ABSTRACT

Context. NRAO 150 is one of the brightest radio and mm AGN sources on the northern sky. It has been revealed as an interesting source where to study extreme relativistic jet phenomena. However, its cosmological distance has not been reported so far, because of its optical faintness produced by strong Galactic extinction.

Aims. Aiming at measuring the redshift of NRAO 150, and hence to start making possible quantitative studies from the source.

Methods. We have conducted spectroscopic and photometric observations of the source in the near-IR, as well as in the optical.

Results. All such observations have been successful in detecting the source. The near–IR spectroscopic observations reveal strong Hr and Hβ emission lines from which the cosmological redshift of NRAO 150 (z = 1.517 ± 0.002) has been determined for the first time. We classify the source as a flat–spectrum radio–loud quasar, for which we estimate a large super–massive black–hole mass (∼ 5 × 10⁶M☉). After extinction correction, the new near-IR and optical data have revealed a high-luminosity continuum-emission excess in the optical (peaking at ~ 2000 Å, rest frame) that we attribute to thermal emission from the accretion disk for which we estimate a high accretion rate, ~ 30% of the Eddington limit.

Conclusions. Comparison of these source properties, and its broad–band spectral–energy distribution, with those of Fermi blazars allow us to predict that NRAO 150 is among the most powerful blazars, and hence a high luminosity –although not detected yet– γ–ray emitter.

Key words. galaxies: active – galaxies: jets – galaxies: quasars: general – galaxies: individual: NRAO 150 – infrared: galaxies – techniques: spectroscopic

1. Introduction

NRAO 150, first catalogued by Pauliny-Toth, Wade & Heeschen (1966), is nowadays one of the strongest radio and mm AGN sources in the northern sky (e.g., Teräsranta et al. 2005; Agudo, Thum, Wiesemeyer & Krichbaum 2010). The source has been monitored at cm and mm wavelengths for decades (e.g., Aller et al. 1985; Reuter et al. 1997; Teräsranta et al. 2004), and references therein), and has displayed flux densities in the range [2, 16] Jy at 2 cm, and [1.5, 9.5] Jy at 3 mm, with absolute maxima at the beginning of year 2009.

At radio wavelengths, on VLBI scales, NRAO 150 displays a compact core plus a one-sided jet extending up to r ~ 80 mas with a jet structural position angle (PA) of ~ 30° (e.g., Fey & Charlot 2000). The first set of ultra-high-resolution mm-VLBI images of NRAO 150 (Agudo et al. 2007) have allowed to report a large misalignment (> 100°) between the cm-wave and the mm-wave jet, which is, together with the one sideness of the jet, a clear sign of jet orientation close to the line of sight. More intriguing is the evidence of fast “jet wobbling” at ~11°/yr in the plane of the sky: the fastest reported for an AGN so far. The observations by Agudo et al. (2007) together with the cosmological redshift measurement presented in this paper and non-contemporaneous X-ray data have allowed to report the first quantitative estimates of the basic physical properties of the inner jet in NRAO 150; i.e., Doppler factor δ ~ 6, the bulk Lorentz factor γ ~ 4, the angle subtended between the jet and the line of sight φ ~ 8°, and the magnetic field intensity of the flow B ~ 0.7 G. Such large B estimate seems to be compatible with the highly non-balsitic superluminal motion of the inner jet in the source revealed by the mm-VLBI images (B = 3 times the speed of light), which have also shown NRAO 150 as a prime target to study the origin of the jet wobbling phenomenon (Agudo 2009).

NRAO 150 was first detected in December 1981 in the optical by Landau et al. (1983). However, no optical classification or distance determination has been reported so far, perhaps due to the difficulties to observe the source in the visible range, where NRAO 150 is strongly affected by Galactic extinction (Galactic latitude b ≈ −1.6°). This problem is partially overcome in the near-IR range, where spectroscopic observations from strong lined objects can be performed from Earth. Independently of the

Galactic absorption along the line of sight of the source, the near-IR range is the adequate spectral range to detect the strong Hα line from AGN at cosmological redshifts between 1.2 and 3.6 (e.g., Babbedge et al. 2004).

