which there is no prediction for halo formation and thus all statistical quantities are weighted by volume rather than by haloes). Therefore, the framework considered here allows us to directly compare the results from the simulations to those from analytical calculations (see e.g. Wang et al. 1998; Marra et al. 2013). For fitting the Hubble relation given by eq. (1), we use haloes with masses \(M_{\text{halo}} > 10^{13} h^{-1}\) Mpc from the \(6h^{-1}\) Gpc simulation box.

Fig. 1 shows the confidence intervals of the probability distribution of \(H_{\text{loc}}\) with respect to its global value \(H_0\) as a function of the maximum radius of observations \(r_{\text{max}}\) (red shaded contours). As expected, the measurement of the Hubble parameter converges to \(H_0\) at large distances. The relative deviation from the global Hubble flow is as small as 1 per cent within \(150h^{-1}\) Mpc. Note also that for \(r_{\text{max}} < 50h^{-1}\) Mpc the mean value of \(H_{\text{loc}}/H_0\) is larger than 1 by a few per cent. This effect results from using a volume-weighted statistic which enhances the contribution of the cosmic outflows inside volume-dominated voids.

It is interesting to compare our results from cosmological simulations with analytical calculations based on linear perturbation theory. According to this theory, the variance of the local Hubble parameter measured within a sphere with radius \(r_{\text{max}}\) is given by the following equation (see e.g. Wang et al. 1998)

\[
\left\langle \frac{(H_{\text{loc}} - H_0)^2}{H_0^2} \right\rangle = \frac{\Omega_m^{0.55}}{2\pi^2} \int_0^\infty P(k) f(x/x^2) dk,
\]

where \(\Omega_m\) is the matter density parameter at the present time, \(x = k r_{\text{max}}\), \(P(k)\) is the power spectrum of the matter density fluctuations and

\[
f(x) = \frac{3}{x^2} \left( \sin x - \int_0^x \frac{\sin y}{y} dy \right).
\]

For \(\Lambda\)CDM, \(\Omega_m^{0.55}\) is an approximation for the linear growth rate of density perturbations \(\delta(a)\), i.e. \(d \ln \delta / d \ln a \approx \Omega_m(a)^{0.55}\) (Linder 2005), where \(a\) is the cosmic scale factor.

The blue dashed contours in Fig. 1 show the confidence intervals for a Gaussian probability distribution with the standard deviation given by eq. (3) for the same cosmological parameters and power spectrum as used in the simulation. The linear approximation recovers the results from the simulations at scales \(r_{\text{max}} > 100h^{-1}\) Mpc. Non-linear evolution effects, such as the mean value being larger than 1, become relevant at scales corresponding to typical sizes of voids, i.e. \(r_{\text{max}} \lesssim 40h^{-1}\) Mpc. As shown by Marra et al. (2013), the linear approximation can be analytically corrected for the non-linear evolution of cosmic voids by assuming a log-normal probability distribution instead of a Gaussian.

For the various cases presented in this section, Table 1 lists the mean and scatter of the relative difference between the local \(H_{\text{loc}}\) and the global \(H_0\) Hubble parameter within three maximum radii \(r_{\text{max}}\): \(50h^{-1}\) Mpc, \(75h^{-1}\) Mpc and \(150h^{-1}\) Mpc. The maximum radius \(r_{\text{max}} = 75h^{-1}\) Mpc, corresponding to the Hubble velocity \(c z_{\text{max}} = 7500 \text{ km s}^{-1}\), is commonly adopted as the limiting value separating low-z SNIa, whose Hubble diagram is likely to be significantly perturbed by local inhomogeneities (Zehavi et al. 1998; Jha et al. 2007), from high-z ones, which are thought to probe the global expansion of the Universe (Riess et al. 2011).

4.2 Observers in random haloes

The most natural way of distributing observers in the cosmic web is by positioning them in random DM haloes. This scheme assumes that typical observers are located in structures which are embedded in DM haloes, such as our own location in the Local Group. This substantially decreases the effective volume of space populated by observers. In this scheme, observers tend
to occupy overdense regions and thus their measurement of the Hubble constant is mostly affected by large scale infall.

Fig. 2 shows the confidence intervals for the local Hubble parameter as measured by observers located in randomly selected DM haloes with masses $M_{\text{halo}} > 10^{13} h^{-1} M_\odot$ in the 6$h^{-1}$Gpc simulation box (red shaded contours). The same minimum mass of $10^{13} h^{-1} M_\odot$ is assumed for haloes used in fitting the linear Hubble relation. These results are compared to the previous case for observers randomly distributed space (blue dashed contours corresponding to the red shaded contours in Fig. 1).