Here, we present the results of our spectroscopic near-IR observations, which were successful on detecting, for the first time, emission lines from NRAO 150. In Sect. 2 such observations and their data reduction procedures are outlined, together with a set of optical and near-IR photometric observations performed in the 2005–2007 time span. The cosmological redshift determination, the classification, the first estimate of the mass of the supermassive compact object in NRAO 150 and its accretion rate, as well as its broad band spectral energy distribution, are presented and discussed in Sect. 3 and 4, whereas a summary of our main results and our conclusions are provided in Sect. 5.

2. Observations and Data Reduction

2.1. Near Infrared Spectroscopy

We have obtained near-IR spectroscopy of NRAO 150 using the Long-slit Intermediate Resolution Infrared Spectrograph (LIRIS, built at the Instituto de Astrofísica de Canarias) on the 4.2 m William Herschel Telescope (WHT) in two epochs (2005 March and 2007 January).

The spectra were obtained using grisms LR$+7$ bands (Z+J) and LR$+H$K (bands H+K). For the observations in 2005, the slit width was selected to be 0.75, providing resolutions of 700 and 600 in the Z+J and H+K bands, respectively. For those in 2007 the slit width was 1″ to match the seeing, providing a resolution of 500 in the Z+J bands. The slit orientation (PA = 118.8°) was chosen to include in the slit aperture both NRAO 150 and the object 2MASS J03592889+5057547. The observations were performed following an ABBA telescope nodding pattern, with each AB cycle repeated 3 times. The exposure time for a single frame was 600 s, giving a total of 3600 s for both spectral ranges. The data were reduced following standard recipes for near-IR spectroscopy, using the dedicated software lirisdr, developed within the IRAF environment by the LIRIS team. The basic reduction steps comprise sky subtraction, flat-fielding, wavelength calibration, and finally, the combination of individual spectra by the common shift-and-add technique. For a more detailed description of the reduction process, see Ramos Almeida et al. (2003, 2009). The flux calibration and telluric absorption correction are usually determined from observations of nearby stars of spectral types A0V or G2V, which are obtained immediately after or before the science observations. In the first epoch the selected correction star resulted to be a multiple stellar system after or before the science observations. In the first epoch the classification, the first estimate of the mass of the supermassive compact object in NRAO 150 and its accretion rate, as well as its broad band spectral energy distribution, are presented and discussed in Sect. 3 and 4, whereas a summary of our main results and our conclusions are provided in Sect. 5.

Table 1. Observing log

| Date      | Spec Range | Dispersion | $T_{exp}$ | Seeing |
|-----------|------------|------------|-----------|--------|
| 2005 March 23 | 0.89-1.33 | 6.1 | 3600 | 0.7 |
| 2005 March 22 | 1.45-2.40 | 9.6 | 3600 | 0.7 |
| 2007 Jan 2  | 0.89-1.33 | 6.1 | 3600 | 1.2 |
| 2007 Jan 4  | 0.89-1.33 | 6.1 | 2400 | 1.2 |

due to atmospheric differential refraction are very small, always below few percent, despite slit was not oriented at the parallactic angle. The flux calibrated spectra are presented in Fig. 1.

2.2. Near Infrared photometry

We obtained images in the J and K$_s$ filters using LIRIS at the same epochs as the near-IR spectroscopy. In both cases the images were obtained following a 5 point dither pattern. Individual frames of 20 and 10 sec were taken in the J and Ks filters, respectively, giving as total exposure times those reported in Table 2. The images were reduced using the task ledither included in the dedicated software package lirisdr, developed under IRAF by the LIRIS team. The main data reduction steps are sky subtraction, flat-field correction and finally a combination of the images after proper alignment.

The photometric calibration was determined by comparison with the 2-MASS catalogue (Cutri et al. 2003). Zero points for our J and K$_s$ photometry were determined using about 20 stars with known 2-MASS magnitudes (brighter than $J \sim 15.5$) included in the LIRIS field. The typical dispersion between instrumental and 2-MASS magnitudes is $\sim 0.08$. 3 IRAF (Image Reduction and Analysis Facility) is distributed by the National Optical Astronomy Observatories, which are operated by AURA, Inc., under cooperative agreement with the National Science Foundation.
Fig. 1. Final reduced spectrum of NRAO 150. The position of the most prominent features are marked. Deep atmospheric absorption bands are indicated by vertical bands. Top panel: Spectra corresponding to the bands $Z$+J observed in two epochs. The thicker red color line corresponds to 2005 Mar, and the thinner blue color line corresponds to 2007 Jan. Middle and bottom panels: Spectrum corresponding to the bands H and K, respectively.
dure, i.e., bias subtraction, flat-fielding, and image combination. The most data were obtained in r’ only (see Table 1).

A larger diameter telescope, the 2.5 m Liverpool robotic telescope (Steele et al. 2004) was used for the remaining observations.

Given the faintness of the source, Table 1). Our target was detected in all bands (see Fig. 2 for examples of I and V images). Given the faintness of the source, a larger diameter telescope, the 2.5 m Liverpool robotic telescope (Steele et al. 2004) was used for the remaining observations. Filters Johnson V and Sloan r’ and i’ were used, although most data were obtained in r’ only (see Table 1).

All data were reduced in IRAF following the standard procedure, i.e., bias subtraction, flat-fielding, and image combination. The photometric calibration was based on images of Landolt fields obtained at photometric conditions. The photometry was obtained using the SEXtractor program (Bertin & Arnouts 1996) and the AUTOMAG parameter. The resulting photometric measurements are listed in Table 2. We estimated that the detection of faint objects in our images is complete down to V = 23.1 (24.0) mag, r’ = 21.7 (23.0) mag and i’ = 20.4 (21.5) mag for S/N = 5 (3) within the observed fields.

Based on our photometric calibration, we propose seven reference stars for r’ and i’ filters which can be used for future monitoring. These stars are marked in Figure 2 and their corresponding magnitudes are listed in Table 3.

### 3. Results

#### 3.1. Near IR spectrum

A very prominent feature is observed in the spectrum of NRAO 150 in the H band at 1.65 μm (see Fig. 1). A less intense, but notable, feature is also seen in the J band at ~ 1.23 μm. These are identified with the Hα and Hβ lines, redshifted by z = 1.517 ± 0.002 and then providing the first redshift determination of NRAO 150. The corresponding luminosity distance of the source is d_L = 11.2 × 10^7 Mpc, for a H_0 = 71 km s^{-1} Mpc^{-1}, Ω_m = 0.27, and Ω_Λ = 0.73 cosmology.

We measured the center, width and flux of the narrow and broad components of Hα and Hβ by fitting two Gaussian components plus a slope as the continuum (see Table 3). We started by fitting Hα since this part of the spectrum has higher signal-to-noise ratio and is not contaminated by other features such as FeII emission. The Hα profile is well fitted by a narrow component of FWHM=170Å (1458 km/s rest-frame) and a broad component of FWHM=666 Å (5745 km/s rest-frame). The broad component is blueshifted with respect to the narrow component by 62Å (532 km/s). In the case of Hβ the S/N ratio is much lower and was not possible to let vary the line widths. Instead they were constrained from the best fitting value of Hα.

Other broad features showing lower S/N are observed around 4300 Å (rest frame), corresponding to the Balmer limit, and at 4450-4700, 4924, 5018 and 5150-5350 Å, associated to blends of FeII emission (see Fig. 1). In order to remove and confirm the importance of FeII emission we have subtracted the empirical FeII emission template of Boroson & Green (1992), scaled to the intensity of the observed features (see Fig. 3). This template was generated from a spectrum of PG 0050+124 (IZw 1), which is well known by the strength of its FeII emission and the narrowness of its H recombination lines (Oke & Laqua 1973). The template (kindly provided by Dr. P. Marziani) was prepared by removing the lines which are not associated with Fe II transitions. It can be seen from Fig. 3 that after the FeII template subtraction the residual spectra show uniquely the broad Hβ feature, plus a shallow bump at 4300Å corresponding to the Balmer limit. Given the radio loud AGN properties of NRAO 150, it is expected to observe intense narrow forbidden emission lines such as [OIII] λ 5007Å, [NII] λ 6548Å, λ 6584Å, and [SII] λλ 6716, 6731Å. However, none of these features are detected at a significant level over the continuum. The implications of weak or absent typical NLR features will be discussed below in section 4.2.