For scales $r_{\text{max}} \lesssim 70 h^{-1}$Mpc, the distribution of deviations of $H_{\text{loc}}$ from $H_0$ differs significantly from that of the case with observers randomly distributed in space. At these scales, the probability distribution of $H_{\text{loc}}$ is skewed towards smaller values and the mean local Hubble parameter is less than $H_0$. This is due to the fact that observers populate preferentially overdense, infall-dominated regions. The size of the scatter at $r_{\text{max}} = 75 h^{-1}$Mpc is comparable to that for observers randomly distributed in space, but the confidence intervals are shifted towards smaller values by 20 per cent of their size. When compared to Fig. 1, it appears that the selection of observers by haloes has a significantly larger effect on the probability distribution of $H_{\text{loc}}$ than the

### Table 1. Mean $\mu$ and scatter $\sigma$ of the relative difference between the local and global expansion rates, i.e. $\mu = \langle H_{\text{loc}}/H_0 - 1 \rangle$ and $\sigma = \langle (H_{\text{loc}}/H_0 - 1 - \mu)^2 \rangle^{1/2}$. The first and second columns describe the selection of observers and the mass range of the haloes used in the calculation. The remaining columns list the mean and the scatter of $(H_{\text{loc}} - H_0)/H_0$ for $r_{\text{max}}$ of 50$h^{-1}$Mpc, 75$h^{-1}$Mpc and 150$h^{-1}$Mpc, respectively.

| observers | $\log_{10} M_{\text{halo}}[h^{-1} M_\odot]$ | $\mu$50[\%] | $\sigma$50[\%] | $\mu$75[\%] | $\sigma$75[\%] | $\mu$150[\%] | $\sigma$150[\%] |

### Figure 2. Probability distribution of the local Hubble parameter $H_{\text{loc}}$ within the radius $r_{\text{max}}$, as measured by observers randomly distributed in DM haloes from the 6$h^{-1}$Gpc simulation box (red shaded contours), and compared to those for the case with observers randomly distributed in space (blue dashed contours). For each case, the contours show the 68.3, 95.4 and 99.7 per cent confidence intervals, whereas the red solid and blue dotted lines show the mean values.

### Figure 3. Probability distribution of the local Hubble parameter $H_{\text{loc}}$ within the radius $r_{\text{max}}$, as measured by observers located in the centres of voids found in the 6$h^{-1}$Gpc simulation box (red shaded contours), and compared to those for the case with observers randomly distributed in space (blue dashed contours). For each case, the contours show the 68.3, 95.4 and 99.7 per cent confidence intervals, whereas the red solid and blue dotted lines show the mean values. The black dash-dotted line shows instead the mean values obtained when only the centres of the 10 largest voids (in terms of the size) are used.

### 4.3 Observers in the centres of voids

The motivation for considering the centres of voids as the locations for the observers comes from observations of SNIa. The Hubble constant appears to be slightly larger at small distances, referred to as the Hubble bubble, is statistically significant and is commonly ascribed to a local void. The location of the Local Group in a void leads to another choice of the prior probability $p(\text{observer})$: observers located in voids. Here we consider a rather extreme possibility and locate the observers in the centres of voids.

We use voids from the 6$h^{-1}$Gpc simulation that are identified as regions devoid of haloes with masses $M_{\text{halo}} > 10^{13} h^{-1} M_\odot$. The total number of voids is of the same order of magnitude as the adopted number of observers, i.e. $10^5$. Fig. 3 shows the confidence intervals of the resulting probability distribution of $H_{\text{loc}}$, as a function of $r_{\text{max}}$ (red shaded
contours), compared to the results for observers randomly distributed in space (blue dashed contours). From this figure one can see that for observers located in voids the local Hubble parameter is affected by large scale outflow. For this case, the mean value of $H_{\text{loc}}$ decreases from 1.06$H_0$ at $r_{\text{max}} = 20h^{-1}\text{Mpc}$ to 1.01$H_0$ at $r_{\text{max}} = 75h^{-1}\text{Mpc}$. Note also that the confidence intervals here are more similar to those for the case with observers randomly distributed in space rather than in DM haloes. This shows how strong the contribution from voids is for a volume-weighted statistic of the local Hubble parameter.