Fig. 3. Top panel: The two NRAO 150 spectra (histogram style line) taken at different epochs are represented together with a scaled version of the EZw1 template (green continuous thin line). Bottom panel: The spectra after subtraction of the template. It can be seen that the residual spectra consist basically on a broad Hβ feature, a shallow bump at 4300Å corresponding to the Balmer jump, and very weak [OIII] lines.

3.2 Optical and near IR variability

Our optical and near-IR photometric measurements span a range of almost 2 years (see Table 2), which is typically a sufficiently long time range to detect intrinsic variability in radio loud AGN (e.g., Teräsranta et al. 2004, 2005). Indeed, NRAO 150 shows a nearly monotonic radio flux increase by a factor ∼4 from 1991 to 2005 (Teräsranta et al. 2004, 2005). However, we cannot make any firm claim about optical variability based on measurements in the r’ band, by far the band with the longer and denser time coverage. The maximum magnitude variations observed are ∼0.2 mag, which are not larger than 3 times the typical measurement uncertainty. It is worth to note that part of the data were taken using different combinations of filters, cameras, and telescopes which does not guarantee their homogeneity. Also, the faintness of the source in the optical range prevents to obtain more accurate photometric measurements.

As in the optical range, our near-IR photometric measurements (performed in 2005 March and 2006 December) do not show significant variability with amplitude above ∼0.3 mag. (∼0.25 or 30%). A similar result is obtained when our near-IR measurements are compared with those of the 2-MASS survey in 1999 (see Table 2). In this case, maximum variability amplitudes of ΔJ = 0.3 mag and ΔK_S = 0.4 mag are found, which contrasts to the factor of 2 flux density increase reported by Teräsranta et al. (2005) at radio wavelengths for the same time range. This suggests that the process responsible for the radio emission is not connected to the one responsible for the optical and near IR emission.

4. Discussion

4.1. Black hole mass and its accretion efficiency

We use the empirical relationships provided by Vestergaard & Peterson (2006) to estimate the central black hole mass in NRAO 150. The black hole (BH) mass can be estimated from the luminosity and width of the broad component of the Hβ line using expression 6 in Vestergaard & Peterson (2006). Given the low S/N ratio of the Hβ line detected in our spectral measurements, the use of the line luminosity is preferred against the value of the continuum at 5100Å (used in expression 5 of Vestergaard & Peterson 2006). The measured broad component luminosity is 5.6 ± 1.2 × 10^14 erg s^{-1} which increases up to 2.3 ± 0.5 × 10^14 erg s^{-1} after applying the galactic extinction correction derived in this work (see Appendix A). Combining these values with those for the line width (see Table 2) the resulting black hole mass is 1.95±10^8 M_☉, which converts to 4.68×10^8 M_☉ after extinction correction. Using the estimate of the black hole mass we can also determine the corresponding Eddington luminosity L_{Edd} = 3.3 × 10^4 (M_{BH}/M_☉) L_☉, which results in a value of 1.54×10^{41} L_☉. In order to compute the accretion rate, this value must be compared with the bolometric luminosity of the accretion disk, which results in L_{disk} ≈ 7.8 × 10^{37} L_☉, and L_{disk} ≈ 46.9 × 10^{37} L_☉ after extinction correction. The disk luminosity was computed by integrating the measured fluxes within the optical-UV range in the rest frame, this value is multiplied by 2πD^2 to obtain the luminosity. Here it is assumed that the radio–mm and the X-ray emission are related to the relativistic jet. This is justified given the uncoupled variability of the optical–UV spectral ranges with regard to the radio–mm one as reported in Section 3.2 Thus the Eddington luminosity ratio is L_{disk}/L_{Edd} = 0.30.

These values can be compared to those previously reported in the literature for similar objects. The black hole mass of NRAO 150 is above the highest masses found in the literature for low redshift AGNs (Vestergaard & Peterson 2006), although the estimated value for M 87, is 3.4 × 10^9 M_☉ (Graham 2007), comparable to the one of NRAO 150. In contrast, the black hole mass of NRAO 150 is well in the range of typical masses of luminous high redshift AGNs (Shemmer et al. 2004). Several works (e.g., McLure & Dunlop 2004; Shen et al. 2008) have tried to measure the dependence on redshift of the mean BH mass. They reach a common result: the mean BH mass increases with redshift, although this dependence is dominated by the Malmquist bias (Vestergaard 2008). Recently, La Rita et al. (2009) claimed that the maximum BH mass evolves with z as log(M_{BH(max)}/M_☉) ∼ 0.3 z + 9, whereas the maximum Eddington
ratio (0.45) is essentially constant with z. However, Labita et al. (2005) suggest that these results are unaffected by the Malmquist bias. Our estimate for the BH mass in NRAO 150 is slightly above the maximum value, and the Eddington ratio is also close to the maximum value, which indicates that NRAO 150 possesses a very massive and efficiently accreting BH.

4.2. Fell emission and weakness of the NLR emission features

As reported above, the spectrum of NRAO 150 presents prominent H recombination lines plus intense FeII emission, in contrast with very weak or absent lines characteristic of the NLR, such as [OIII] (see Fig. 3). Netzer et al. (2004) found that about one third of very high luminosity AGNs do not show strong [OIII] lines. In addition, an anticorrelation between EW(FeII)/EW(Hβ) and EW([OIII]) (Boroson & Green 1992; Yuan & Wills 2003; Netzer et al. 2004) is reported. In our NRAO 150 spectra, the estimated EW for Hβ, FeII and [OIII] are around 55, 60 and 6, although the uncertainties are large given the difficulty to deblend the spectral features. These values are consistent with the mentioned results. Using these values we checked that NRAO 150 is placed in Fig. 9 of Netzer et al. (2004) at the locus of high luminosity and high-redshift QSO sample. The location of NRAO 150 in Fig. 3 of Netzer et al. (2004) is intermediate between the one of PG QSOs (Bennert et al. 2002) and z > 2 QSOs, according to its Hβ luminosity. Netzer et al. (2004) suggest that for highly luminous QSOs the NLR becomes extremely large (even larger than the size of the largest galaxies) as expected from the “natural” R_{NLR} ∝ L_{Hβ}^{1/2} dependence, which makes NLR to disappear becoming dynamically unbound. The equivalent size of the NLR in NRAO 150, as predicted from the Hβ luminosity (∼ 4 × 10^{42} erg/s), is about 20 kpc (Fig. 3 in Netzer et al. 2004), which is well above the sizes commonly reported for typical NLR, hence explaining the weakness of the NLR emission features in our spectra.

4.3. The spectral energy distribution

Fig. 4 shows the spectral energy distribution (SED) of NRAO 150. In addition to the photometric data presented here, we searched for data covering the widest possible wavelength range, from radio to X-rays. At radio bands, the lowest frequency measurements, obtained at 4, 8.4, 22, and 43 GHz with the VLA on March 2005, were taken from the National Radio Astronomy Observatory 5 data archive. The next three measurements were observed at 86, 142, and 229 GHz under the general IRAM 30-meter Telescope AGN Monitoring Program (Reuter et al. 1997 and references therein) on March 2005 (August 2005 for the larger frequency one). The optical-UV rest frame observations corresponds to the near-IR and the optical observations presented here, and were acquired on March 2005 and November 2005, respectively. On this spectral region, empty triangles indicate the extinction uncorrected optical and near-IR measurements. Empty circles symbolize such measurements corrected for the Galactic extinction estimated from IRAS far-IR emission maps (Schlegel et al. 1998), whereas filled circles indicate the same measurements corrected for the more accurate Galactic extinction estimated here (see Appendix A). The X-ray data, acquired by ROSAT from August 1990 and February 1991, were corrected by Galactic extinction as reported in Aguado et al. (2007). For the plot in Fig. 4 a photon index Γ = 1.7 ± 0.1 was assumed based on the synchrotron spectrum measured from the IRAM 30 m observations presented here at 86 and 142 GHz (spectral index α = 0.7 ± 0.1).