As the most extreme example, we also plot the mean local Hubble parameter as measured with respect to the centres of the 10 largest voids selected by size, with radii between 90$^{-1}$Mpc and 100$^{-1}$Mpc (black dash-dotted line). In this case, the mean of $H_{\text{loc}}$ is $\sim 5$ per cent larger than $H_0$ within all radii up to $\sim 100h^{-1}\text{Mpc}$. Then, it drops to $\sim 1$ per cent of $H_0$ within $\sim 200h^{-1}\text{Mpc}$. At scales between 90$^{-1}$Mpc and 150$^{-1}$Mpc, the local Hubble parameter reaches the upper limit of the 99.7 per cent confidence interval of the probability distribution obtained for observers distributed in the centres of all voids.

4.4 Observers in groups or clusters of galaxies

Massive haloes tend to populate denser environments, which are surrounded by large scale infall. Therefore, when selecting observers by haloes one should consider the dependence on the halo mass. We show this effect by considering haloes with masses $10^{12}h^{-1}\text{M}_\odot < M_{\text{halo}} < 10^{13}h^{-1}\text{M}_\odot$ from the 2.5$h^{-1}\text{Gpc}$ simulation box. These haloes correspond to massive galaxies or galaxy groups, with the mass range including the mass of the Local Group estimated at $5 \times 10^{12}h^{-1}\text{M}_\odot$ (Li & White 2008; Partridge et al. 2013). This halo population may be regarded as a random sample drawn from the most natural prior probability of $p(\text{observer})$ describing observers resembling our location in the local cosmic web (we belong to a group, but not to a cluster). We use the same halo population to both select observers and fit the linear Hubble relation.

Fig. 4 shows the probability distributions of $H_{\text{loc}}$ as measured by observers located in randomly selected Local-Group-like haloes, i.e. haloes with masses $10^{12}h^{-1}\text{M}_\odot < M_{\text{halo}} < 10^{13}h^{-1}\text{M}_\odot$ (blue dashed contours). This distribution is compared to the case for observers located in massive haloes of $M_{\text{halo}} > 10^{13}h^{-1}\text{M}_\odot$ from the 6$h^{-1}\text{Gpc}$ simulation box (red shaded contours, the same as in Fig. 2). It can be seen from this figure that the local Hubble flow is less affected by the large-scale infall when using less massive haloes. As expected, the differences due to halo masses become negligible at large scales. Comparing to Fig. 1, one can see that the confidence intervals of $H_{\text{loc}}/H_0$ at $r_{\text{max}} < 75h^{-1}\text{Mpc}$ for observers located in less massive haloes are more similar to those obtained with simple analytical calculations based on linear perturbation theory than those for observers in more massive haloes (see also Table 1).

4.5 Reference frame

Until now, we have assumed that observers are at rest in the comoving coordinate system. This means that the velocities used for fitting the Hubble relation of eq. 1 are measured in the CMB rest frame, as in the standard practice of transforming the observed redshifts to the CMB rest frame by using the bulk velocity of the Milky Way as determined from the CMB dipole. Here we consider a hypothetical situation in which velocities are measured instead in the local rest frames of the haloes.

Fig. 5 compares the predictions for the measurement of the local Hubble parameter in two reference frames: the CMB rest frame (red shaded contours, the same as in Fig. 2) and the local halo rest frames (blue dashed contours). In both cases, observers are located in random haloes with
masses $M_{\text{halo}} > 10^{13}h^{-1}M_\odot$ from the $6h^{-1}\text{Gpc}$ simulation. The figure shows that the change of reference frame has a significant effect. At scales of $r_{\text{max}} \lesssim 80h^{-1}\text{Mpc}$, the mean local Hubble parameter measured in the halo rest frames is smaller than the mean determined in the CMB rest frame by 50–70 per cent of the intrinsic scatter. Among all effects summarised in Table 1, the change of the reference frame is the largest.