The SED of NRAO 150 shows two prominent bumps: one peaking around 1 mm and another one at 2000 Å. The low frequency bump observed on the SED resembles those typical of high power flat-spectrum radio-loud sources (e.g., Ghisellini, Tavecchio, Ghirlanda 2008; Ghisellini et al. 2009). This first bump is attributed to strong Doppler-bosted synchrotron relativistic-jet-emission. Also the X-ray domain of the SED is typical from inverse Compton emission from the jet, whereas the large luminosity optical-UV bump (L ∼ 10^{43} erg/s at ν ∼ 10^{14.5} Hz) is not so commonly reported for this kind of sources. A prominent peak at optical-UV (rest frame) wavelengths is typical of Seyfert galaxies and is thought to be produced by thermal emission from the AGN accretion disk. However, there is an increasing number of high–power radio–loud blazars for which this emission feature is being reported (e.g., Raiteri et al. 2007; Abdo et al. 2009; D’Ammando et al. 2009; Ghisellini & Tavecchio 2009; Ghisellini, Tavecchio, Ghirlanda 2008; Ghisellini et al. 2009). Indeed, nearly half of the radio loud blazars in the sample considered by Ghisellini, Tavecchio, Ghirlanda (2009) were recently reported to show a similar optical-UV large excess. There is a consensus to consider this emission to come from thermal emission from the accretion disk (e.g., Raiteri et al. 2007; Abdo et al. 2009; D’Ammando et al. 2009; Ghisellini & Tavecchio 2009; Ghisellini, Tavecchio, Ghirlanda 2008; Ghisellini et al. 2009). This synchrotron bump from the jet when such bump peaks at ν << 10^{14.5} Hz. We also agree on such explanation for the case of NRAO 150 for the reasons outlined by Ghisellini et al. (2009). Moreover, this also explains the above-reported lack of variability in the observed optical and near-IR bands of NRAO 150, whereas the radio and mm spectral ranges showed a factor 5 long term variability. This is easily explained if such observed optical and near-IR (rest frame optical-UV) emission is produced in the

| Line     | Center (Å) | FWHM (Å) | Flux (ergs cm^{-2} s^{-1}) | Lum. (ergs cm^{-2} s^{-1}) |

Table 4. Flux units are 10^{-15} ergs cm^{-2} s^{-1}. Luminosity units are 10^{41} ergs s^{-1}
or source, its optical spectral lines have remained hidden to us. The fact that the forbidden \([\text{OIII}]\) lines are weak points to a very inactive accretion disk. The large accretion rate is consistent with the BH mass, which is also supported by INSU/CPAP (France), MPG (Germany) and IGN (Spain).

5. Summary and conclusions

We have determined, for the first time, the cosmological distance of NRAO 150, one of the brightest radio to mm AGN sources in the northern sky; by means of its spectroscopic redshift \((z=1.517)\) or \(d_L = 11164\) Mpc). The radio to X-rays SED of the source shows two prominent bumps: one peaking at millimetre wavelengths –typical of synchrotron radiation from high power blazar jets–, and another in the near–UV \((\sim 2000\AA)\) that is attributed to thermal emission from the accretion disk. The spectral distribution of the disk emission allows us to make a reliable measurement of the bolometric luminosity of the disk, which turns out to be accreted at \(\sim 30\%\) of the Eddington rate.

This, together with the large BH mass of the source, its prominent BLR line luminosity, and its highly luminous synchrotron spectrum sets NRAO 150 among the most powerful FSRQ blazars. Such sources are also the most luminous hard X–ray and \(\gamma\)-ray inverse–Compton blazar emitters, and are routinely monitored by high energy space observatories as \(\text{Fermi}\). We predict that NRAO 150 is one of such sources. However, it has not still been detected in \(\gamma\)-rays. The low Galactic latitude of the source implies a challenge for \(\gamma\)-ray observatories to detect it. If that is possible in the future, modeling of the whole broad–band spectrum SED would allow for further investigation of the intrinsic physical parameters of this powerful blazar.

The line width of \(\text{H}^\alpha\) points out that NRAO 150 is a broad line AGN, whose disk axis must be oriented close to the line of sight, consistent with having a powerful one-sided superluminal radio–mm jet. Based also on the radio to mm spectral and variability properties (including those observed with VLBI), we classify NRAO 150 as a FSRQ blazar. Consistent with previous observations of high redshift and highly luminous quasars, the optical rest frame spectrum of the source show weak or absent spectral features typical of the NLR –such as \([\text{OIII]}\)5007 Å. This supports the idea that the highest luminosity accretion disks (and probably the most massive BH) favour the unbounding of their NLR by accretion disk radiation.

Using empirical relationships between \(\text{H}^\beta\) line width and luminosity we estimate that the central engine in NRAO 150 possesses a large black hole with mass \(\sim 5 \times 10^{10}\) \(\text{M}_\odot\). The radio to X–rays SED of the source shows two prominent bumps: one peaking at millimetre wavelengths –typical of synchrotron radiation from high power blazar jets–, and another in the near–UV \((\sim 2000\AA)\) that is attributed to thermal emission from the accretion disk. The spectral distribution of the disk emission allows us to make a reliable measurement of the bolometric luminosity of the disk, which turns out to be accreted at \(\sim 30\%\) of the Eddington rate.

This, together with the large BH mass of the source, its prominent BLR line luminosity, and its highly luminous synchrotron spectrum sets NRAO 150 among the most powerful FSRQ blazars. Such sources are also the most luminous hard X–ray and \(\gamma\)-ray inverse–Compton blazar emitters, and are routinely monitored by high energy space observatories as \(\text{Fermi}\). We predict that NRAO 150 is one of such sources. However, it has not still been detected in \(\gamma\)-rays. The low Galactic latitude of the source implies a challenge for \(\gamma\)-ray observatories to detect it. If that is possible in the future, modeling of the whole broad–band spectrum SED would allow for further investigation of the intrinsic physical parameters of this powerful blazar.
Appendix A: Galactic Extinction correction

We have already mentioned that the low galactic latitude of NRAO 150 and its associated high galactic extinction has defied the optical identification and studies of this radio–source. In order to compute the intrinsic properties of NRAO 150 we have to correct for the galactic extinction. At a first approach, we have taken the extinction from SIMBAD database, which is estimated from far infrared emission maps build by combining IRAS and COBE/DIRBE data (Schlegel et al. 1998). The quoted value is $E(B-V) = 1.474$, which implies $A_V = 4.5$ to $A_K = 0.54$.

In order to have another estimate of the galactic extinction towards the direction of NRAO 150, we built a color-magnitude diagram (Fig. A.1) using the near infrared colors (J and K from 2MASS database Cutri et al. 2003) of neighboring stars. The color magnitude $(J-K, J)$ diagram stellar distribution was compared with the theoretical isochrones for 2MASS filters retrieved from Girardi et al. (2002). We intend to recognize part of the Main Sequence in the color–magnitude diagrams. Indeed, we recognized two possible Main Sequences (see Fig. A.1), one of them, more crowded, showing an excess $J - K \sim 0.7$ and a second sequence, less populated, with $J - K \sim 1.3$. We identified the first population to be in front of the Galactic disk and the other one to be behind the disk and presenting a higher galactic extinction.

If we consider the solar metallicity, $z=0.019$, we found that the best possible fits for both stellar populations correspond to isochrones with $log t = 9.1$ Gyr and $z=0.019$ of Girardi et al. (2002). Continuous line fits the more distant and extincted stellar population while dashed line represents the fit to a less extincted population of stars.