5 COMPARISON WITH OBSERVATIONS

To compare the probability distribution of the local Hubble parameter to realistic observations, one needs to account for the incompleteness in the observational selection of the objects used to trace the Hubble flow, as e.g. SNIa. A convenient way to include the selection in redshift space is to assign distance-dependent weights $w(r)$ to the haloes used for fitting the Hubble flow. The local Hubble constant is then given by a weighted estimator of the following form

$$H_{\text{loc}} = \frac{\sum_i w(r_i)(v_{\text{pec}} + r_i + H_0 r_i) r_i / \sum_i w(r_i) r_i^2}{\sum_i w(r_i) r_i^2}.$$  

(5)

The weights in this equation are the ratios of the density of supernovae to the density of DM haloes at comoving distances $r_i$. The density of the observed supernovae can be easily obtained by converting their redshift distribution to the density in the comoving coordinates. For this conversion, we assume $H_0 = 70\text{ km s}^{-1}\text{ Mpc}^{-1}$.

We adopt the redshift distributions of three different samples of nearby SNIa used in measurements of the Hubble parameter. The first and second samples were compiled by Jha et al. (2007) and have supernovae at redshifts $z < 0.025$ and $0.025 < z < 0.10$, respectively. These two data sets revealed that the expansion rate of closer supernovae is higher than the rate determined from the distant ones (see also Zehavi et al. 1998). The third sample includes all supernovae from Hicken et al. (2009) at redshifts $0.02 < z < 0.10$. This is nearly the same data compilation that was used in the measurement of $H_0$ by Riess et al. (2011).

We calculate the probability distributions of $H_{\text{loc}}$ using the redshift distributions of these three SNIa samples. The reference observers are randomly distributed in DM haloes with masses $10^{13}h^{-1}M_\odot < M_{\text{halo}} < 10^{15}h^{-1}M_\odot$ from the $2.5h^{-1}\text{Gpc}$ simulation box and the local Hubble flow is measured in the rest frame of the CMB. Comparison with observational constraints on $H_{\text{loc}}$ can only be made in terms of the relative differences between the Hubble parameters determined from data sets probing $H_{\text{loc}}$ at different scales. Here we consider two combinations of measurements which have recently attracted considerable attention: i. the difference in the determination of $H_{\text{loc}}$ between the $z < 0.025$ and $0.025 < z < 0.10$ SNIa samples reported by Jha et al. (2007) and ii. the difference between the expansion rate determined by using nearby SNIa with an improved distance calibration from Cepheids (Riess et al. 2011) and that by using CMB observations from Planck (Planck Collaboration et al. 2013). In the latter case, we assume that the Hubble constant measured from the CMB is not affected by large-scale structures, i.e. $H_{\text{loc}} = H_0$.

Fig. 6 shows the predicted probability distributions of the relative differences in $H_{\text{loc}}$ for the two combinations of observations (red solid and blue dashed lines, respectively) as well as the corresponding measurements from Jha et al. (2007), 6.5 ± 1.8 per cent, and from combining results from SNIa (Riess et al. 2011) and the CMB (Planck Collaboration et al. 2013), 8.9 ± 3.7 per cent. All quoted errors include only the statistical uncertainties of the measurements.

The 3.6σ tension between the expansion rates obtained from nearby $(z < 0.025)$ and distant $(0.025 < z < 0.10)$ SNIa can be easily alleviated by assuming the existence of a local void. For this case, the 99.7 per cent interval of the predicted relative difference in $H_{\text{loc}}$ reaches 5.8 per cent. Taking into account the dispersion of the theoretical distribution in the error budget yields a 2.2σ deviant of the observational results from the predictions of the $\Lambda$CDM model assumed here, i.e. 6.9±3.0 per cent (with the mean of the theoretical probability distribution equal to −0.4 per cent).

The effect of cosmic variance is too small to reduce the tension between the value of the Hubble constant determined from nearby SNIa and that from the CMB. The standard deviation of the theoretical probability distribution is 0.8 per cent, which is 30 per cent smaller than the value obtained in analytical calculations by Marra et al. (2013). This value has a negligible effect on the error budget of the relative difference in the expansion rates obtained from SNIa and the CMB, for which the tension remains unchanged at 2.4σ statistical significance (neglecting all systematic er-
The excess of the local Hubble parameter with respect to the global expansion rate. This happens due to an uneven volume distribution of DM haloes on the measurement of the local Hubble parameter, which accounts for 55 per cent of the measured value and thus decreases the tension between the two measurements to 1σ. On the other hand, the mean relative difference between \( H_{\text{loc}} \) from \( z < 0.025 \) and 0.025 < \( z < 0.10 \) SNIa is 1.6 per cent (see the red arrow in Fig. 3). Such a small value results from the fact that the local Hubble parameter is nearly independent of radius within the range of distances to nearby SNIa (see the black profile in Fig. 3, the median of the distances is 75 \( h^{-1} \) Mpc and the distribution strongly decays at larger radii).

6 SUMMARY AND CONCLUSIONS

We made use of large-scale cosmological N-body simulations to study the effects of inhomogeneities and the distribution of DM haloes on the measurement of the local Hubble parameter, \( H_{\text{loc}} \). We find that the probability distribution of \( H_{\text{loc}} \) depends not only on the peculiar velocity field resulting from inhomogeneities in the matter distribution of a given cosmological model, but also on the distribution of observers used as a prior for the calculation, and on the reference frame of the measurement.

For observers randomly distributed in space, the local Hubble parameter is preferentially larger than the global expansion rate. This happens due to an uneven volume distribution of voids and overdense regions: voids occupy more space and thus they enhance the contribution from cosmic outflows. The excess of the local Hubble parameter with respect to the global value, \( H_0 \), is stronger when locating observers in the centres of voids. The opposite effect occurs if one distributes observers in randomly selected DM haloes. Here the measurement is affected by a large-scale infall and thus the local Hubble value is preferentially smaller than the global expansion rate. The deviation from the global Hubble flow depends on the mass of the haloes occupied by observers, with \( H_{\text{loc}} \) being smaller when measured with respect to more massive haloes. Among all effects considered in the paper, changing the reference frame from the CMB rest frame to the local halo rest frame appears to be the largest. The new reference frame acts as a phantom infall so that the local Hubble parameter is smaller than what is measured in the CMB rest frame.

The local Hubble parameter converges to the global value at large scales. Within radii \( r_{\text{max}} \geq 150h^{-1} \) Mpc, the distribution of the local Hubble parameter is well-approximated by a Gaussian with a dispersion that can be straightforwardly calculated with linear perturbation theory. At these scales, all the effects related to the positions of observers in the cosmic web or the reference frame used are negligible and the intrinsic scatter in \( H_{\text{loc}} \) is fully determined by large-scale inhomogeneities, with values of 1 and 0.3 per cent within 150 \( h^{-1} \) Mpc and 300 \( h^{-1} \) Mpc, respectively.

The 68.3 per cent confidence interval of the relative difference between \( H_{\text{loc}} \) and \( H_0 \), as measured by observers located in Local-Group-like DM haloes, is (−2.3, 1.8) per cent. After accounting for the redshift selection function of SNIa with a redshift range 0.023 < \( z < 0.10 \) and used for determination of the Hubble constant to a percent precision, the scatter in \( H_{\text{loc}}/H_0 \) becomes 0.8 per cent. This means that cosmic variance will be a relevant systematic error in upcoming SNIa measurements that are planned for achieving a 1 per cent precision by further improving the distance calibration for these objects. The only way to reduce the effect of cosmic variance in such measurements is to increase the number of supernovae at large distances. This would shift the effective distances of supernovae to scales less affected by inhomogeneities.

We compared our theoretical expectations based on cosmological simulations of the current ACDM model with observational constraints on the Hubble parameter at different scales. We find that the 2.4σ discrepancy between the determination of the Hubble parameter from SNIa (Riess et al. 2011) and from CMB observations of Planck (Planck Collaboration et al. 2013) cannot be ascribed to cosmic variance, unless one assumes that the Local Group is located close to the centre of one of the largest voids permitted by the standard ACDM cosmological model. On the other hand, the 3.6σ discrepancy between the measurements of \( H_{\text{loc}} \) from SNIa with \( z < 0.025 \) and with 0.025 < \( z < 0.10 \) can be easily explained by the location of the Local Group in an underdense region. When taking into account the scatter in \( H_{\text{loc}} \) due to inhomogeneities, the tension between both measurements is reduced to 2.2σ.

ACKNOWLEDGEMENTS

The Dark Cosmology Centre is funded by the Danish National Research Foundation. RW is grateful to Jens Hjorth for his comments and critical reading of the manuscript, and Corinne Toulouse-Aastrup for organising the DARK Out workshop. The authors thank the anonymous referee for constructive comments that improved our work.

The Jubilee simulation has been performed on the Jülich supercomputer of the Jülich Supercomputing Centre (JSC). The BigMultidark simulations have been performed on the SuperMUC supercomputer at the Leibniz-Rechenzentrum (LRZ) in Munich, using the computing resources awarded to the PRACE project number 2012060963.
